The most serious drawback in the use of morphine and other narcotic analgesics is their addictive potentiality. The characteristics of drug addiction include psychological need or habituation, tolerance and physical dependence. Habituation consists of an emotional and psychic dependence, and in addiction, the habituation becomes an overpowering desire to take the drug. Tolerance is a phenomenon whereby the dosage of the drug must be continually increased to maintain equivalent pharmacological effects. Physical dependence develops when the tissues of the body become so adapted to the effects of the drug that the cells of the tissues cannot function normally without the drug in the environment. This is the most vicious characteristic of drug addiction.

The mechanisms underlying the development of tolerance are not fully understood. Biochemically, it may be attractive to explain tolerance by decreased absorption, altered distribution, increased biotransformation, and/or increased excretion of the drug. However, these processes have been shown to be unrelated to the development of tolerance. Thus, cellular adaptation offers the greatest likelihood for clarifying the phenomenon. Evidence for cellular adaptation is the finding that the respiration of chemically stimulated cortical slices of brain from normal rats is markedly depressed by morphine, whereas the respiration of those from rats chronically dosed with morphine is unaffected.

Heroin is diacetylmorphine (diamorphine hydrochloride) and is prepared by the action of acetic anhydride on morphine, possessing four times the analgesic affect of morphine, but having a considerably less depressant effect. Addiction is common, the drug being taken in the form of snuff, or by injection.

Nalorphine, the allyl ($-CH_2-CH=CH_2$) derivative of morphine (N-allylnormorphine) is remarkable in that it is antagonizing to almost all the effects of narcotics. The antagonizing action is specific for the narcotic analgesics. For instance, nalorphine will antagonize the respiratory depression due to morphine or other narcotics, but not that caused by other depressants, such as hypnotics or anesthetics. This property of nalorphine makes it a particularly useful antidote in cases of acute morphine poisoning. The agent can also precipitate acute withdrawal symptoms if administered to persons addicted to narcotics. The agent has become a useful biochemical tool for studying the mechanism of action of narcotics and tolerance. Since the chemical structures between morphine and nalorphine are so similar, it has been suggested that nalorphine acts by competing with morphine for the receptor site. The antagonistic effect of nalorphine cannot be explained by a simple competitive inhibition if equal affinity for the receptor site with the agonist and antagonist is assumed, because small doses of nalorphine antagonize the effects of much higher doses of the narcotic. Nalorphine also antagonizes the effects of synthetic narcotics of varying chemical structures, such as methadone and meperidine.

Morphine, $C_{17}H_{19}NO_3{\cdot}H_2O$, is a white powder melting at 253°C and is derived from opium which is the dried juice obtained from unripe capsules of the poppy plant (*Papaver somniferum*), variously cultivated in the Near East and Far East. The opium poppy is an annual. When the petals drop from the white flowers, the capsules are cut. The juice exudes and hardens, forming a brownish mass which is crude opium. It contains a total of about 20 narcotics, including morphine. See also **Alkaloids**; and **Analgesics, Antipyretics, and Antiinflammatory Agents**.

MOSLEY, HENRY (1887–1915). A British chemist who studied under Ernest Rutherford and brilliantly developed the application of X-ray spectra to the study of atomic structure; his discoveries resulted in a more accurate positioning of elements in the periodic table by closer determination of atomic numbers. Tragically for the development of science, Mosely was killed in action at Gallipoli in 1915.

MOSLEY'S LAW. The square root of the frequency of a given line of an element in the X-ray spectrum is directly proportional to the atomic number of the element.

MOSSBAUER EFFECT. The phenomenon of recoilless resonance fluorescence of gamma rays from nuclei bound in solids. It was first discovered in 1958 by R.L. Mössbauer. The extreme sharpness of the recoilless gamma transitions and the relative ease and accuracy in observing small energy differences make the effect an important tool in nuclear physics, solid-state physics, and chemistry.

If a gamma ray is emitted by an atomic nucleus, the system to which the emitting atom belongs must recoil, in order to conserve momentum, in a direction opposite to that in which the gamma rays is emitted. Similarly, if an atomic nucleus absorbs a gamma ray, the system must continue to move, following absorption, in such a way that momentum is conserved. If the recoiling system is a single atom, such as in a gas and shown schematically in Fig. 1(a), the emitting atom carries away enough energy from the transition for the observed energy $E_0 - R$ of the emitted gamma ray to be measurably less than the energy E_0 of the nuclear transition that caused the gamma ray to be emitted, also indicated in (a) of the diagram. Furthermore, a gamma ray that is absorbed by a single atom must transfer a measurable kinetic energy to that atom, as well as the energy of the nuclear transition. On the other hand, if the emitting or absorbing nucleus belongs to an atom that is bound into a crystalline structure, such that the structure as a whole can recoil, and as indicated schematically in Fig. 1(b), the kinetic energy that must be given to the crystalline system to conserve momentum is greatly reduced, compared to the energy that must be given to a single atom, because of the much larger mass of the system. The recoil energy is then so small that the gamma ray carries away essentially the full energy E_0 of the transition in the case of emission, transferring such a small fraction of its energy to the absorbing system that emission and absorption appears to be recoil-free.

This process is observed, of course, in the analogous case of the resonance radiation in atomic transitions, in which case, the photons have energies in the range of light, commonly visible light. However, the protons of gamma radiation are so much more energetic that their energy loss by recoil of the nucleus emitting them is great enough, in the case of free atoms, for the resonance effect not to occur.

Mössbauer discovered, however, that in the case of atoms which are not free, but bound in a solid, the effect can often be observed. It is easily demonstrated when the normal, free-atom recoil energy is comparable to the energy of the quantizied lattice vibrations. Under these conditions, zero-phonon processes are possible in which the entire energy of the nuclear

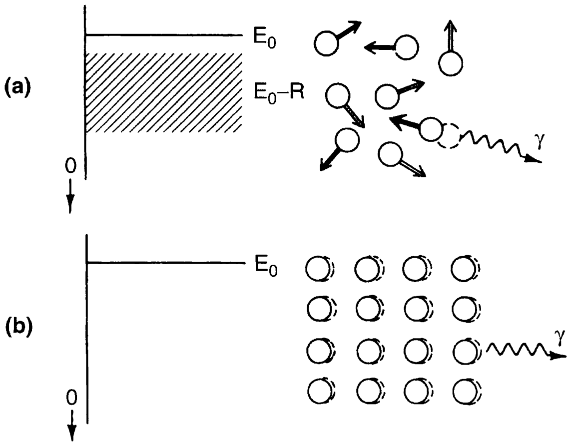

Fig. 1. (**a**) Emission of a gamma-ray by a single atom moving randomly in a gas transfers appreciable energy to the emitting atom in the form of recoil kinetic energy, and reduces the energy of the gamma ray from the transition energy E_0 to some lower energy E_0-R. (**b**) Emission of a gamma ray by an atom bound into a crystalline structure may sometimes cause recoil of the whole crystal, in which case, the loss of energy in the form if kinetic energy of the crystal is negligibly small and the gamma ray appear to be emitted with an energy E_0

transition goes into the gamma ray and the recoil momentum is taken by the solid as a whole. The resulting gamma rays then have the proper energy to be resonantly absorbed or scattered in an analogous zero-phonon process.

The Mössbauer effect is useful in determining nuclear level widths and Doppler effects. Another application is based upon the measurement of nuclear hyperfine structure, a measurement which is possible when the line-width of the gamma ray is smaller than the hyperfine interaction (that due to the coupling of the nuclear moments with external fields). In this application, the Mössbauer effect is almost unique because one obtains the splitting of both the ground and the first excited nuclear states. This effect, in turn, makes possible the determination of nuclear moments of the excited states, which can be important tests of nuclear models. Another important feature is the so-called isomer or chemical shift (terms used interchangeably) which measures the simple electrostatic interaction of the nucleus with its own s-electron and has given information about the difference in the nuclear radii of the ground and excited states.

MOTOR OCTANE NUMBER. See **Petroleum**.

MUCILAGES. See **Gums and Mucilages**.

MULLIKEN, ROBERT S. (1896–1986). An American chemist, physicist, and educator who won the Nobel prize for chemistry in 1966 for his fundamental work concerning chemical bonds and the electronic structure of molecules by the molecular orbital method. Mulliken received is B.Sc. Degree in 1917 at the Massachusetts Institute of Technology, Cambridge, MA. and a Ph.D. degree at the University of Chicago, IL., in 1921.

MULLIS, KARY BANKS (1944–). An American who won the Nobel prize for Chemistry in 1993 for his invention of the polymerase chain reaction (PCR) method.

MUON. The *muon* (μ^-) is an elementary particle of the lepton family. Properties include: Spin, $\frac{1}{2}$; mass (MeV), 105.66; lifetime, 2.20×10^{-6} second. The antiparticle is the positive muon (μ^+). The muon neutrino (ν) has spin, $\frac{1}{2}$; 0 mass; and is stable. The muon family appears to be simply a duplicate of the electron family except for a change in the unit of mass. See also **Particles (Subatomic)**.

The positive muon was discovered in cloud chamber photographs made by C.D. Anderson and S.H. Neddermyer on Pike's Peak in 1935, and the negative muon almost simultaneously in cloud chamber photographs made by J.C. Street and E.C. Stevenson. These particles have long been called mu-mesons, but since they are fermions (spin $\frac{1}{2}$ while all other mesons are bosons, the name *muon* is preferred, as is their classification with the leptons because of their small rest mass, which is about 206 m_e, where m_e is the mass of the electron. Another reason is their inability to interact with other particles through the nuclear forces.

Their charges are equal in magnitude to that of the electron. They are produced by the decay of pions (*pi mesons*) and (to a limited extent) by the decay of kaons and hyperons. Positive-negative muon pairs also can be generated by the action on matter of gamma-rays of energy greater than the rest masses of the particles, i.e., exceeding 211 MeV. Their lives are short, about 2.2×10^{-6} seconds in the free state, and the negative muon usually decays into an electron, a neutrino, and an antineutrino, while the positive muon usually gives a positron, as well as a neutrino and antineutrino. As explained in the entry on neutrino, there are two types of neutrinos and antineutrinos (ν_e or $\overline{\nu_e}$) like that produced in the decay of radionuclides, and a muon-associated neutrino or antineutrino (ν_μ or $\overline{\nu}_\mu$) so that these reactions would be written

$$\mu^- \rightarrow e^- + \nu_\mu + \overline{\nu}_e$$

$$\mu^+ \rightarrow e^+ = \overline{\nu}_e + \nu_e$$

Muons can easily penetrate many meters of iron and can sometimes cause problems in particle physics research. For example, the upsilon experiment at Fermilab in 1977, conducted by L.M. Lederman and others, required building a simple magnetic system that would remeasure each muon's energy after it emerged from the main detector. See also **Upsilon Particle**; and **Particles (Subatomic)**.

MUONIUM. The atom consisting of a positive muon and an electron. Thus, muonium may be regarded as a light isotope of hydrogen in which the positive muon replaces the proton. When a beam of positive muons is stopped in a gas (argon under such pressures as 50 atmospheres has been used in much of this research), muonium is formed directly in its ground state by the capture of an electron by a positive muon. The reaction is important because of its bearing upon the nature of the muon-electron interaction and the muon itself. The study has included measurement of the hyperfine structure interval in the ground state of muonium, and measurement of muon polarization as a function of time and impurity concentration. By adding such gases as oxygen (O_2) and nitric oxide (NO) as impurities to the argon, data on spin exchange of electron and muon is obtained, while with impurities such as nitrogen dioxide (NO_2) and ethylene (C_2H_2), evidence of such reactions as $NO_2 + M \longrightarrow NO + OM$ and $C_2H_4 + M \longrightarrow C_2H_4M$ is obtained.

MUTATION. See **RECOMBINANT DNA**.

MYOSIN. See **Contractility and Contractile Proteins**.

MYRISTIC ACID. [CAS: 544-63-8]. Also called tetradecanoic acid, formula $CH_3(CH_2)_{12}COOH$. At room temperature, it is an oily, white crystalline solid. Soluble in alcohol and ether; insoluble in water. Specific gravity 0.8739 (80°C); mp 54.4°C; bp 326.2°C. Combustible. The acid is derived by the fractional distillation of coconut oil. Myristic acid is used in soaps; cosmetics; in the synthesis of esters for flavorings and perfumes; and as a component of food-grade additives. Myristic acid is a constituent of several vegetable oils. See also **Vegetable Oils (Edible)**.

N

NACREOUS PIGMENT. A pigment, containing guanine crystals obtained from fish scales or skin, that produces a pearly luster. May be applied as surface coatings, as in simulated pearls, or incorporated into plastics. The pigment particle is generally a very thin platelet of high index of refraction. The crystals are readily oriented into parallel layers because of their shape. Being transparent, each crystal reflects only part of the incident light reaching it and transmits the remainder to the crystal below. The nacreous effect is obtained from the simultaneous reflection of light from the many parallel microscopic layers.

NANOTECHNOLOGY (Molecular). Molecular nanotechnology is the production of functional materials and structures in the 0.1 to 100 nm range (the nanoscale) by any of a variety of physical and chemical methods. These methods include nanolithography, direct atomic and molecular manipulation with nanoscale probes, biotechnological selection and production of useful nanomaterials, and chemical synthesis and self-assembly of functional molecules and molecular aggregates. Nanoscale structures and devices may be constructed synthetically from their atomic or molecular constituents (the synthetic or "bottom-up" approach, also referred to as nanochemistry), or by fabrication techniques that use methods to form small structures from larger ones (the reductive or "top-down" approach). A natural analogy to nanotechnology can be found in the biosphere, wherein small and large molecules interact to form complex structures necessary for all the functions of living organisms.

Synthetic vs Reductive Technologies

Many of the devices that have thus far been envisioned as products of nanotechnology (e.g., nanoscale environmental sensors, information processors, and actuators) cannot be produced by the large-scale microfabrication techniques currently in use. The further development of nanotechnology hinges on the understanding and manipulation of physical laws and processes at the nanometer level, such as electronic, interatomic, and intermolecular interactions that can be manipulated to allow efficient assembly of nanostructures.

Biological systems employ a variety of synthetic strategies and processes that make efficient use of these interactions to form highly ordered molecular and supermolecular units that perform a wide variety of functions. The distribution and functional success of biological nanostructures in living organisms are an evolutionally directed balance between the internal stability of the nanostructures (by atomic and molecular interactions) and their responses to the external environment. Thus, biological systems form important existence theorems and design criteria for the production of functional, nanoscale materials through nanotechnology employing the synthetic approach to nanostructures.

An important nature-mimicking methodology involves the use of covalent synthesis followed by molecular self-assembly of the synthesized molecules. These molecules are generally small mono- or oligomers that interact with each other and with other kinds of mono- or oligomers to form thermodynamically stable, nanoscale structures. See also **Molecular Recognition**.

Existence Theorem: Nanobiology

Analogies: Structure and Function. Biology is replete with complex, functional nanoscale structures formed by directed synthesis and subsequent self-assembly of the component molecules. Initially, the small molecules are produced by covalent synthesis, with the larger, functional structures resulting from many weak, noncovalent interactions that energetically overcome interactions with the solvent and the entropic advantages of disintegration of the ordered aggregates. The final structure represents a thermodynamic minimum, and incorrect subunits are rejected in the dynamic, equilibrium assembly. In this process, complementarity in shape and polarity provides the foundation for the association (binding) between components (e.g., phospholipids, polypeptide chains, proteins, nucleic acids). Shape-dependent association based on the nonspecific van der Waal's and hydrophobic interactions are made stronger and more specific by hydrogen bonds and electrostatic interactions, as well as, in some cases, covalent bonds (e.g., disulfides). Often, positive cooperativity is displayed, i.e., conformations of individual subunits change upon binding in such a manner that their affinity for other components of the final structure increases. Moreover, the amount of information required to execute the assembly of a particular structure (e.g., a protein) is minimized by use of only a few types of molecules and a limited number of binding interactions.

For example, a polypeptide is synthesized as a linear polymer derived from the 20 natural amino acids by translation of a nucleotide sequence present in a messenger RNA (mRNA). The mature protein exists as a well-defined three-dimensional structure. The information necessary to specify the final (tertiary) structure of the protein is present in the molecule itself, in the form of the specific sequence of amino acids that form the protein. This information is used in the form of myriad noncovalent interactions (such as those in Table 1) that first form relatively simple local structural motifs (helix and sheet structures associated through networks of hydrogen bonds); these motifs then tend to aggregate in ways that associate hydrophobic regions with one another and out of reach of water, and to place hydrophilic regions close to each other and to water. Thus, proteins self-assemble by two types of processes after synthesis: formation of relatively simple local structures from an unfolded polypeptide chain; and more complex structure-specific association (i.e., associations involving some form of molecular recognition) of these local structures.

In addition to self-assembly of protein structures, in living systems the complex maneuvers needed to achieve properly folded tertiary structures are facilitated by the function of a pre-existing protein machinery, of which, the molecular chaperones are an illustrative example. Chaperones are proteins that bind to and stabilize an otherwise unstable conformer of another protein, and by controlled binding and release, facilitate its correct fate *in vivo*. Molecular chaperones may be said to be the natural

TABLE 1. TYPES OF BONDS AND INTERACTIONS THAT ARE POTENTIALLY USEFUL IN THE ENGINEERING OF FUNCTIONAL NANOSCALE MATERIALS

	Examples	
Bond type	Natural	Synthetic
covalent bonds	peptide (amide), disulfide (RSSR), and phosphodiester (DNA) bonds	palytoxin, oligomers of peptides, nucleotides, and thiophenes
electrostatic interactions	salt bridges in proteins, zinc fingers	metal-coordinated crowns
hydrogen bonds	nucleotide base pairs, amide hydrogen bonds in proteins	peptide cylinders, DNA objects, replicating systems
hydrophobic interactions	hydrophobic cores of proteins; lipid–lipid and lipid–protein interactions	pockets within cyclodextrins and cyclophanes
van der Waals interactions	membranes, vesicles	Langmuir and self-assembled monolayers, lipid bilayers
aromatic π-stacking and charge transfer	nucleic acids	porphyrins

counterparts of assemblers and transporters envisaged as products of nanotechnology.

Analogies: Molecular Devices. Among the many examples in biology of complex nanoscale structures and devices, one of the most ubiquitous and versatile classes is that of the membrane proteins. Membrane proteins, i.e., proteins that are associated with cellular and organellular membranes, serve myriad functions including recognition, adhesion, chemical triggering, ion and molecular transport, light harvesting, chemical and mechanical sensing, and actuation. Humans have attempted to mimic the function of some of these structures for a wide variety of uses, including chemical sensing, selective chemical transport (pumping), and tissue engineering.

An interesting class of proteins which may prove to be an illustrative archetype for future nanotechnological devices, if not integral components of such, are a class of molecular devices collectively known as motor proteins. Motor proteins are enzymatic protein complexes whose catalytic function results in a distinct mechanical function; a variety of examples are known, including those that perform functions analogous to levers, rotary motors, pumps and springs. The structures and mechanisms of action of a variety of motor proteins are being investigated.

Reductive Approaches

Conventional methods of microfabrication of integrated circuits and devices constitute the reductive (top-down) approach to the construction of micrometer and submicrometer-scale structures. The smallest features in commercial integrated circuits have measured 0.35 μm across, and technologies for further reduction in size have succeeded in forming feature sizes as small as 0.18 μm. Further miniaturization, however, will require major technological breakthroughs in the processes underlying microfabrication, especially photolithography, the heart of microfabrication. The technological barriers faced by the lithographers may not be completely insurmountable.

Limitations. The number of transistors present on a chip has doubled approximately every 18 months since the integrated circuit was first developed. The main reason for this continuing decrease in the minimum feature sizes of transistors (and consequent increase in density of transistors on the chip) has been the development of photolithography. The most important limitation for further size reduction remains the development of new photo- and other lithographic techniques.

Current Advances. New light sources are currently being developed, such as the krypton—fluoride ultraviolet laser (wavelength 0.248 μm for features as small as 0.25 μm) and excimer lasers (wavelength 0.193 μm for features below 0.2 μm). But these technologies still need to overcome several obstacles before they can be implemented by the semiconductor industry. For example, for wavelengths below 0.2 μm, the current photoresists absorb so much light that throughput suffers. Also, the fused silica glass lenses used to demagnify the image absorb light and heat up, resulting in a degradation of the image. Problems associated with depth of focus become more acute, requiring further innovation in planarization technology. New photoresist materials, based on the deposition and patterning of monomolecular layers (e.g., self-assembled monolayers and Langmuir-Blodgett films), are also being developed to address the issues of further reduction in the limits of photolithography.

Further reduction in feature size to achieve nanoscale structures by photolithography will necessitate the use of ever smaller wavelengths of light.

Focused particle-based lithography, such as ion-, neutral atom-, and electron-beam lithography, are capable of achieving very high resolutions. However, the method of writing each circuit feature separately is serial and inherently slow so that the technology cannot be used for simultaneous fabrication of many chips. To speed up the process of electron-beam lithography, methods are being explored to scan a broad electron beam across the entire chip by projecting the beam through an appropriate mask (in mimicry of photolithography).

The most recent approach to reductive nanofabrication that can indeed construct nanoscale structures and devices uses microscopic tools (local probes) that can build the structures atom by atom, or molecule by molecule. Optical methods using laser cooling (optical molasses) are also being developed to manipulate nanoscale structures.

Atomic and Molecular Manipulation

Scanning Probe Microscopy. The scanning tunneling microscope (STM) can image and manipulate matter on the atomic scale. In general, when a small conducting probe (the tip, consisting of one or a few atoms, or a metal) is placed close (less than 10 nm) to the surface of a conducting substrate, an electronic current results under a suitable bias due to the overlapping of the electronic wave functions of the probe and the surface. Because this tunneling current is exponentially dependent on the separation of the probe from the surface, imaging resolutions of fractions of an angstrom can be obtained. These images reflect both the topography and the electronic structure of the surface. The STM can also be used to modify surfaces locally. As a result, individual atoms and molecules can be manipulated with atomic-scale precision.

In parallel processes, e.g., field-assisted diffusion and sliding, the bond between the surface and the adatom is never completely broken. Field-assisted diffusion of an adatom on the surface occurs due to the presence of the intense, inhomogeneous electric field between the probe tip and the surface, which gives rise to a potential gradient.

The second class of atomic manipulations, the perpendicular processes, involves transfer of an adsorbate atom or molecule from the STM tip to the surface or vice versa. The tip is moved toward the surface until the adsorption potential wells on the tip and the surface coalesce, with the result that the adsorbate, which was previously bound either to the tip or the surface, may now be considered to be bound to both. For successful transfer, one of the adsorbate bonds (either with the tip or with the surface, depending on the desired direction of transfer) must be broken. The fate of the adsorbate depends on the nature of its interaction with the tip and the surface, and the materials of the tip and surface. Directional adatom transfer is possible with the application of suitable junction biases. See also **Scanning Tunneling Microscope**.

Optical Manipulation. Laser beams provide another means of capturing individual atoms or molecules. When an atom is irradiated from both sides by laser light at a frequency slightly lower than the frequency at which the atom absorbs photons, then the atom loses some of its momentum. In particular, the laser beam propagating in a direction opposite that of the motion of the atom increases in frequency due to the Doppler effect, resulting in light absorption with subsequent isotropic emission (scattering). The light propagating in the same direction as the atom is not absorbed, so that the atom is pushed in a direction opposite its motion and slows down. By surrounding the atom with three sets of counterpropagating laser beams orthogonal to each other the atom can be cooled (i.e., slowed) in all three dimensions. Because the light field acts as a viscous drag force, the combination of laser beams is known as optical molasses.

Synthetic Approaches

The synthetic (bottom-up) approach offers a level of control over the selection and placement of atoms and molecules that is ultimately much higher than that offered by other methods of large-scale microfabrication (e.g., fabrication of integrated circuits). Such synthesis can employ a variety of chemical methods utilizing some or all of the forces and interactions listed in Table 1 to produce nanoscale molecules. Most chemical synthetic reactions that produce large molecules (e.g., collections of atoms that can act as nanodevices) generate polydisperse materials. These materials are mixtures of oligo- or polymeric chains of varying molecular weights. For nanotechnological applications, it is important to have synthetic strategies that yield compounds of uniform length, size, and shape; inhomogeneities can be detrimental to the designated function of the molecule. Thus, the specific objectives of synthesis are to discover and develop rapid and efficient methods for the precise control of composition, molecular weight, stereochemistry, aggregation, and placement of functional molecules. Four strategies are currently in use (either separately or in combination with one another) for the fabrication of large molecules (substances with molecular weights of a few hundred to a few million): biotechnological synthesis, sequential covalent synthesis, covalent polymerization, and molecular self-assembly.

In nature, complex functional molecules are produced by using the chemical synthetic approach. The molecules are first formed by covalent synthesis. In particular, the polypeptides are formed by the directional joining of amino acids through amide bonds. The primary structure of the amino acids (i.e., sequence) during synthesis is specified by the mRNA (a transcript of the original gene encoded in the DNA). Once a polypeptide is produced, it then undergoes many conformational changes that reduce its size to a compact, native form that is the functional protein. These conformational changes are termed folding.

RNA is also capable of folding into specific shapes for ligand recognition and catalysis. Although there are only four naturally occurring bases

available for the formation of tertiary structures through noncovalent interactions (while proteins have twenty different amino acids to choose from), myriad RNA shapes can be produced. Metal ions have been shown to confer extraordinary stability to RNA and RNA fragments.

Thus, protein and RNA folding studies form a fundamental paradigm for the design and synthesis of new, functional macromolecules with both final structure and function built into the primary structure of the macromolecule. Such synthetic strategies could be applied to the rational design of functional nanostructures, including drugs, sensing elements, photonic and electronic components, catalysts, and even mechanical devices.

Biotechnological Synthesis. Biotechnological synthesis of new nanomaterials (e.g., proteins) and biotechnological modification of living systems (e.g., conferring specific therapeutic properties, new genetic traits) exploit the many ways in which this protein manufacturing machinery can be modified. In particular, the DNA of an organism can be altered in a specific manner, resulting in a modified mRNA, and consequently, a modified or new protein.

Recombinant DNA technology provides a powerful tool for analysis, synthesis, and alteration of genes and proteins. It is based on the ability to rapidly synthesize polynucleotides with any sequence using nucleic acid enzymology (e.g., using DNA polymerases, restriction enzymes or endonucleases, DNA ligases). The unique base-pairing attributes of the constituents of the DNA and the ability to express the modified or synthetic DNA in microorganisms and eukaryotic cells result in a powerful tool for the production of synthetic molecules with specific biological functions.

Covalent Synthesis. The first strategy for chemical synthesis employs elaborate and sophisticated methods for assembling atoms into molecules based on the general strategy of sequential formation of covalent bonds. The atoms can also be assembled into subunits that are then reacted to form more complex, designed molecules (convergent synthesis).

Covalent synthesis of complex molecules involves the reactive assembly of many atoms into subunits with aid of reagents and established as well as innovative reaction pathways. These subunits are then subjected to various reactions that will assemble the target molecule. Very complex molecules can be synthesized in this manner.

Molecular Self-Assembly. Reductive techniques, such as those used in the microelectronics industry, can produce structural features smaller than about 200 nm. The use of proximal probes and other nanomanipulative techniques can be considered to be a hybrid of the reductive lithographic techniques and the synthetic strategies of assembling functional nanostructures atom by atom, or molecule by molecule. The organization of nanostructures and devices by the self-assembly of the component atoms and molecules, a ubiquitous phenomenon in biological systems, forms the noncovalent synthetic approach to nanotechnology.

In this approach, well-defined subunits (small molecules similar to, e.g., nucleotides) are first formed through covalent synthesis. Second, these subunits aggregate with themselves or with other subunits through covalent or noncovalent (or both) interactions to form large, stable, structurally defined assemblies. For the final supramolecular structure to be stable and to have a well-defined shape, the noncovalent connections must be collectively stable. Therefore, molecules must be stabilized by many noncovalent interactions.

Conclusions and Outlook

Much of the current progress in nanotechnology is confined to understanding and harnessing pre-existing, exquisitely evolved nanomachinery, i.e., natural living systems. Table 2 summarizes the various reductive and synthetic strategies that are employed.

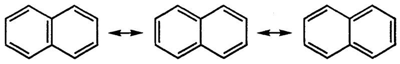
NAPHTHALENE. [CAS:91-20-3]. Naphthalene $C_{10}H_8$, is a white solid with a strong smell; is also called mothballs, moth flakes, white tar, and tar camphor. Naphthalene is a natural component of fossil fuels such as petroleum and coal; it is also formed when natural products such as wood or tobacco are burned.

The accepted configuration of naphthalene, i.e., two fused benzene rings sharing two common carbon atoms in the ortho position, was established in 1869 and was based on its oxidation product, phthalic acid. Based on its fused-ring configuration, naphthalene is the first member in a class of aromatic compounds with condensed nuclei. Naphthalene is a resonance hybrid:



In chemical reactions, naphthalene usually acts as though the bonds were fixed in the positions, as shown in the first structure above at the left.

Some selected chemical and physical properties of naphthalene are given in Table 1. Naphthalene is very slightly soluble in water but is appreciably soluble in many organic solvents, e.g., 1,2,3,4-tetrahydronaphthalene, phenols, ethers, carbon disulfide, chloroform, benzene, coal-tar naphtha, carbon tetrachloride, acetone, and decahydronaphthalene.

TABLE 1. PROPERTIES OF NAPHTHALENE

Property	Value
molecular wt	120.1732
mp, °C	80.290
normal bp at 101.3 kPa[a], °C	217.993
flash point (closed cup), °C	79
ignition temperature, °C	526
heat of vaporization, kJ/mol[b]	43.5
heat of fusion at triple point, kJ/mol[b]	18.979
heat of combustion, at 15.5°C and 101.3 kPa[a], kJ/mol[b]	−5158.41
density at 25°C, g/mL	1.175

[a] To convert kPa to atm, divide by 101.3.
[b] To convert J to cal, divide by 4.184.

The ir, uv, mass, nmr and ^{13}C-nmr spectral data for naphthalene and other related hydrocarbons have been reported in the literature. Additionally, information regarding the properties of naphthalene has been published.

Reactions

Substitution. Substitution products are formed by the substitution of one or more hydrogen atoms with other functional groups. Substituted naphthalenes of commercial importance have been obtained by sulfonation and alkali fusion, alkylation, nitration and reduction, and chlorination.

Sulfonation. Sulfonation of naphthalene with sulfuric acid produces mono-, di-, tri-, and tetranaphthalenesulfonic acids. Naphthalenesulfonic acids are important starting materials in the manufacture of organic dyes. They are also intermediates used in reactions.

Nitration. Naphthalene is easily nitrated with mixed acids, e.g., nitric and sulfuric, at moderate temperatures to give mostly 1-nitronaphthalene and small quantities, 3–5%, of 2-nitronaphthalene.

Halogenation. Under mild catalytic conditions, halogen substitution occurs, and all of the hydrogen atoms of the naphthalene molecule can be replaced. The only commercially significant halogenated naphthalene products are the mixed chlorinated naphthalenes. Uses for the chlorinated naphthalenes include solvents, gauge and instrument fluids, capacitor impregnants, components in electric insulating compounds and electroplating stop-off compounds.

Alkylation. Naphthalene can be easily alkylated. Isopropylnaphthalenes produced by alkylation of naphthalene with propylene have gained commercial importance as chemical intermediates, e.g., 2-isopropylnaphthalene, and as multipurpose solvents, e.g., mixed isopropylnaphthalenes.

Chloromethylation. The reactive intermediate, 1-chloromethylnaphthalene, has been produced by the reaction of naphthalene in glacial acetic acid and phosphoric acid with formaldehyde and hydrochloric acid.

Addition. The most important addition products of naphthalene are the hydrogenated compounds used in solvents, paints and other products. Of less commercial significance are those made by the addition of chlorine.

Oxidation. The vapor-phase reaction of naphthalene over a catalyst based on vanadium pentoxide is the commercial route used throughout the world to form phthalic anhydride. In the United States, the one phthalic anhydride plant currently operating on naphthalene feedstock utilizes a fixed catalyst bed, the preferred route worldwide.

Manufacture

Two sources of naphthalene exist in the U.S.; coal tar and petroleum. Coal tar was the traditional source until the late 1950s, when it was in short supply. In 1960, the first petroleum-naphthalene plant accounted for over 40% of total naphthalene production. The availability of large quantities of *o*-xylene at competitive prices during the 1970s affected the position of naphthalene as the prime raw material for phthalic anhydride. Production for 1992 was less than 50% of the levels in the early 1980s. The last dehydroalkylation plant for petroleum naphthalene was shut down late in 1991. Coal tar has stabilized at around 85×10^3 t/yr, and petroleum-naphthalene production is around $6–8 \times 10^3$ t/yr. The reduction of petroleum production has opened the door for imported naphthalene, mainly from Canada.

Coal-Tar Process. The largest quantities of naphthalene are obtained from the coal tar that is separated from the coke-oven gases. The coal tar first is processed through a tar-distillation step where ca the first 20 wt% of distillate, i.e., chemical oil, is removed. The chemical oil contains practically all the naphthalene present in the tar. It is processed to remove the tar acids by contacting with dilute sodium hydroxide and, in a few cases, is next treated to remove tar bases by washing with sulfuric acid. Principal U.S. producers obtain their crude naphthalene product by fractional distillation of the tar acid-free chemical oil.

Economic Aspects

Total nameplace capacity for all U.S. naphthalene producers in 1993 was 124×10^3 t, with 114×10^3 t produced from coal tar and 10×10^3 from petroleum.

The economics of naphthalene recovery from coal tar can vary significantly, depending on the particular processing operation used. A significant factor is the cost of the coal tar. As the price of fuel oil increases, the value of tar also increases.

The high price of the petroleum product results from its higher quality. The price of the crude coal-tar naphthalene is primarily associated with that of *o*-xylene, its chief competitor as phthalic anhydride feedstock.

The preferred route to higher purity naphthalene, either coal-tar or petroleum, is crystallization. This process has demonstrated significant energy cost savings and yield improvements. There are several commercial processes available: Sulzer-MWB, Brodie type, Betz, and Recochem.

Health and Safety Factors

Handling. Naphthalene is generally transported in molten form in tank trucks or tank cars that are equipped with steam coils. Storage tanks containing molten naphthalene have a combustible mixture in the vapor space and care must be taken to eliminate all sources of ignition. Naphthalene dust also can form explosive mixtures with air, which necessitates care in the design and operation of solid handling mixtures. Perhaps the greatest hazard to the worker is the potential for operating or maintenance personnel to be accidentally splashed with hot molten naphthalene while taking samples or disassembling process lines (ASTM D3438). Molten naphthalene tank vents must be adequately heated and insulated to prevent the accumulation of sublimed and solidified naphthalene.

Toxicology. The acute oral and dermal toxicity of naphthalene is low, with LD_{50} values for rats from 1780–2500 mg/kg orally and greater than 2000 mg/kg dermally. The inhalation of naphthalene vapors may cause headache, nausea, confusion, and profuse perspiration, and if exposure is severe, vomiting, optic neuritis, and hematuria may occur. Chronic exposure studies conducted by the NTP in mice for two years showed that naphthalene caused irritation to the nasal passages, but no overt toxicity was noted. Rare cases of such corneal epithelium damage in humans have been reported. Naphthalene can be irritating to the skin, and hypersensitivity does occur. In other chemical carcinogen tests, little cancer risk was indicated. No incidents of chronic effects have been reported as a result of industrial exposure to naphthalene. Threshold limit value of 10 ppm (50 mg/m^3) has been set by the ACGIH.

Alkylnaphthalenes

Methyl- and dimethylnaphthalenes are contained in coke-oven tar and in certain petroleum fractions in significant amounts. In the U.S., separation of individual isomers is seldom attempted; instead, a methylnaphthalene-rich fraction is produced for commercial purposes. Such mixtures are used for solvents for pesticides, sulfur, and various fluids. They also can be used as low freezing, stable heat-transfer fluids. Mixtures that are rich in monomethylnaphthalene content have been used as dye carriers (qv) for color intensification in the dyeing of synthetic fibers, e.g., polyester. They also are used as the feedstock to make naphthalene in dealkylation processes. Phthalic anhydride also can be made from methylnaphthalene mixtures by an oxidation process that is similar to that used for naphthalene. A mixed monomethylnaphthalene-rich material can be produced by distillation and can be used as feedstock for further processing. Applications include use in solvents, drugs, polyesters, surfactants, and detergent products.

Acenaphthene. [CAS: 83-32-9]. Acenaphthene is a hydrocarbon, $C_{12}H_{10}$, present in high temperature coal tar. Acenaphthene may be halogenated, sulfonated, and nitrated in a manner similar to naphthalene. Oxidation first yields acenaphthenequinone, followed by 1,8-naphthalenedicarboxylic acid anhydride and pesticides.

NAPHTHALENE DERIVATIVES

Naphthalenesulfonic Acids

Naphthalenesulfonic acids are important chemical precursors for dye intermediates, wetting agents and dispersants, naphthols, agricultural formulations, leather tanning agents, photographic materials, and air-entrainment agents for concrete. The production of many intermediates used for making azo, azoic, and triphenylmethane dyes involves naphthalene sulfonation and one or more unit operations, e.g., caustic fusion, nitration, reduction, or amination.

Generally, the sulfonation of naphthalene leads to a mixture of products. Naphthalene sulfonation at less than ca 100°C is kinetically controlled and produces predominantly 1-naphthalenesulfonic acid (**1**). Sulfonation of naphthalene at above ca 150°C provides thermodynamic control of the reaction and 2-naphthalenesulfonic acid as the main product. Reaction conditions for the sulfonation of naphthalene to yield desired products are given in Figure 1; alternative paths are possible. A list of naphthalenesulfonic acids and some of their properties are given in Table 1.

Nitronaphthalenes and Nitronaphthalenesulfonic Acids

The nitro group does not undergo migration of the naphthalene ring during the usual nitration procedures. Therefore, mono- and polynitration of naphthalene is similar to low temperature sulfonation. The nitronaphthalenes and some of their physical properties are listed in Table 2. Many of these compounds are not accessible by direct nitration of naphthalene but are made by indirect methods, e.g., nitrite displacement of diazonium halide groups in the presence of a copper catalysts, decarboxylation of nitronaphthalenecarboxylic acids, or deamination of nitronaphthalene amines. They are used in the manufacture of chemicals, dye intermediates, and colorants for plastics.

A by-product of some of these naphthalene derivatives, 2-naphthylamine, is carcinogenic. Respirators, protective clothing, proper engineering, controls and medical monitoring programs for workers involved with them should be used. The National Institute of Occupational Safety and Health (NIOSH) has published recommendations for working with this product.

Aminonaphthalenesulfonic Acids

Many aminonaphthalenesulfonic acids are important in the manufacture of azo dyes or are used to make intermediates for azo acid dyes, direct and fiber-reactive dyes. Usually, the aminonaphthalenesulfonic acids are made by either the sulfonation of naphthaleneamines, the nitration–reduction of naphthalenesulfonic acids, the Bucherer-type amination of naphtholsulfonic acids, or the desulfonation of an aminonaphthalenedi- or trisulfonic acid. Most of these processes produce by-products or mixtures which often are separated in subsequent purification steps. A list of commercially important aminonaphthalenesulfonic acids is given in Table 4.

Naphthalenols and Naphthalenediols

Naphthalenols, naphthalenediols, and their sulfonated and amino derivatives are important intermediates for dyes, agricultural chemicals, drugs, perfumes, and surfactants. The methods of manufacture include caustic fusion of naphthalene-1-sulfonic acid, hydrolysis of 1-chloro- or

bromonaphthalene, pressure hydrolysis of 1-naphthaleneamine, oxidation–aromatization of tetralin, and hydroperoxidation of 2-isopropylnaphthalene. As the toxic hazard of the 1-naphthaleneamine was recognized, its commercial use was minimized. The sulfonation–caustic fusion process is more difficult to operate than in the past because of increasing difficulties posed by product purity requirements, high investment and replacement cost, and by-product effluent handling problems. In the U.S., the naphthalenols are made by hydrocarbon oxidation routes.

The chemical properties of the naphthalenols are similar to those of phenol and resorcinol, with added reactivity and complexity of substitution because of the condensed ring system. Some of the naphthols and naphthalenediols are listed with some of their physical properties in Table 5.

Hydroxynaphthalenesulfonic Acids

Hydroxynaphthalenesulfonic acids are important as intermediates either for coupling components of azo dyes or azo components, as well as for synthetic tanning agents. Hydroxynaphthalenesulfonic acids can be manufactured either by sulfonation of naphthols or hydroxynaphthalenesulfonic acids, by acid hydrolysis of aminonaphthalenesulfonic acids, by fusion of sodium naphthalenepolysulfonates with sodium hydroxide, or by desulfonation or rearrangement of hydroxynaphthalenesulfonic acids (Table 6).

Aminonaphthols and Aminonaphtholsulfonic Acids

The aminonaphthols are of minor use but the aminohydroxynaphthalenesulfonic acids are intermediates for dyes, e.g., fiber-reactive azo dyes and plain and metallized azo dyes (Table 7). A number of *N*-acyl-, *N*-alkyl-, and *N*-arylaminonaphthaleneosulfonic acids are used as couplers for azo dyes.

Naphthalenecarboxylic Acids

Physical properties for naphthalene mono-, di-, tri-, and tetracarboxylic acids are summarized in Table 8. Most of the naphthalene di- or polycarboxylic acids have been made by simple routes such as the oxidation of appropriate di- or polymethylnaphthalenes, or by complex routes, e.g., the Sandmeyer reaction of the selected aminonaphthalenesulfonic acid, to give a cyanonaphthalenesulfonic acid followed by fusion of the

3-amino-5-hydroxy-2,7-naphthalene-disulfonic acid	RR-acid; 2R-acid	[a]	azo dyes, e.g., CI Direct Brown 31

[a] By alkali fusion or hydrolysis of appropriate aminonaphthalenesulfonic acid.
[b] By nitrosation of 2-naphthalenol and reaction of nitroso compound with sodium bisulfite.
[c] By nitrosation/reduction of 6-hydroxy-2-naphthalenesulfonic acid.

1- and 2-Naphthalenecarboxylic Acids. Naphthalenecarboxylic acids are useful intermediates for dyes and photographic materials. These acids are also used in the preparation of antitumor agents and also in the preparation of cholecystokinin-agonist tetrapeptide. The acids are prepared readily by the oxidation of 1- or 2-alkylnaphthalenes with dilute nitric acid, chromic acid, or permanganate. The oxygen or air oxidation of alkylnaphthalenes in an alkanoic acid solvent in the presence of Ce-, Co-, or Mn-containing catalyst and a Br-containing catalyst gives good results. The direct carboxylation catalyst naphthalene with CO and oxygen in the presence of Pd-carboxylate catalysts has been patented. The photo carboxylation of naphthalene in the presence of carbon dioxide and an electron donor has been described. About 67% naphthoic acids were obtained by this method, upon visible light irradiation with phenazine as a sensitizer. Over 90% of the naphthoic acids was 1-naphthoic acid.

TABLE 8. SELECTED PROPERTIES OF NAPHTHALENECARBOXYLIC ACIDS

Compound	Mp, °C	Other

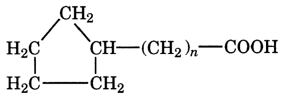
NAPHTHENIC ACIDS. The term *naphthenic acid*, as commonly used in the petroleum industry, refers collectively to all of the carboxylic acids present in crude oil. Naphthenic acids are classified as monobasic carboxylic acids of the general formula RCOOH, where R represents the naphthene moiety consisting of cyclopentine and cyclohexane derivatives. Naphthenic acids are composed predominantly of alkyl-substituted cycloaliphatic carboxylic acids, with smaller amounts of acyclic aliphatic (paraffinic or fatty) acids. Aromatic, olefinic, hydroxy, and dibasic acids are considered to be minor components. Commercial naphthenic acids also contain varying amounts of unsaponifiable hydrocarbons, phenolic compounds, sulfur compounds, and water. The complex mixture of acids is derived from straight-run distillates of petroleum, mostly from kerosene and diesel fractions. See also **Petroleum**.

Chemical Structure

Naphthenic acids are based on saturated single or multicyclic condensed ring structures. The low molecular weight naphthenic acids contain alkylated cyclopentane carboxylic acids, with smaller amounts of cyclohexane derivatives occurring. The carboxyl group is usually attached to a side chain rather than directly attached to the cycloalkane. The simplest naphthenic

acid is cyclopentane acetic acid (**1**, $n = 1$).



(**1**)

Naphthenic acids are represented by a general formula $C_nH_{2n-z}O_2$, where n indicates the carbon number and z specifies a homologous series. The z is equal to 0 for saturated, acyclic acids and increases to 2 in monocyclic naphthenic acids, to 4 in bicyclic naphthenic acids, to 6 in tricyclic acids, and to 8 in tetracyclic acids.

Physical and Chemical Properties

Naphthenic acids are viscous liquids, with phenolic and sulfur impurities present that are largely responsible for their characteristic odor. Their colors range from pale yellow to dark amber. Naphthenic acids have wide boiling point ranges at high temperatures (250–350°C). They are completely soluble in organic solvents and oils but are insoluble (50 mg/L) in water. Commercial naphthenic acids are available in various grades and are marketed by acid number, impurity level, and color. Chemically, naphthenic acids behave like typical carboxylic acids with similar acid strength as the higher fatty acids.

Naphthenic acid corrosion has been a problem in petroleum-refining operations since the early 1990s. Refineries processing highly naphthenic crudes must use steel alloys; 316 stainless steel is the material of choice. Conversely, naphthenic acid derivatives find use as corrosion inhibitors in oil-well and petroleum refinery applications.

Occurrence

Not all crudes contain sufficient quantities of usable acids to make recovery an economic process. Heavy crudes from geologically young formations have the highest acid content, and paraffinic crudes usually have low acid content. Typical concentrations of acids are shown in Table 1.

Manufacture

The commercial production of naphthenic acid from petroleum is based on the formation of sodium naphthenate. Naphthenic acids are recovered by caustic extraction of petroleum distillates rather than from crude petroleum. Crude naphthenic acid is obtained by acidulating the sodium naphthenate, and can be further refined to remove impurities.

Interest in synthetic naphthenic acid has grown as the supply of product has fluctuated. Oxidation of naphthene-based hydrocarbons, free-radical addition of carboxylic acids to olefins, and addition of unsaturated fatty acids to cycloparaffins have been studied but not commercialized.

Production

Nameplate capacities of naphthenic acid producers in North America are 9000 metric tons of crude and refined acid at Merichem (Tuscaloosa, Ala.), and 3600 t of crude acid at Hewchem (Gulfport, Miss.). However, actual production capacity may vary widely as a result of the mix of feedstocks being processed. Naphthenic acid products are shipped in tank cars, tank trucks, and drums under DOT 9137/UN 3082 identifications numbers.

Economic Aspects

Naphthenic acid availability exceeds demand, although some minor market disruptions occurred in North America during the early 1990s. Long-term yearly feedstock is expected to meet market growth projections with recent discoveries of high naphthenic-content oil.

TABLE 1. ACID CONTENT OF VARIOUS CRUDES

Crude oil source	Petroleum acids, wt %
Pennsylvania	0.03
West Texas	0.4
Gulf Coast	0.6
California	1.5
Russia, Balakhany light	1.0
Russia, Balakhany heavy	1.6
Romania, waxy	0.2
Romania, asphaltic	1.6
Venezuela, Lagunillas	1.2

Health and Safety Factors

Naphthenic acids are only slightly toxic to mammals but are toxic to fish, bacteria, and wood-destroying insects. The lethal oral dose for humans is approximately 1 L. Naphthenic acid is not listed as a carcinogen.

Commercial Uses

More than two-thirds of the naphthenic acids produced is used to make metal salts, with the largest volume being used for copper naphthenate consumed in the wood preservative industry. Oil field uses are primarily imidazolines for surfactant and corrosion inhibition. See also **Petroleum**. Besides the lubrication market for metals salts, the miscellaneous market is comprised of free acids used in concrete additives, motor oil lubricants, and asphalt-paving applications. See also **Lubricant**; and **Lubricating Agents**.

Naphthenic acid is ideal for synthesizing metal carboxylates that require a ligand with some oxidative stability, solubility in hydrocarbons and oils, and insolubility in water.

Another market application for naphthenic acid is the tire industry, where cobalt naphthenate is used as an adhesion promoter. Naphthenic acid esters have been repeatedly cited as surfactants, lubricants, and replacements for phthalates as plasticizers for PVC resins.

Naphthenyl alcohols are formed by reduction of the acids or their simple esters. They are valuable as surfactants, solvents, and components of lubricants. The acid halides are of value mainly as chemical intermediates.

NASCENT. Descriptive of the abnormally active condition of an element, for example, the atomic oxygen released from hydrogen peroxide and sulfur atoms evolved from thiuramsulfide accelerators. The term is now obsolete.

NATROLITE. The mineral natrolite, one of the zeolites, is a sodium aluminum silicate corresponding to the formula $Na_2Al_2Si_3O_{10} \cdot 2H_2O$. It is orthorhombic, crystallizing in slender prisms of nearly square cross-section which are terminated by relatively flat pyramids. There are also fibrous to compact varieties. Natrolite is a brittle mineral; hardness, 5–5.5; specific gravity, 2.2; luster, vitreous; color, red, yellow, white, or colorless; transparent to opaque. Natrolite is found with other zeolites in fissures and cavities in basaltic and related rocks. Czechoslovakia, France, Italy, Norway, Scotland, Ireland, Iceland, Greenland, and South Africa contain well-known localities for natrolite. In the United States it is found in the Triassic traps of New Jersey; also from Oregon, Washington, Montana, Colorado, and as exceptional crystals from San Benito County, California. Superb crystals occur at Mt. St. Hilaire, Quebec, Canada, and from an asbestos mine in Quebec, crystals up to 3 feet (0.9 meters) long and 4 inches (10 centimeters) in diameter have been found. The name natrolite refers to its soda content.

NATTA, GIULIO (1903–1979). An Italian chemist along with Karl Ziegler won the Nobel prize for chemistry in 1963 for his fundamental work on catalytic polymerization. In 1954 he developed isotactic polypropylene at his laboratory at the Polytechnic Institute of Milan, which led to wide application of various stereospecific polymers with organometallic catalysts

such as triethylaluminum. He was for many years consultant for the Montecatini chemical firm. The researchers of Natta, together with those of Karl Ziegler, made possible the chemical manipulation of monomers to form specifically ordered 3-dimensional polymers having predetermined properties, to which the term *tailor-made* is often applied.

NATURAL GAS. A major source of energy for industrial, commercial, and domestic needs, natural gas is consumed by numerous countries worldwide. Because natural gas is comparatively easy to transport over long distances, usage is not confined to regions that produce it. In addition to energy, natural gas also is a critically important source of industrial chemicals, including numerous hydrocarbon-based organics that find ultimate usage in plastics, films, fibers, solvents, and coatings.

In terms of interest as a fossil fuel for generating electrical power and other energy-conversion processes, natural gas is gaining favor. Compared with coal, natural gas frequently is termed the "clean-burning" fuel. As compared with coal as an energy raw material, the "add-on" costs for treating combustion effluents to satisfy environmental requirements are less for natural gas than for coal, and, consequently, the lower cost benefits of coal are eroding. Further, improvements in natural gas production technology and a brighter outlook for natural gas reserves are contributing to the expansion of natural gas consumption. In addition, large advances have been made in the combustion efficiency of natural gas. For example, the efficiency of some domestic heating appliances has increased to about 95% as compared with 60% or 70% efficiency a relatively few years ago. The cogeneration of heat and electricity in industrial utilities is tending to favor natural gas as the raw fuel. In terms of local natural gas distribution, utilities are finding the use of polyethylene pipe an important cost-saving factor.

In a summary of the Gas Research Institute (GRI)[1], the following observation is made: "The United States, the gas industry, and the gas consumer have entered a dynamic new decade filled with change, challenge, and opportunity. These include the reemergence of the environmental movement, the continuing deregulation of the U.S. natural gas market, the expansion of global trade in the former Soviet Bloc, the emergence of more competitive international and national energy markets, and the rapid expansion of technology options. Three strategic needs are likely to dominate the 1990s for the U.S. gas industry and the gas consumer: (1) ensuring gas deliverability while controlling costs to the consumer; (2) responding to increased concern for the environment; and (3) satisfying a demand for higher quality of energy service."

Composition of Natural Gas

The composition of natural gas varies with the source, but essentially is made up of methane, ethane, propane, and other paraffinic hydrocarbons, along with small amounts of hydrogen sulfide, carbon dioxide, nitrogen, and, in some deposits, helium. Natural gas is found underground at various depths and pressures, as well as in solution with crude-oil deposits. Principal gas deposits are found in the United States, Canada, the former Soviet Bloc, and the Middle East. The analysis of a gas sample taken from the Panhandle natural gas field in Texas is given in Table 1. Because numerous parts of the earth do not have natural gas at all, or where supply is less than demand, much natural gas is transported, notably by pipeline in the gaseous or liquid phase and across the seas in specially-designed LNG (liquefied natural gas) carriers.

TABLE 1. ANALYSIS OF NATURAL GAS FROM NATURAL GAS FIELD IN TEXAS PANHANDLE

Component	Mole percent
Methane	76.2
Ethane	6.4
Propane	3.8
Normal butane	1.3
Isobutane	0.8
Normal pentane	0.3
Isopentane	0.3
Cyclopentane	0.1
Hexane plus other hydrocarbons	0.35
Nitrogen	9.8
Oxygen	Trace
Argon	Trace
Hydrogen	0.0
Hydrogen sulfide	0.0
Carbon dioxide	0.2
Helium	0.45

Note: Heating value of various natural gases averages between 975 and 1180 Btu/cubic foot (8678–10,502 Calories/cubic meter) at 60°F (15.6°C) and 30 inches (76.2 centimeters) mercury pressure.

Origin and Geology of Natural Gas

The most commonly accepted theory concerning the formation of natural gas is the organic theory. Methane is a product of decaying vegetable matter and in areas of stagnant water is found as *marsh gas* or *swamp gas*. It is theorized that over millions of years, the remains of plants and animals were washed down into lakes, the accumulations covered with layers of mud and stone. The latter became stone while the organic matter decayed through the action of heat and pressure and perhaps from effects of bacteria and radioactivity, forming various hydrocarbons. The hydrocarbons were held in tiny spaces between the particles of sand and porous rock and formed natural gas and petroleum. Often the natural gas so formed made its way through the rock to the surface and escaped. In some areas, however, the layers of sand and porous rock were covered by impermeable rock to form huge reservoirs of natural gas at various levels of pressure. See also **Petroleum**.

The organic theory as usually presented is rather general and vague in many respects. As observed by Ourisson (UniversitÉ Louis Pasteur, Strasbourg) and colleagues, natural gas, as well as coal and petroleum, are fossil fuels, but fossils of what? Fossil fuels form only if the organic matter is buried before it can become completely oxidized to carbon dioxide by microorganisms. According to the microbial origin concept, as the carbon compounds sink deeper into the Earth under accumulating sediments, they are subjected to high temperatures and undergo chemical reaction, during which oxygen and most other elements are eliminated. This yields a mixture composed in the case of gas and petroleum almost entirely of hydrocarbons (carbon in the case of coal). Since the beginnings of photosynthesis on Earth, it is estimated that 10 quadrillion (1016) tons of carbonaceous material has been stored in sediments. Most of this material is stored in very dilute form and only under exceptional geologic conditions, is it concentrated to become a viable fuel source. In a twenty-year study, which might be called molecular paleontology, Ourisson and coworkers have been studying the detailed genesis of fossil fuels. Thus far, chemical analysis of the most varied organic sediments reveals a surprising commonality—all appear to derive much of their organic matter from once unknown microbial lipids. This topic is presented in more detail in entry on **Petroleum**.

A few scientists, notably Thomas Gold (Cornell University), have proposed that, in contrast with the organic sediments theory, the prime source of natural gas is primordial, abiotic methane rising from deep within the Earth's mantle. This is sometimes referred to as the "deep-earth gas" hypothesis. In this view, methane flows up around the edges of the shield and is responsible for the oil and gas fields in the North Sea and the southern Baltic. Admittedly, this reservoir of natural gas is presently out of the reach of any foreseeable drilling technology. In some areas, it is suggested that the granite crust may have been fractured and subsequently became porous to the extent that methane may have risen into the crust and have become trapped at accessible depths. Other scientists point out that no evidence supports the concept that a large amount of methane was incorporated in the Earth when it was formed. Available geochemical evidence suggests that the early atmosphere, produced by outgassing of the planetary interior, could not have been rich in hydrogen. Further, if the Earth did at one time contain primordial methane or other hydrocarbons, most of that volatile material would have long since escaped by way of volcanism and diffusion. It is also suggested that the analysis of volcanic basalts shows that the rock in the upper mantle is highly oxidizing, in which case any methane present would have been converted to carbon dioxide.

Some experimental drilling programs underway in Sweden, including a well some 5000 meters in granite bedrock, may shed further light on Gold's hypothesis.

In searching for new fields during the 1960s and 1970s, drillers seeking gas and oil in traditional suspect source reservoirs, would find gas and/or oil in only about 9 of 100 wells drilled. Usually, only 2 or 3 of these wells produced sufficient gas and/or oil to be of commercial value. Whereas the

[1] "1993–1997 Research & Development Plan," Gas Research Institute, Chicago, Illinois.

average depth of gas well drilled during this period ranged between 5000 and 6000 feet (1524–1829 meters), some drillers are now aiming at the 30,000-foot (9144-meter) depth. For many years, the deepest gas well in Texas was 28,600 feet (8717 meters). In the early days of offshore drilling, operations were conducted in water only 20–25 feet (6–7.5 meters) deep. There are now many platforms in waters that are deeper by a factor of 20–30 times.

In terms of the conventional or traditional sources, natural gas is found in areas close to exposed or buried mountain ranges. Major deposits of natural gas are found in inclined strata where the rock formations dip away from the crest of a buried hill or the ridge of a buried mountain. Some of the common types of formations in which natural gas is found are shown in Fig. 1. Although natural gas and crude oil are frequently found together, the largest natural gas reserves (about 70% of the estimated reserves) are in deposits neither in contact with, nor dissolved in, oil.

Forecasting Natural Gas Reserves

Since the 1920s, natural gas reserves have been based upon the amount of gas that most likely will be found with oil. Although numerous experts in the field have claimed over the years that this methodology overlooks large amounts of "unassociated" gas, the professionals have been slow to revise their procedures. The concept that much natural gas occurs quite apart from oil is now taking hold. The U.S. Geological Survey, which has proclaimed a gas resource base at about 400 trillion cubic feet, undertook a major study to be completed in the late 1990s. Survey techniques have undergone several dramatic improvements, including the use of computer techniques that will project three-dimensional survey information, as contrasted with past reliance on two-dimensional mapping. A number of experts now believe that the reserves are well over 1,200 trillion cubic feet (34 trillion cubic meters). One independent gas producer has estimated the figure at about 1,500 trillion cubic feet (42.5 trillion cubic meters).

Traditional estimates of oil-associated natural gas reserves historically have rated the former Soviet Bloc as holding nearly 40% of the reserves, Iran about 14%, and the United States nearly 6%, with additional fairly high reserves in Qatar, Algeria, and Saudi Arabia. At one time, North America was attributed to have a 60-year supply, but with revisions in estimating procedures, coupled with increased efficiency in natural gas production and gas combustion efficiency, the future is now believed to be in terms of at least a few centuries. Interest continues, however, in upgrading low-Btu natural gases and developing so-called *substitute natural gas.*

The principal gas fields within the continental United States are indicated in Fig. 2.

Ultimate Recovery of Natural Gas Reserves

It has been traditional for many years to categorize ultimate recovery of gas reserves by reservoir lithology which involves the compilation of such data by three types of reservoirs: (1) *Sandstone reservoir*—consisting of sedimentary rock composed predominantly of quartz grains or other noncarbonate mineral or rock detritus. Included in this reservoir type are unconsolidated sand, sandstone, siltstone, graywacke, arkose and granite wash, conglomerate, and breccia. (2) *Carbonate reservoir*—composed of sedimentary rock made up predominately of calcite (limestone) and/or dolomite. (3) *Other reservoirs*—including igneous and metamorphic rocks and some sedimentary rocks, such as fractured shale.

Estimated ultimate recovery is also reported by type of entrapment, of which there are two major types: (1) *Structural trap*—an entrapment in which migration of hydrocarbons in the reservoir rock has terminated

Fig. 2. Location of principal natural gas fields in the lower 48 of the United States. Alaska, not shown, ranks third in terms of holding estimated reserves. (*Batelle Memorial Institute*)

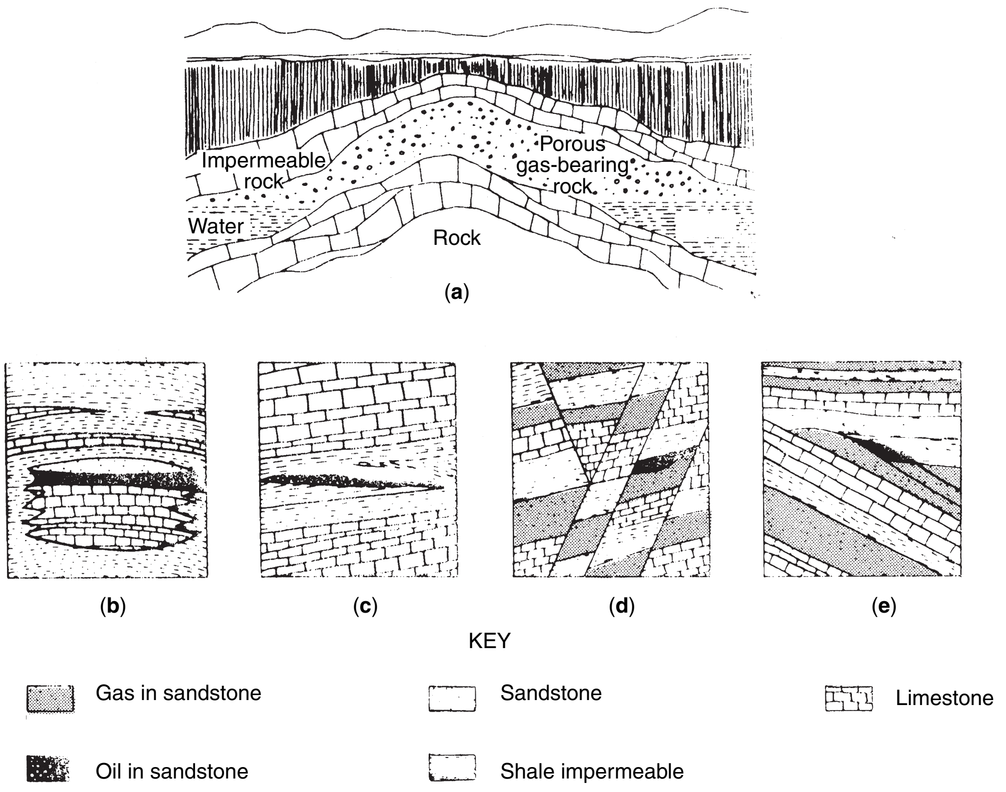

Fig. 1. Types of natural gas reservoirs and entrapments: (**a**) anticlinal trap; (**b**) coral reef trap; (**c**) stratigraphic trap; (**d**) fault trap; and (**e**) unconformity

primarily because of closure induced by structural deformation, such as folding or faulting. Within this category should also be included entrapments attributed to hydrodynamic forces. (2) *Stratigraphic trap*—an entrapment in which migration of hydrocarbons has terminated because of the pinchout of reservoir rock due either to truncation or to nondeposition or to a facies change in the form of diminished permeability of reservoir rock. Also included in this category are entrapments in which a pinchout of facies change provides part of the barrier to migration of hydrocarbons, with structural elements providing the remaining closure for the entrapment. In these cases, it is recognized that the dominant cause of the accumulation is the lenticularity of truncation of the reservoir rock.

Some estimates indicate that about 65.8% of ultimately recoverable natural gas in the United States will be found in structural traps; the remaining 34.2% in stratigraphic traps.

The estimated ultimate recovery is also reported by the geologic age of the reservoir. It is recognized that problems may arise where the geologic age of a reservoir cannot be determined specifically, such as Permo-Pennsylvanian and Cambro-Ordovician, or where production from reservoirs of different geologic age is combined.

Natural gas liquids occur in either the gaseous phase or in solution with crude oil in the reservoir. They are recovered at the surface as liquids by separation from produced natural gas, by such processes as condensation and absorption in field separators, gasoline plants, and other surface facilities. In this processing, valuable by-products are recovered, such as light oils, natural gasoline, and other petroleum gases such as ethane, propane, and butane. Natural gasoline is blended with gasoline from petroleum refineries to improve starting properties, especially desirable in cold weather. Ethane is a major petrochemical raw material. Propane and butane are made available as LPG (liquefied petroleum gas). Processing of natural gas also removes unwanted material, such as nitrogen, sulfur compounds, carbon dioxide, and water vapor. Some gas fields produce helium, which is extracted cryogenically.

Unconventional Sources of Natural Gas

These include: (1) tight sandstones, (2) Devonian shales, (3) geopressured zones, (4) deep basins, (5) gas associated with coal seams, and (6) gas in the form of methane hydrates.

1. *Tight Sandstones.* In the United States, tight sandstones of the western basins range from the northern tier states to the Mexican border. Some tight gas sands also occur in the eastern United States. To date, resource development has occurred only in the limited areas characterized by thick, fairly uniform, blanket-type formations which, when hydraulically fractured, provide sufficient gas production rates to merit commercial exploitation. In these areas, as pointed out by Sharer (Gas Research Institute, GRI), state-of-the-art technologies can be used because only a limited knowledge of the formation characteristics is required for economic production. However, a majority of the resource base is associated with lower permeability and more complex blanket and lenticular sand formations, for which current technology is not adequate. GRI is concentrating research in these areas.
2. *Devonian Shales.* The large eastern Devonian gas shales resource base underlies approximately 174,000 square miles (453,000 km^2) of the eastern U.S. Estimates of recoverable gas range from 2 to 15% of the gas in place. Natural gas has been produced from these shales for decades. Well production rates are relatively low, but after the first few years of production it does not usually decline rapidly with time. A major constraint to present-day exploitation has been the extraordinary inability to predict with confidence the gas production rates that may be obtained in wells drilled outside the traditional production areas. Presently, the GRI is studying the systematics of historically successful fields, including the Appalachian, Illinois, and Michigan Basins.
3. *Geopressured Zones.* A test well in a geopressure zone was drilled some years ago in Tigre Lagoon in the coastal marshes of southern Louisiana. Known as Edna Delcambre #1, this well produced at a rate of up to 10,000 barrels of water per day from a sandstone aquifer some 12,600 feet (3840 meters) below the surface. Pressure at that depth is nearly 11,000 pounds per square inch (748 atmospheres) and the temperature is 116°C. Quite an elaborate manifold system is required to collect the gas. The water is disposed by forcing it by its own pressure into another well bore, which penetrates to a depth of 2500 feet (762 meters). Scientists associated with this project had expected about 20 cubic feet/barrel (42 gallon); about 0.6 cubic meter/barrel (159 liters). In actuality, reports indicate that the yield of gas was about 2.5 times that amount.

As explained by specialists in geopressure technology, at great depths (in terms of present technology), the solubility of natural gas in water may be as much as 1000 cubic feet/barrel (28.3 cubic meters/159 liters) at depths of 30,000 feet (9144 meters), whereas that solubility will be reduced by a factor of ten at a depth of 20,000 feet (6096 meters). Under the right combination of geologic and hydrologic conditions, this gas-laden water will move toward the surface, during which process some of the gas will be released from the water in the form of very small bubbles. Ultimately, this gas collects beneath a geologic trap, where conventional free-gas reservoirs are formed. Some authorities now believe that the very deep aquifers are much more extensive than the free-gas reservoirs. It is this gas-saturated water that some scientists believe will be a great source of future natural gas.

The GRI has been investigating the coproduction of gas and water for a number of years. Natural gas from watered-out reservoirs, geopressured aquifers, and high-water-saturated gas-bearing reservoir strata are prime targets. This natural gas is trapped by water such that special production techniques must be used to move the water and remobilize the gas. Although some gas is also dissolved in the water, it is of less significance than the free gas trapped as dispersed bubbles or in pockets or stringers of various sizes in the reservoir rock matrix.

4. *Deep Basins.* These are found at depths between 15,000 and 30,000 feet (4572–9144 meters) and are estimated to contain significant quantities of gas, but generally await the development of advanced production technology and economic incentive.
5. *Gas Associated with Coal Seams.* Methane, the principal constituent of natural gas, is generated during the geologic process of coal formation. A significant portion of this gas is trapped by impermeable strata, and it is present within the fractures and micropores of the coal. (The presence of methane is an ever-present hazard in coal mining.) Major variations in resource estimates are due to uncertainties in the gas content and size of the deeper, not minable coal deposits in the western states that form the major portion of the resource base. Seeking such gas may involve depths as great as 6000 feet (1829 meters) underground. Except for reasons of safety, little effort has been made to recover any of this resource due to high recovery costs, potential uncertainties in production, and deficiencies in state-of-the-art equipment, particularly for the deeper coals. The GRI is concentrating its research efforts on unminable coal because of its large potential as a resource base. While the gas resource associated with mining amounts to about 10% of the energy value of the coal, producers rarely apply new gas recovery technology except where safety is a requirement. Targets of the GRI program are deep coal seams, multiple seams interbedded with shales and sandstones, and deep multiple beds that are too thin to mine.
6. *Methane Hydrates.* Within a certain range of pressures and temperatures, methane and water form hydrates. Described as icelike substances, these hydrates are believed to occur in very substantial quantities, particularly beneath permafrost and in deep-ocean bottoms. Although slush has occurred in gas pipelines under certain conditions for many years, the existence of hydrates in nature was not made known until the mid-1960s. Geologists and hydrologists had previously assumed that gas of this type would have dissipated during earlier geologic ages. This is another area of natural gas resource research awaiting economic incentives.

Exploratory Methods

The principal exploratory methods used are: (1) *Airborne magnetometers*, which seek out anomalies in the magnetic field. Experienced geologists relate these irregularities to the probability of gas reservoirs below the surface. (2) *Satellite imagery*, from which surface structures and patterns can be related to previous pattern recognition studies made of surfaces below which gas reservoirs exist. (3) *Gravitometers* are used to detect subtle variations in gravitational pull inasmuch as this is less for a gas reservoir than for continuous dense rock formations. (4) *Seismic methods*,

which constitute the most widely-used of exploration methods. (5) *Data logging methods*, wherein an instrument is lowered into the borehole and which telemeters back to the surface readings of sonic absorption in an effort to determine the nature and thickness of rock formations. Data loggers operate on the basis of several physical phenomena. (6) *Fossil inspection*. The careful examination of microfossils can assist in fixing the age of rocks that are being penetrated. The condition of the fossils also can be related to probable temperatures to which they have been exposed over geologic periods and these, in turn, can be advantageous in locating possible gas deposits. Usually a combination of two or more exploratory techniques is used.

Liquefied Natural Gas (LNG)

The liquefaction of natural gas for storage and transportation and regasification for final distribution dates back several decades. A few major accidents in the handling of LNG thwarted the progress of the field for a while, but in the early 1970s, LNG was again considered in a major way because of energy-short nations. One of the more serious LNG accidents occurred in Cleveland, Ohio on October 20, 1944, when a storage tank developed a leak with spillage and subsequent fires in the surrounding neighborhood in which 135 persons lost their lives. While liquefaction offers marked storage space savings and convenience, the predominant advantage occurs in connection with both pipeline and ship transportation. Energy-short nations, such as Japan, and some of the European nations, have turned in recent years to the concept of shipping LNG by ship. For example, a large LNG plant at Lumut, Brunei, Borneo went onstream in mid-1974 essentially to furnish LNG to Japan.

Oil- and gas-rich nations, which at one time flared to the atmosphere much of the natural gas that accompanied the production of crude oil, have turned toward conservation—either through reinjection of much of the natural gas underground or through constructing LNG production facilities for shipment of the product overseas. Concurrent with such planning was reevaluation by a number of nations of their own valuable resources and a growing reluctance toward exporting inordinate quantities of gas and oil strictly for money. As of the early 1990s, the shipment of LNG overseas competes with other ways and means for alleviating energy shortages, including coal conversion and gasification, nuclear energy, solar energy, etc.

Three types of liquefaction processes may be used for production of LNG. The standard cascade process, which uses three refrigerants—methane, ethylene, and propane—all circulating in closed cycles, is shown in Fig. 3. There is a separate compressor for each of these refrigerants. The methane and propane are available from the feed gas (natural gas). The ethylene must be furnished separately. Ethane may be used in place of ethylene at a subatmospheric suction pressure. The cascade process has the highest rank in terms of thermal efficiency. As a possible improvement over the cascade process, the mixed refrigerant process was developed in the early 1960s. A single-pressure mixed refrigerant cascade (MRC) system is shown in Fig. 4. In one plant using this process, a hydrocarbon-plus-nitrogen mixture of relatively wide boiling range (N2 through C5) is used as the refrigerant. All of these components can be recovered from natural gas in separate apparatus. In still another system, shown in Fig. 5 a propane and mixture-refrigerant cycle is used. In this process, the cooling load is divided horizontally at about −34.4°C into an upper portion absorbed by propane and a lower portion absorbed by the mixed refrigerant. In essence, the system is a dual refrigerant cascade in which the lower boiling fluid is a mixture refrigerant. The cascade combination with propane makes it possible to reduce the boiling range of the mixture refrigerant substantially, which improves the thermodynamic efficiency over that of the straight MRC process.

Cryogenic Upgrading of Low-Btu Natural Gases

Worldwide, there are substantial reserves of natural gas in which the reservoir formation hydrocarbons are contaminated with nonburning components. The presence of components, such as helium, nitrogen, or carbon dioxide, reduces the heating value of the gas mixture. This can result in the gas being unsuitable for existing transmission and distribution systems. Such contaminated mixtures are termed low-Btu gases if their heating values fall below the minimum standards, regulations, or contract heating value requirements.

Cryogenic processing can be used to upgrade some of these low-Btu gases so as to produce an acceptable high-Btu product. Cryogenic upgrading is a physical process in which subambient temperatures are

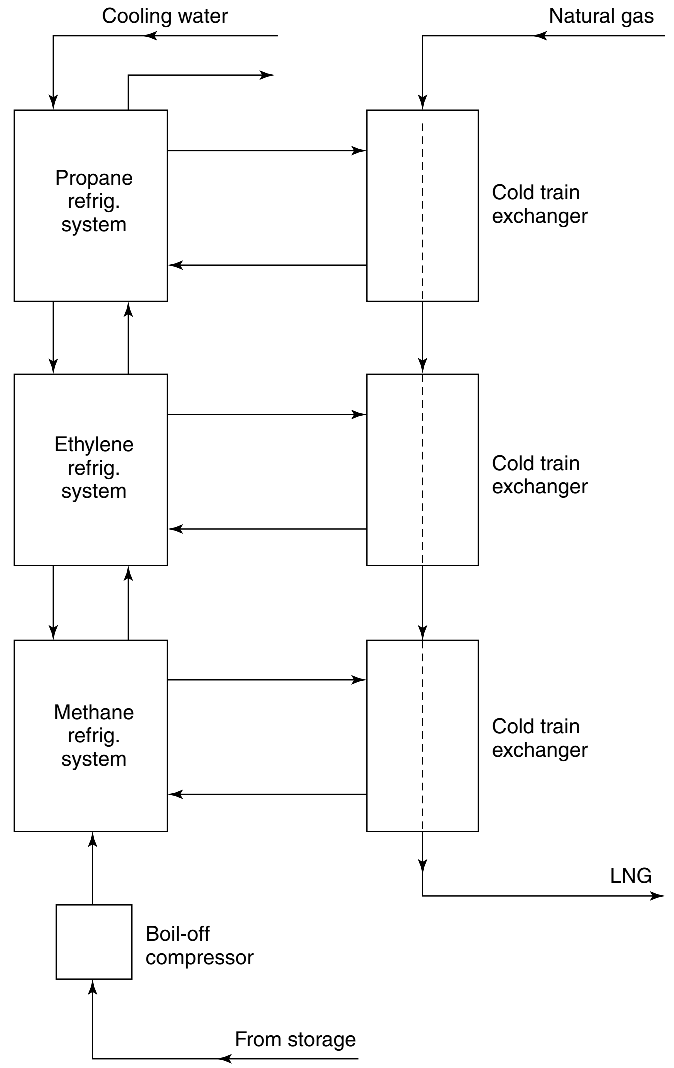

Fig. 3. Conventional or standard cascade system for producing liquefied natural gas (LNG)

employed to bring about a separation between the hydrocarbons and nonhydrocarbons in the mixture. The reduction of temperature occurring during cryogenic processing produces a two phase (gas-liquid) mixture. The relative volatilities between the components in the mixture result in selective mass transfer between the two phases. One phase becomes enriched with hydrocarbons and then has a heating value higher than the original gas. The second phase becomes denuded of hydrocarbons and has a heating value below that of the original gas mixture. Frequently, the mass transfer operation requires several theoretical stages in order to achieve the desired product heating value and high hydrocarbon recoveries. While cryogenic upgrading can be applied to gas mixtures containing carbon dioxide or hydrogen sulfide, it has so far only been applied commercially to those hydrocarbon mixtures contaminated with nitrogen and helium.

One of the main considerations in the design and operation of cryogenic upgrading plants is to identify and remove any component from the gas that could adversely affect the operation of the cold sections of the plant. Such components are carbon dioxide, water vapor, and heavy hydrocarbons that have high solidification temperatures and low solubilities. In general, if these components are allowed to remain in the gas to the cryogenic unit, they will form solids during the cooling process that will be deposited on the heat exchanger surfaces. This will lead to fall-off in performance and, possibly, to blockages and plant shutdown.

Particular attention should be paid to identifying any high freezing point components in the low-Btu gas. There exists a range of absorption and adsorption processes to pretreat the low-Btu gas to remove these undesirable components.

A simplified flowsheet of cryogenic upgrading plant is given in Fig. 6. The plant, consisting of two identical trains, is capable of processing 260

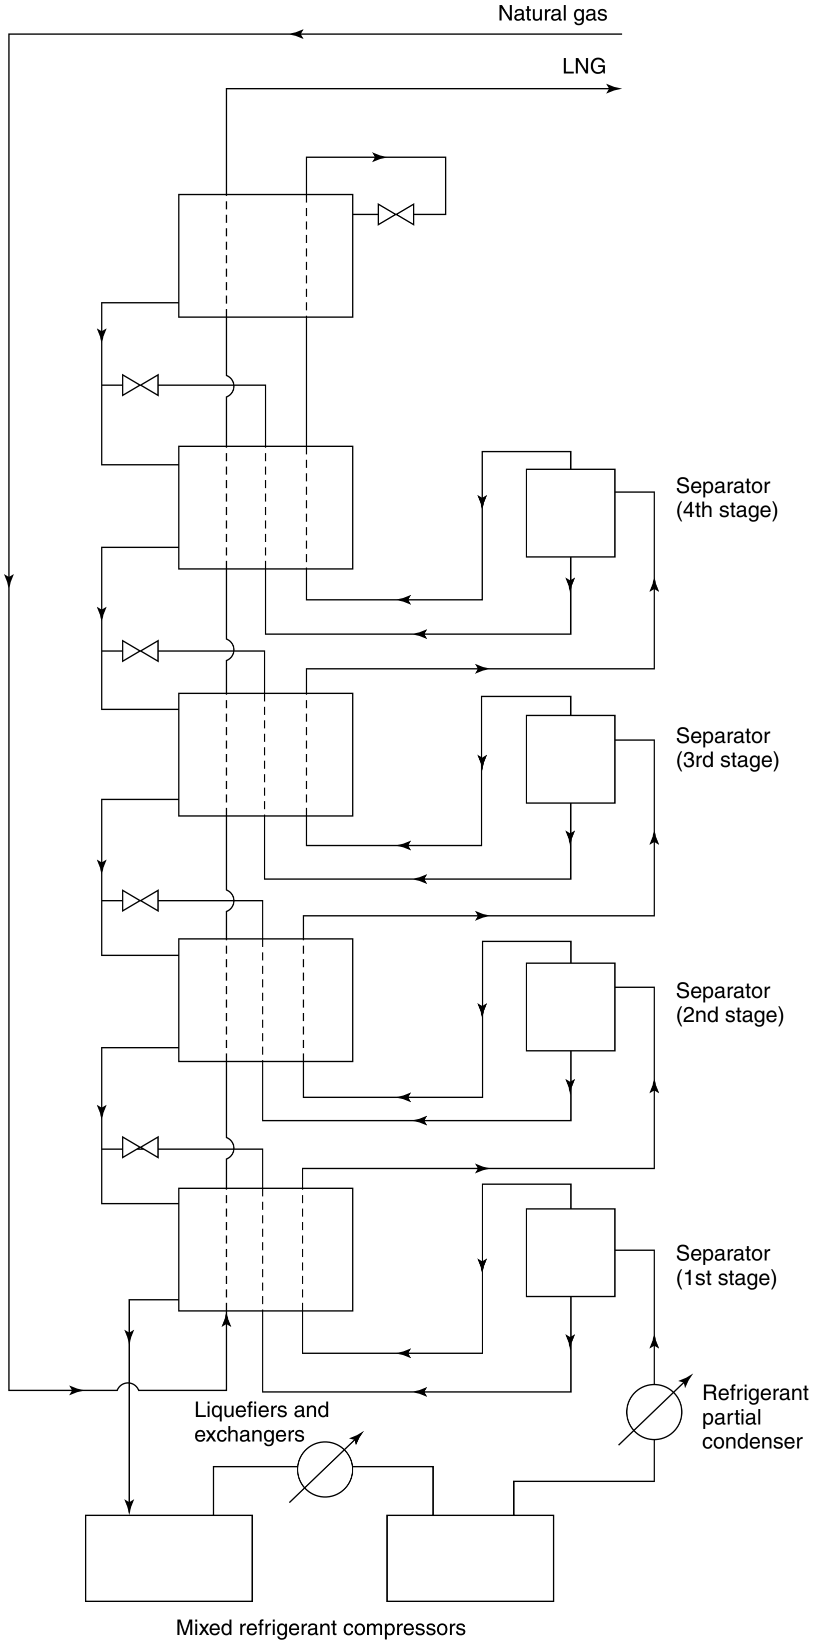

Fig. 4. Single-pressure, mixed refrigerant cascade system for producing LNG

million standard cubic feet (7.3 million cubic meters) per day of low-Btu gas (580 Btu/standard cubic foot) (5162 Calories/cubic meter) and upgrading the gas into 143 million standard cubic feet (4 million cubic meters) of high-Btu gas (980 Btu/standard cubic foot; 8722 Calories/cubic meter). The plant stream parameters are indicated in Table 2.

The low-Btu gas is available at 800 psig (54 atmospheres) and is mainly a nitrogen-methane mixture. In addition to a small quantity of helium, the gas also contains small quantities of carbon dioxide, water vapor, and heavy hydrocarbons. The carbon dioxide is removed by washing with monoethanolamine (MEA), the water is taken out on molecular sieve, and the heavy hydrocarbons by adsorption on activated carbon. The gas is then cooled in aluminum plate-fin exchangers against the returning high-Btu product gas and vent gas. The gas is then expanded to 380 psig (26 atmospheres) and a vapor-liquid mixture passes into the H.P. (high

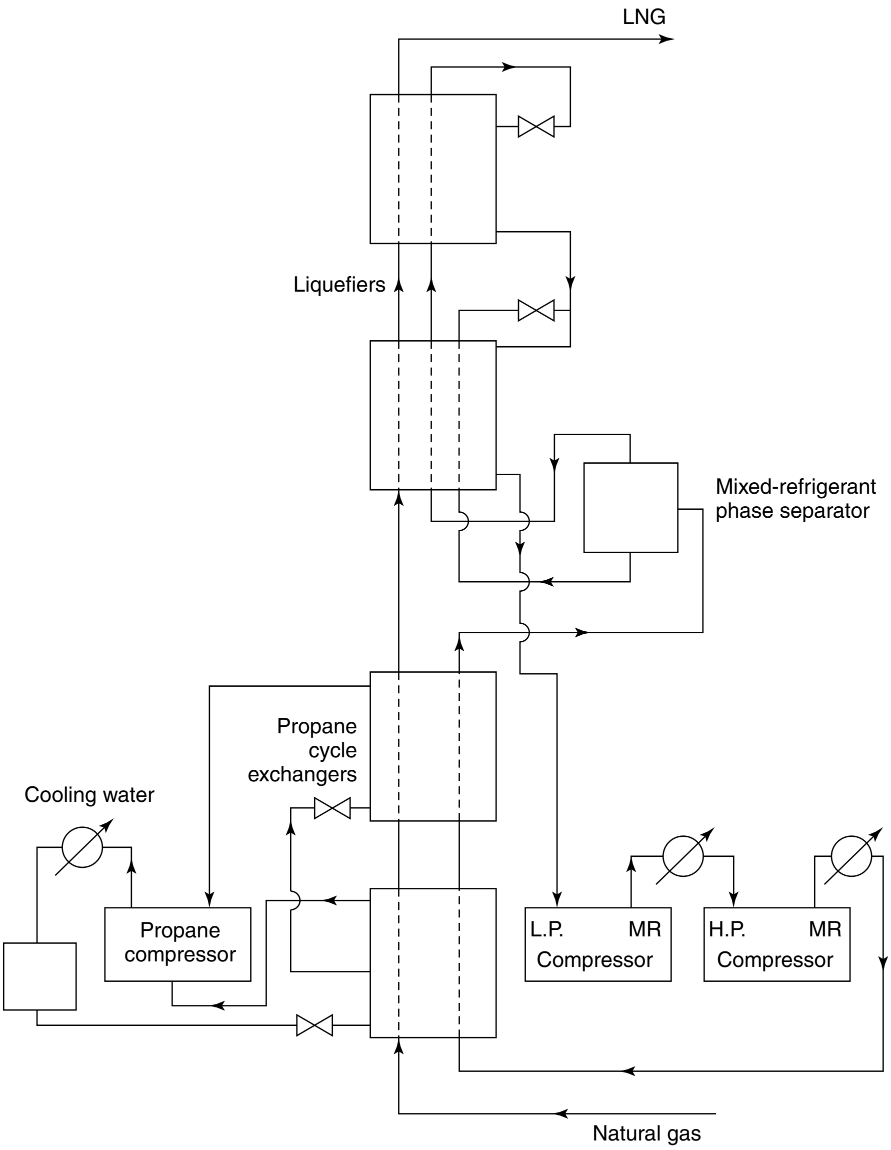

Fig. 5. Propane-mixed-refrigerant liquefaction system for producing LNG. L.P. = low pressure; H.P. = high pressure; MR = mixed refrigerant

pressure) fractionator. The purpose of this fractionator is to bring about an initial separation of the nitrogen-methane and to produce a liquid reflux for the L.P. (low pressure) fractionator.

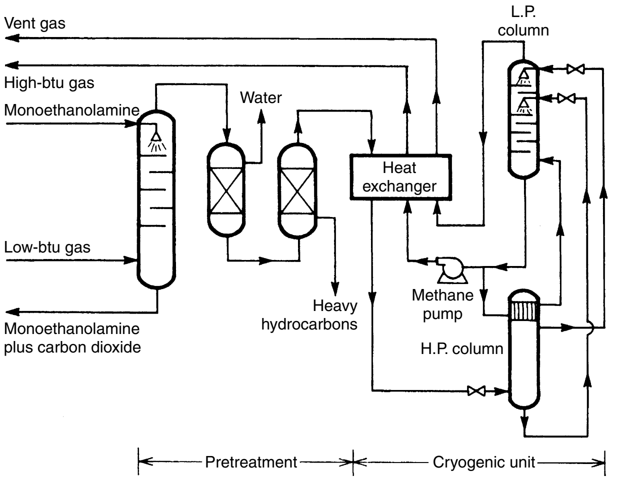

Fig. 6. Plant for nitrogen removal from natural gas using cryogenic upgrading. (*Petrocarbon Developments, Ltd*)

TABLE 2. CRYOGENIC UPGRADING OF NATURAL GAS—STREAM PARAMETERS COMPOSITION—MOL.%

	Low-Btu gas	High-Btu gas	Vent gas	Helium
Helium	0.40	—	0.09	100.00
Nitrogen	42.75	4.00	98.95	—
Methane	56.02	95.09	0.96	—
Ethane +	0.53	0.91	—	—
CO_2	0.30	—	—	—
Flow (million standard cubic feet/day)	246	143	100	0.43
Flow (million cubic meters/day)	7	4	2.8	0.012
Heating value (Btu/standard cubic foot)	580	980	—	—
Heating value (Calories/cubic meter)	5162	8722	—	—

A nitrogen-enriched vapor flows up the H.P. fractionator, while methane is returned to the sump of this column by a nitrogen reflux stream produced in the tubes of the overhead condenser. The refrigeration required to produce this nitrogen reflux is provided by evaporating some of the liquid

methane, from the L.P. column, in the shell of the overhead condenser. Two liquid streams are taken from the H.P. fractionator, and these become the feed and reflux for the L.P. fractionator. The L.P. feed is an enriched methane stream taken from the base of the H.P. fractionator. The L.P. reflux is a high purity nitrogen liquid taken off the H.P. fractionator just below the condenser. The upgrading is completed in the L.P. fractionator. The feed stream is stripped to produce a high-Btu liquid containing 4% nitrogen and having a heating value of 980 Btu/standard cubic foot (8722 Calories per cubic meter). The liquid is pumped from the column sump, evaporated, and superheated against the incoming low-Btu gas. The gas from the top of the L.P. column is mainly nitrogen and is also heated to ambient temperature against the incoming low-Btu gas. By using this arrangement of two distillation columns, the separation of nitrogen and methane can be achieved using only the pressure energy available in the low-Btu gas.

Transportation of Natural Gas

The mode selected for gas transportation depends mainly on: (a) the distance over which the gas must be moved; (b) the geographical and geological characteristics of the terrain (considering both overland and overseas [underseas]) across which the gas must be moved; (c) environmental factors directly associated with the gas transportation mode; (d) the physical characteristics of the gas to be transported, notably, the phase—whether gaseous or liquid; and (e) the construction and projected operating costs of the transportation system, based upon trading off the advantages and limitations over which some flexibility of selection may be present. Aside from economic factors, a system can be engineered to transport either the gaseous or liquid phase, thus giving rise to considerable flexibility in certain situations.

Overland Pipelines. Detailed maps of gas pipelines in the United States and other parts of the world can be found in several references, particularly among the periodicals serving the pipeline industry. Notable among these references is the international petroleum encyclopedia and atlas issued periodically by Petroleum Publishing Co., Tulsa, Oklahoma. Numerous trade associations serving the pipeline industry are also excellent sources on pipeline statistics. There are so many pipelines that presentation of this type of information is beyond the scope of this encyclopedia.

Historically, Texas, Louisiana, Oklahoma, and New Mexico have been large producers of natural gas, as well as some significant fields in the West Virginia-Ohio-Pennsylvania area. New developments in Alaska are and will continue to influence the gas transportation and distribution pattern.

Much of the installed gas pipeline ranges from 14 to 30 inches (36 to 76 centimeters) in diameter, the most common ranging from 20 to 35 inches (51 to 89 centimeters) but there is a strong trend toward larger-diameter lines, from 42 inches (107 centimeters) upward. Line pipe is made from high-strength plates, 3/38 inch to 1 inch (1 to 2.5 centimeters) in thickness. Sections of pipe are usually 40 feet (12 meters) long, minimum, ranging up to 60 or 80 feet (18 or 24 meters). Lengths of pipe arrive at the scene most often by truck and are strung out by special pipe carriers along the right-of-way so that the construction crews will find them near the place where they are to be installed. Helicopter delivery of pipe is sometimes used where it is impossible for trucks to do the job. The total weight of steel going into a long-distance pipeline is impressive. For example, a pipe with a wall thickness of 1/2 inch (13 millimeters) and a diameter of 30 inches (76 centimeters) will weigh more than 400 tons (360 metric tons) per mile.

In building very long pipelines, the pipeline company usually employs several construction contractors. The total length of line is divided into a number of sections with separate equipment and crews. Usually, each crew works on not more than 100 miles (161 kilometers). By partitioning the construction task, the entire operation can be speeded up, particularly important in areas where freezing temperatures or rain and mud may interfere with the work.

The numerous machines needed to dig the trench, weld the sections of pipe, apply protective coating to prevent corrosion, lower the pipe into the trench, and cover the trench with earth are known collectively as a *main line spread*. The trench is usually 3 or more feet (1 meter or more) in depth, sufficiently deep to prevent damage by plowing and earth-moving equipment. Depending on the size of the pipe, the trench will range from 2 to 4 feet (0.6 to 1.2 meters) or more in width.

Teams of welders join the pipe sections into a continuous tube. The most modern welding techniques involve automatic welding machines. X-ray equipment is used to inspect welds. When several sections of pipe have been welded together, the continuous tube is lowered gently into the trench by *sideboom tractors*. These machines have cranes or derricks slanted over to one side so that they can pick up the pipe and lower it several feet away from the tractor itself. Pipe purchased from steel mills may come with a coating and wrapping already applied. The thick coating may be of coal tar or asphaltic material, which is then covered with heavy paper or fiberglass. This protective coat-and-wrap is needed to prevent rusting. If bare pipe is used, there are special machines that coat and wrap right on the job just before the pipe is lowered into the trench.

A special piece of equipment, known as the *holiday detector*, is a hoop of metal placed around the pipe after it is coated and wrapped. A small electrical current flows through the hoop. If there is a “holiday,” i.e., a spot where there is no coating, the detector alerts the operator. This is brought to the attention of a special crew that coats and wraps bare spots in the pipe.

Since pipelines do not follow an absolutely straight line, bending machines are used to curve the pipe in the vertical, horizontal, or both directions. When a pipeline must cross a river, the contractor will dig or dredge a deep trench in the river bed. The pipe is then surrounded by heavy weights and encased in concrete so that it will not be carried away by the current. If there is a suitable bridge across the river, the pipeline may be hung from the underside of the steel girders of the bridge. In some cases, a special bridge is constructed to carry the pipe across the stream. In crossing a highway or railroad, the pipeline must be put through a tunnel under the structure. A giant auger will be used to bore under the road to accommodate a section of somewhat larger-diameter pipe, forming the tunnel through which the main pipeline passes.

Gas pressures in long-distance pipelines may range from 500 to 5,000 pounds per square inch (34 to 340 atmospheres) with 1,000 psi (68 atmospheres) being quite common. Pressure is boosted to make up for frictional losses by use of compressor stations located every 50 to 100 miles (80 to 161 kilometers) along the pipeline. In terms of lineal velocity, natural gas may travel at a rate of about 15 miles (24 kilometers) per hour; thus, about three days are required to move a molecule of gas over a distance of 1,000 miles (1609 kilometers).

All along the pipeline, there are valves and regulators that may be opened or shut to control the internal pressure, or to cut off the flow entirely if an unexpected break in the line is caused by a flood, earthquake, or other disaster. The valves and regulators can be operated by microwave radio long before any crew could reach them. Stations for reducing the pressure, located near points of consumption, frequently are called *city gates*. These stations measure the amount of gas leaving the main pipeline at this point as well as reducing the pressure.

Marine Pipelines for Gas

With some alterations, the techniques that apply to construction and laying of marine pipelines for gas also apply to fluids, such as oil. Marine pipelines can be underwater in a river, marsh, or ocean, but the predominant industry effort in recent years is the construction of pipelines in the open ocean at increasingly deeper levels. The trend toward deepwater pipelining and construction in harsher environments naturally follows the expansion of the search for offshore gas and oil. This search began in earnest after World War II and is expanding at an ever-increasing rate; even if slowed to some extent by some environmental concerns in the United States, the rate is rapid in other parts of the world. Worldwide energy needs have caused oil companies to move into areas that only a few years ago would have been too expensive to develop on a practical basis. Lines are now being laid in water depths of several hundred feet (meters) and cover distances of 200 miles (320 kilometers) or more from field to shore. These longer lines are major trunk lines bringing gas and oil to land terminals. Other lines are necessary out at the field to connect platforms to each other; or possibly to connect platforms to sea berths.

The sizing of the pipeline, the design of the pumping and compression systems needed to move the products, the design of the automation systems, and many of the corrosion control procedures are the same regardless of whether the pipeline is on land or at sea. The two major areas of design difference between land and marine pipelines are (1) the stresses incurred in getting the pipeline to the sea bottom, and (2) the necessity of keeping the line stable and in place while it is exposed to forces induced by current and wave.

The stability problem is theoretically simple but is complicated somewhat by the uncertainty of precise values for some of the coefficients

used in the calculations. Basically, it is a matter of providing enough weight in the pipe and pipe coating system to provide a net downward force when balanced against the buoyance and the lift force caused by the seawater moving by the pipe. This net downward force, in conjunction with the coefficient or friction for the particular pipe-soil combination under examination, can then mobilize a horizontal resisting force. This should be somewhat larger than the drag force exerted on the pipe by the water motion in order to give the desired safety factor.

Different safety factors or horizontal water velocities may be utilized depending on the operating conditions that will be encountered during the life of the pipeline. For example, many pipelines will be buried beneath the sea bottom at some time interval, ranging from a few weeks to a year or two, after their construction. The exposure of this line to maximum horizontal water velocities caused by storm current and waves is obviously much less than that of a line that will remain on the surface of the sea bottom. It is also obviously necessary to consider whether the line will contain gas, oil, or other substance at the time the design loads may occur.

It is important to carefully consider the foregoing points in the design of the weight coating since the ability of a contractor to safely construct the line relates very closely to the negative buoyancy of the pipe and coating.

The most common method of marine pipeline construction utilizes a floating vessel on which the pipe is assembled in a horizontal position. As additional joints or sections of pipe are added to the already-completed segment, the barge is moved forward, actually moving out from under the completed pipeline. This is sometimes called the "stovepipe" method, named after the manner the pipe sections are added, one after another. This pipeline extends off the stern of the vessel and spans down to the sea bottom. It is supported part of the way down by a construction aid called a "pontoon" or "stinger." This is basically a slender structure pinned to the vessel on one end and with built-in buoyancy that can be controlled so that it floats at the proper angle to the water surface to provide support to the pipeline.

In shallow water, the pipeline is then allowed to span from the end of the pontoon to the sea bottom as a simple beam. As water depths increase, it becomes necessary to add tension to the pipe on the barge. This, of course, changes the analytical problem from one of a simple beam to one of a beam under tension. This analysis must take into account the weight of the pipe, the wall thickness, the type of steel in the pipe, the tension on the pipe, the support of the pontoon, the geometrical configuration of the tension on the pipe, the geometrical configuration of the pipe-pontoon-barge system, and the pipe end condition at the sea bottom.

There are three basic configurations of pipelay vessels in common usage: (1) the barge-type hull; (2) the ship-shape hull; and (3) the semi-submersible vessel. The barge-type hull (Fig. 7) is the most common because of its economy and simplicity, its ability to provide the space and stability for heavy lifts and deck cargo, including pipe, and its shallow draft, permitting work close inshore. The primary disadvantage is its relative sensitivity to sea conditions. In particular, roll and heave motions will shut down pipelay operations in 6-foot to 14-foot (1.8- to 4.2-meter) waves, depending on wave direction and period.

Overseas Shipping of LNG. A key feature of most LNG carriers in operation is the insulation system, which maintains the cargo at −162°C. In one type of ship, the cargo is carried in five tanks constructed of a thin welded membrane of special steel. Each tank is separated from the inner hull by insulating material. The small fraction of the cargo that boils off because of heat leakage is used as boiler fuel for the propulsion of the ship. On a loaded voyage, this may provide about 90% of the fuel needed. The ships are ballasted for return voyage with seawater carried in separate wing tanks. Some LNG is left in the cargo tanks to ensure a nonexplosive gaseous atmosphere and to keep the tanks cool for the next voyage. Again, boil-off gas provides part of the propulsion fuel. One configuration of an LNG ship-loading system is shown in Fig. 8.

Safety in handling LNG in ships and at loading and unloading terminals of large scale has been a matter of constant concern. The observation has been made that the LNG gas carried would bury a football field under 125 feet (38 meters) of liquefied gas, or, after conversion to the gaseous phase, 600 football fields to the same depth. One factor that has not been routinely considered in the past is a phenomenon called a *flameless vapor explosion*. It is well known that, if water, for example, could be heated without nucleation occurring on the sides of the vessel, the water temperature could be raised well above the boiling point of 100°C. If this could be done, and with the continued application of heat, the liquid would suddenly explode in its transition from the liquid to the vapor phase. Although not probable, it is possible that conditions favoring flameless vapor explosion could occur if liquefied natural gas were permitted to escape over a water surface. One scientist has observed that an explosion of this kind is possible when a liquid is 4 to 6% (no more, no less) above its normal temperature of vaporization. It is further observed that an explosion of this nature would not occur when LNG first spreads across a volume of water, but with time and the warming of the LNG such a hazard could occur. While an explosion of this type is not comparable to that from a chemical reaction, the explosion could greatly disperse the LNG over a greater area, thus spreading the zone of risk.

Underground Storage

The largest additional supply of natural gas for peak demands comes from underground storage reservoirs located, for example, close to the northern cities, as compared with the producing wells which may be located in the southwestern area of the country. Some of the storage pools are operated by pipeline companies, but most of the gas in underground storage is owned by the local gas companies that serve metropolitan areas.

The underground reservoirs are filled with gas from the pipelines during the summer months, when all of the fuel that the lines can deliver is not consumed. This method allows the producing wells and the pipelines to operate at fairly steady rates at all times of the year. Also, it is established that a gas field will produce more gas over a longer period if the gas is withdrawn at a steady rate.

Four states—Michigan, Pennsylvania, Illinois, and Ohio—have half of the total underground gas storage pools in the United States, with a total

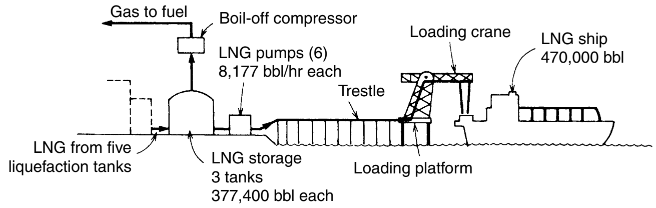

Fig. 8. LNG ship-loading system. Trestle is 2.6 miles (4.3 km) long

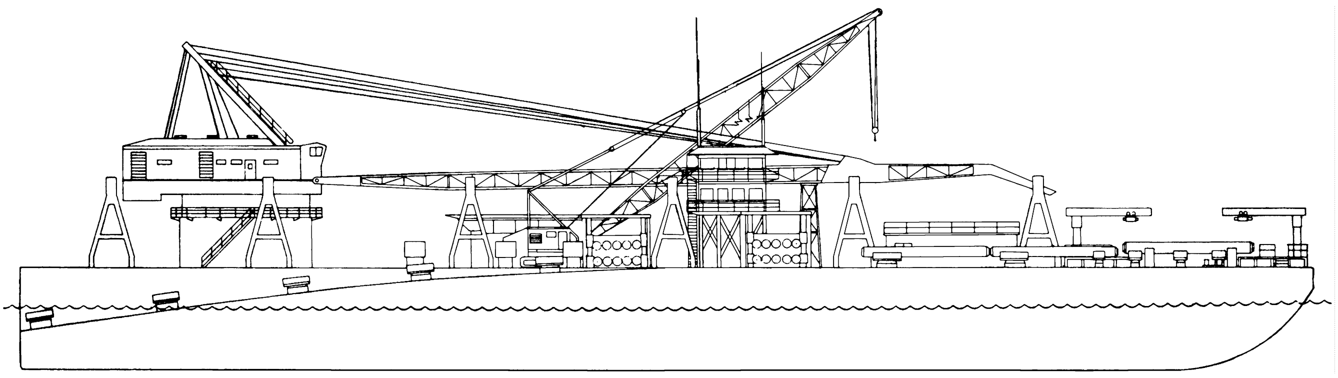

Fig. 7. Pipelay vessel with barge-type hull

capacity of over 5 trillion cubic feet (142 billion cubic meters). In a typical year, about one-fourth of this volume will be used during cold waves to furnish the additional gas needed to supply homes and apartments.

The most common type of underground reservoir now storing gas is a previously producing gas or oil field. The supplies remaining in these pools are too small, and at too low a pressure, to justify continued production. But, the reservoir rock can hold gas pumped down through the same wells that once took gas out of the ground.

About 90% of the storage pools being used once produced gas or oil. In Pennsylvania there are over 60 such pools close to the large industries and centers of population. There are over 30 such pools in West Virginia, Michigan, Ohio, Kansas, Indiana, New York, and Kentucky, as well as smaller numbers in 13 other states. The gas to be stored is pumped into the old wells by compressors similar to those used to move gas in pipelines. The gas is stored under about the same pressure as originally existed in the field. In developing a gas storage reservoir, a company obtains a lease from the landowners in much the same manner that gas producers do.

The gas industry has been developing underground storage reservoirs for more than 60 years. The first known experiment in storing gas underground was conducted in 1915 in Welland County, Ontario, Canada by the National Fuel Gas Company. The success of this effort prompted the Iroquois Gas Corporation, a subsidiary of National Fuel, to develop, in 1916, the Zoar field south of Buffalo, New York. It was the first storage operation in the United States and is the oldest continuously used reservoir.

During the past 60 years, over 80 companies have invested several billions of dollars in underground storage facilities.

Another kind of underground storage reservoir is called an aquifer. An aquifer is an underground rock structure holding large quantities of water. The underground rock is porous and permeable. The pore spaces are filled with water, and impermeable rock covers the porous rock. Wells are drilled into such formations, and gas is forced into the pores under pressure. As the gas pressure increases, the gas pushes the water farther down into the porous rock, making room for the gas.

There are over 40 aquifers in the United States, located in Illinois, Indiana, Iowa, Kentucky, Minnesota, Missouri, Utah, and Washington. Three unusual reservoirs have been developed: an abandoned coal mine in Colorado; and salt domes in Michigan and Mississippi.

History of Natural Gas as an Energy Resource

It is reported that, perhaps 2,000 years ago, the Chinese piped natural gas from shallow wells through bamboo poles, for burning under large pans to evaporate seawater for salt. The first commercial use of natural gas in the western world was for lighting the streets of Genoa, Italy, circa 1802. The first evidence of natural gas deposits in the United States is found in reports of "burning springs" in various parts of New York, Pennsylvania, Ohio, and West Virginia. As early as 1626, French missionaries visiting the Indians in northwestern New York recorded that they could ignite gases rising from shallow waters. Many early reports were given of the presence of natural gas along the shores of Lake Erie and in the streams flowing into it. There also are references to "burning springs" in the Ohio River valley and along the Pacific shores of California. It is reported that General George Washington was fascinated by a "burning spring" in the Kanawha Valley, near Charleston, West Virginia, in 1775. Early settlers who drilled wells for water often reported the presence of traces of natural gas. The generally accepted birthplace of the natural gas industry in the United States is Fredonia, New York. Fredonia is located on Canadaway Creek, which empties into Lake Erie in the northwest corner of New York State. William A. Hart is reported to have dug a well in 1825 and obtained sufficient natural gas to light two stores, two shops, and a grist mill. Hollow logs were used for piping. Sufficient gas would accumulate in the well riser during the day to supply the gas lights at dusk. Hart was also instrumental in building the first natural gas lighthouse in 1829 along Lake Erie. The lighthouse, consisting of 13 gas lamps and reflectors in two tiers, served until 1859. In 1858, the first natural gas company in the United States was formed, The Fredonia Gas Light Company.

The consumption of natural gas gradually increased prior to World Wars I and II as more and more small pipelines brought communities within reach of natural gas fields accompanied by the retirement of previous manufactured or town gas facilities (the early forerunners of the substitute natural gas).

Natural Gas–powered Vehicles. The concept of natural gas–powered vehicles has become a *limited* reality in terms of the millions of gasoline- and diesel-fluid-power vehicles. In 1993, Mack Trucks (Allentown, Pennsylvania) and the Gas Research Institute have teamed to research and develop a natural-gas version of the Mack E7™ heavy-duty engine. A prototype of the design was scheduled for testing on a refuse vehicle in the Boston area. If successful, the engine also could be applied to a variety of heavy-duty vehicles, including long-haul tractor/trailers, construction equipment, and road maintenance trucks. The development was propelled by the needs of truck fleet owners who may be required by legislation to operate alternatively fueled vehicles. The engine will be required to meet applicable U.S. Environmental Protection Agency and California Air Resources Board emissions standards while maintaining the performance and reliability of its diesel-fueled counterpart. A 6-cylinder, 12-liter engine will be developed. The vehicle's onboard gas storage will hold the energy equivalent of about 45 gallons (170 liters) of diesel fuel.

Substitute Natural Gas. The oil crisis of the 1970s spawned a number of attempts to create synthetic natural gas. Some of these processes reached pilot and demonstration plant stages and beyond in their development. For example, substitute natural gas (SNG) from sewage wastes has enjoyed impressive success. The anaerobic digestion of a solid waste and water or sewage sludge slurry will produce a methane-rich gas.

NÉEL TEMPERATURE. The transition temperature for an antiferromagnetic material. Maximal values of magnetic susceptibility, specific heat, and thermal expansion coefficient occur at the NÉel temperature.

NEF REACTION. Formation of aldehydes and ketones from primary and secondary nitroparaffins, respectively, by treatment of their salts with sulfuric acid.

NEF SYNTHESIS. Addition of sodium acetylides to aldehydes and ketones to yield acetylenic carbinols; occasionally and erroneously referred to as the Nef reaction.

NEGATOL. A condensation product of *m*-cresolsulfonic acid with formaldehyde. A polymerized dihydroxydimethyldiphenylmethanedisulfonic acid. It is dispersible in water, forming very acidic colloidal solutions. The pH of a 5% dispersion is approximately 1.0.

NEGATRON. A term sometimes applied to the normally occurring negatively charged electron when it must be distinguished from a positron. In many parts of the world the name *negaton* is used instead of negatron. The word negatron is used in this encyclopedia wherever distinction is made between positively and negatively charged electrons.

NEMATIC LIQUID CRYSTALS. See **Liquid Crystals**.

NENCKI REACTION. The ring acylation of phenols with acids in the presence of zinc chloride, or the modification of the Friedel-Crafts alkylation-acylation procedure by substitution of ferric chloride for aluminum chloride.

NENITZESCU INDOLE SYNTHESIS. Hydrogenative acylation of cycloolefins with acid chlorides in the presence of aluminum chloride; with five- and six-membered rings, no change in ring size occurs, but with seven-membered rings, rearrangement takes place with formation of a cyclohexane derivative.

NEODYMIUM. [CAS: 7440-00-8]. Chemical element symbol Nd, at. no. 60, at. wt. 144.24, third in the Lanthanide Series in the periodic table, mp 1,016°C, bp 3,068°C, density 7.004 g/cm^3 (20°C). Elemental neodymium has a close-packed hexagonal crystal structure at 25°C. The pure metallic neodymium is silver-gray in color, the luster becoming dull upon exposure to moist air at room temperatures. When pure, the metal is soft and malleable and may be worked with ordinary equipment. Because the metal is pyrophoric, it must be stored in an inert atmosphere or vacuum. There are seven natural isotopes, ^{142}Nd through ^{146}Nd, ^{148}Nd, and ^{150}Nd. ^{144}Nd is mildly radioactive with a half-life of $10^{10}-10^{15}$ years. Seven artificial isotopes have been produced. Of the light (or cerium-group) rare-earth metals, neodymium is the third most plentiful and ranks 60th in abundance of elements in the earth's crust, exceeding tantalum, mercury, bismuth, and the precious metals, excepting silver. The element was first identified by C.A. von Welsbach in 1885. Electronic configuration $1s^22s^22p^63s^23p^63d^{10}4s^24p^64d^{10}4f^35s^25p^65d^16s^2$. Ionic radius Nd^{3+} 0.995 Å. Metallic radius 1.821 Å. First ionization potential 5.49 eV; second 10.72 eV.

Other important physical properties of neodymium are given under **Rare-Earth Elements and Metals**.

Primary sources of the element are bastnasite and monazite, which contain from 15 to 25% neodymium. Plant capacity involving liquid-liquid or solid-liquid organic ion-exchange processes for recovering the element is in excess of 200,000 pounds (90,720 kilograms) Nd_2O_3 annually. Metallic neodymium is obtained by electrolysis of fused anhydrous $NdCl_3$ or by the electrolytic reduction of the oxide in molten NdF_3.

Use of elemental neodymium as a colorant for glass was one of the early applications. The color ranges from pure violet to purple and finds use in sunglasses, protective glasses for industry, art objects of glass, tableware, and decorative fiber optics. Use of neodymium in amounts of 3–5% by weight imparts dichroic properties to glass. Neodymium-doped single-crystal yttrium-aluminum oxide garnets (Nd:YAG) have been used in lasers. Research has shown the Nd ion to exhibit laser characteristics in a wide range of compounds and glasses. A formulation of 75% neodymium and 25% praseodymium, frequently called didymium, is used as a metallurgical additive. Within the last several years, it has been found that the use of Nd_2O_3 in barium titanate capacitors increases the dielectric strength of these electronic components over a wider temperature range. Neodymium also has been used as an ingredient of phosphate-type phosphors. Investigations continue into further electronic and optical uses of the element and its compounds.

EDITOR'S NOTE: Extensive research during the early 1980s led to the development of a new and powerful magnet material with the probable composition, $R_2Fe_{14}B$ (where R = a light rare earth). The rare earth predominantly used thus far is neodymium. The recent neodymium-iron-boron material exhibits extremely powerful magnetic qualities as compared with traditional magnet materials. More detail is given under **Rare-Earth Elements and Metals**. Also see **Magnetism**.

Scientists (California Institute of Technology) reported that the isotopic composition of Drake Passage (Antarctica) seawater had been determined. The Antarctic Circumpolar Current, which controls interocean mixing, flows through the Drake Passage. The ratio, ^{143}Nd/^{144}Nd, was found to be uniform with depth at two experiment stations—with an intermediate value between those of the Atlantic and Pacific Oceans. Further, Piepgras and Wasserburg determined that the Antarctic Circumpolar Current is made up of approximately 70% Atlantic water. It was further reported that cold bottom water from a site in the south-central Pacific has the Nd isotopic signature of the water in Drake Passage. The investigators used a box model to emulate the exchange of water between the Southern Ocean and ocean basis to the north with the isotopic results. An upper limit of about 33 million cubic meters/second was calculated for the rate of exchange between the Pacific and the Southern Ocean. Further determinations of samarium and neodymium were made and found to increase approximately linearly with depth. In essence, the findings suggest that Nd may be a valuable tracer in oceanography and possibly useful in paleo-oceanographic studies. See also Ocean; and Polar Research.

NEON. [CAS: 7440-01-9]. Chemical element, symbol Ne, at. no. 10, at. wt. 20.183, periodic table group 18, mp −248.68°C, bp −246.01°C, density 1.204 g/cm^3 (liquid). Specific gravity compared with air is 0.674. Solid neon has a face-centered cubic crystal structure. At standard conditions, neon is a colorless, odorless gas and does not form stable compounds with any other element. Due to its low valence forces, neon does not form diatomic molecules, except in discharge tubes. It does form compounds under highly favorable conditions, as excitation in discharge tubes, or pressure in the presence of a powerful dipole. However, the compound-forming capabilities of neon, under any circumstances, appear to be far less than those of argon or krypton. No known hydrates have been identified, even at pressures up to 260 atmospheres. First ionization potential, 21.599 eV.

Neon occurs in the atmosphere to the extent of approximately 0.00182%. In terms of abundance, neon does not appear on lists of elements in the earth's crust because it does not exist in stable compounds. However, because of its limited solubility in H_2O, neon is found in seawater to

the extent of approximately 1.5 tons per cubic mile (324 kilograms per cubic kilometer). Commercial neon is derived from air by liquefaction and fractional distillation. For most applications, the gas need not be in a highly pure form, but may be supplied along with small quantities of the other rare gases, such as argon and krypton. The gas finds principal applications in various electronic devices and lamps, but the most familiar application is the neon tubes used mainly in signs. The use of neon signs for identification and advertising signs reached the Iron Curtain countries at a date much later than in the Western countries. Neon emits the familiar orange light. Neon also has been used in certain lasers.

In the 1983 Luberoff reference, the author observes that neon signs, once considered vulgar symbols of a consumer society, are fast becoming icons of a bygone era. However, in recent years a group of preservationists, people who formerly decried the impact of neon advertising, now often defend it. Luberoff points out how a blue-lettered sign (5878 neon-filled glass tubes) became an integral part of the Boston skyline. A study of Boston's signs and lights by the Boston Redevelopment Authority showed that this sign (Citgo) was the only commercial sign that the public thought should remain.

There are three natural isotopes, ^{20}Ne through ^{22}Ne, and four radioactive isotopes, ^{18}Ne, ^{19}Ne, ^{23}Ne, and ^{24}Ne, all with half-lives of less than 5 minutes. Ramsay and Travers first found the element when investigating the properties of liquid air in 1898. The element is easily identified spectroscopically. Neon emits characteristic red and green lines in its spectrum.

Neon in Meteorites

As pointed out by Lewis and Anders, the noble gases are unique among the elements found in meteorites. They are highly volatile and unreactive and they did not condense in even the most primitive meteorites and thus are present at only a minute fraction of their proportion in the sun, ranging from about 10^{-5} for xenon to 10^{-9} for neon and helium. However, very small quantities of these gases are tightly bound in the meteorite and are freed when the host mineral begins to melt or decompose at high temperatures.

Scientists have found three types of neon in meteorites: (1) Primordial or planetary neon (called neon *A*); (2) solar neon (neon *B*), which consists of solar-wind neon ions implanted in meteorites that happen to have been at the surface of their parent body; and (3) cosmogenic neon (neon *S*), formed when cosmic rays passing through the meteorite spall, or shatter, atomic nuclei in their path. Each type has different proportions of the three isotopes of neon. Although the procedure is too detailed for inclusion here, Lewis and Anders explain how, through the use of stepped heating of meteorite materials, the types of neon can be measured. Their ratios to each other provide clues as to what type of star may have been the source of a given meteorite.

NEPHELINE. Nepheline, of hexagonal crystallization, is a sodium-potassium aluminum silicate (Na, K)($AlSiO_4$). It is found in silica-poor geological environments, where there had been insufficient silica to form feldspar. Nepheline rocks are characterized by the absence of quartz within them. They constitute a mineral family group known as the *feldspathoids*. Crystals are extremely rare; usually occurs massive to compact. Luster, is greasy in the massive varieties; vitreous in crystals. Color grades from yellowish to colorless in crystals; gray, green and reddish in massive material. It ranges from transparent to translucent. Hardness is of 5.5–6, specific gravity of 2.55–2.65.

Immense masses of nepheline-rich rocks occur on the Kola Peninsula, the former U.S.S.R., in Norway and in the Republic of South Africa; also in the Bancroft, Ontario, Canada region. Smaller deposits are found in Maine and Arkansas in the United States. Fine crystals are found in lavas on Mt. Vesuvius, Italy.

Nepheline is used extensively in the manufacture of glass.

Elmer B. Rowley
Union College
Schenectady, New York

NEPHELOMETRY. Sir John Tyndall noted that particles that are invisible when directly in the path of a strong light become discernible when viewed from the side. Now known as the Tyndall effect, the phenomenon derives from reflection of part of the incident light by the particles. The reflected light is directly proportional to the number of particles in suspension. An instrument for measuring the intensity of reflected light so produced in a nephelometer and may be used for the quantitative determination of small amounts of diverse materials that have the ability to reflect light when in liquid suspension. Examples include the measurement of traces of silver wherein the chloride ion is added to a solution of material containing silver to produce insoluble silver chloride in suspension form. Small amounts of calcium in titanium alloys may be determined by measuring suspensions of the stearate formed in a suitable medium. Nephelometry also finds application in the measurement of bacterial growth rates; for the analysis of cholesterol, glycogen, and enzymes; for controlling the clarity of beverages, water, and wastewater; for solution control in tanning operations; and for any measurement situation where an unknown composition may be transformed into, or related to, a form of suspension.

Nephelometric methods are similar to fluorometric methods in that both involve measurement of scattered light. However, the scattering is inelastic in nephelometry and elastic in fluorometry. Thus, the scattered light measured in fluorometry is of a longer wavelength than the incident light, and both incident and scattered light are of the same wavelength in a nephelometric determination. In fact, the two functions sometimes are combined into one instrument, which may be termed a nefluoro-photometer. When the instrument operates as a nephelometer, it utilizes two Tyndall windows, located opposite each other in a cylindrical sample cell and with their common axis perpendicular to the path of the entering light. The concentration of suspended particles is determined by summing the photocurrents of the two cells. When used as a fluorometer, the instrument measures light emitted by a sample that is excited by incident radiation in the appropriate spectral band. Further, the same instrument can be set up for use as a photometer to measure light transmitted by the sample. Three light sources may be used—an incandescent source for colorimetric or nephelometric applications; a mercury-arc source for fluorometry; and a sodium-arc source with principal emission at 320 and 590 nanometers, when a sharp peak at either of these wavelengths is required, as in the instance of vitamin A determinations.

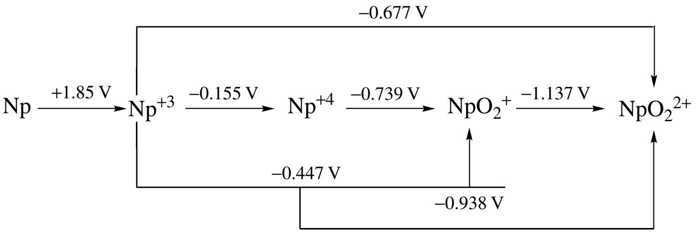
NEPTUNIUM. [CAS: 7439-99-8]. Chemical element, symbol Np, at. no. 93, at. wt. 237.0482 (predominant isotope), radioactive metal of the Actinide series, also one of the Transuranium elements. Neptunium was the first of the Transuranium elements to be discovered and was first produced by McMillan and Abelson (1940) at the University of California at Berkeley. This was accomplished by bombarding uranium with neutrons. Neptunium is produced as a by-product from nuclear reactors. ^{237}Np is the most stable isotope, with a half-life of 2.20×10^6 years. The only other very long-lived isotope is that of mass number 236, with a half-life of 5×10^3 years.

^{237}Np is parent of the neptunium $(2n + 1)$ alpha decay series. Other isotopes include those of mass numbers 229–235 and 238–241; metastable forms of ^{236}Np, ^{240}Np and two of ^{237}Np are known. Electronic configuration $1s^2 2s^2 2p^6 3s^2 3p^6 3d^{10} 4s^2 4p^6 4d^{10} 4f^{14} 5s^2 5p 5d^{10} 5f^5 6s^2 6p^6 \text{-} 6d^1 7s^2$. Ionic radii Np^{4+} 0.88 Å; Np^{3+} 1.02 Å (Zachariasen). Oxidation potential $Np \longrightarrow Np^{3+} + 3e^-$, 1.85 V; $Np^{3+} \longrightarrow Np^{4+} + e^-$, −0.155 V; $Np^{4+} + 2H_2O \longrightarrow NpO_{2+} + 4H^+ + e^-$, −0.739 V; $NpO_2{}^+ \longrightarrow NpO_2{}^{2+} + e^-$, −1.137 V. See also **Chemical Elements**.

Neptunium has the oxidation states (VI), (V), (IV), and (III) with a general shift in stability toward the lower oxidation states as compared to uranium. The compounds which are formed are very similar to the corresponding compounds of uranium.

The ionic species corresponding to the oxidation states vary with the acidity of the solution; in acid solution of moderate strength the species are Np^{3+}, Np^{4+}, NpO_2^{+}, and NpO_2^{2+} as in the case of uranium and plutonium. The potential scheme in 1-*M* HCl is as follows:



It will be seen that the metal is highly electropositive, in common with the other actinide elements. The $Np^3 \longrightarrow Np^{4+}$ couple is reversible and this oxidation can be accomplished by the oxygen of the air. The (IV) state is stable, not oxidized by air, and only slowly oxidized to NpO_2^{+} by nitric acid. The $Np^{4+} \longrightarrow NpO_2^{+}$ couple is not readily reversible, whereas the $NpO_2^{+} \longrightarrow NpO_2^{2+}$ couple is reversible; this is reasonable on the basis that the former involves making or breaking the neptunium-oxygen bonds, whereas the latter does not. The oxidation of NpO_2^{+} to NpO_2^{2+} requires moderately strong oxidizing agents. Neptunium differs from uranium and plutonium in that its potential relations are such as to render NpO_2^{+} moderately stable with respect to disproportionating, even in solutions containing moderate concentrations of hydrogen ion.

The potentials are altered extensively by change in the hydrogen ion concentration and by the presence of any of a number of anions capable of forming complex ions.

Neptunium ions in aqueous solution possess characteristic colors: pale purple for Np^{3+}, pale yellow-green for Np^{4+} green-blue for Np^{5+}, while NpO_2^{2+} varies from colorless to pink or yellow-green depending on the acid present.

The precipitation reactions of Np^{3+} are similar to those of the tripositive rare earths, those of Np^{4+}, to the other tetrapositive actinides and to Ce^{4+}, and those of NpO_2^{2+} to the corresponding ions of uranium and plutonium. All of the simple salts of NpO^{2+} appear to be soluble.

The neptunium oxide system exhibits complexity similar to that found in the uranium oxide system. Thus, the important oxide is NpO_2 and there exists a range of compositions, depending upon conditions, up to Np_3O_8.

As a metal, Np has a relatively low melting point (~640°C), is very dense (20.45 g/cm^3), and is ductile. The alpha form reacts with hydrogen, carbon, oxygen, sulfur, the halogens, and phosphorus to yield a number of binary compounds.

The important halides of neptunium are the trifluoride, NpF_3, purple or black and hexagonal, the hexafluoride, NpF_6, brown and orthorhombic, the trichloride, $NpCl_3$, white and hexagonal, the tetrachloride, $NpCl_4$, red-brown and tetragonal, and the tribromide, $NpBr_3$, α-form green and hexagonal, β-form green and orthorhombic.

In research at the Institute of Radiochemistry, Karlsruhe, West Germany, during the early 1970s, investigators prepared alloys of neptunium with iridium, palladium, platinum, and rhodium. These alloys were prepared by hydrogen reduction of the neptunium oxide in the presence of finely divided noble metals. The reaction is called a *coupled reaction* because the reduction of the metal oxide can be done only in the presence of noble metals. The hydrogen must be extremely pure, with an oxygen content of less than 10^{-25} torr.

Industrial utilization of neptunium has been very limited. The isotope ^{237}Np has been used as a component in neutron detection instruments. Neptunium is present in significant quantities in spent nuclear reactor fuel and poses a threat to the environment. A group of scientists at the U.S. Geological Survey (Denver, Colorado) has studied the chemical speciation of neptunium (and americium) in ground waters associated with rock types that have been proposed as possible hosts for nuclear waste repositories. See Cleveland reference.

NERNST EFFECT. If heat is flowing through a strip of metal and the strip is placed in a magnetic field perpendicular to its plane, a difference of electric potential develops between the opposite edges. This phenomenon, discovered by Nernst in 1886, is analogous to the Hall effect, but with a longitudinal flow of heat replacing the longitudinal electric current. See also **Hall Effect and Quantized Hall Effect**.

NERNST HEAT THEOREM. For a homogeneous system, the rate of change of the free energy with temperature, as well as the rate of change of heat content with temperature, approaches zero as the temperature approaches absolute zero.

NERNST, HERMANN WALTHER (1864–1941). Nernst was a German Chemist and Physicist. In 1894 he received invitations to the Physics Chairs in Munich and in Berlin, as well as to the Physical Chemistry Chair in Göttingen. He accepted this latter invitation. At Göttingen Nernst founded the Institute for Physical Chemistry and Electrochemistry and became its Director. In 1905 he was appointed Professor of Chemistry, later of Physics, in the University of Berlin, becoming Director of the newly-founded "Physikalisch-Chemisches Institut" in 1924. He remained in this position until his retirement in 1933.

He made major contributions to electrochemistry, thermodynamics, and photochemistry. Nernst's early studies in electrochemistry were inspired by Arrhenius' dissociation theory which first recognized the importance of ions in solution. His heat theorem, known as the Third Law of Thermodynamics, was developed in 1906. In 1918 his studies of photochemistry led him to his atom chain reaction theory. In later years, he occupied himself with astrophysical theories, a field in which the heat theorem had important applications.

He is remembered best for the Nernst Effect, named after him. For his work in thermochemistry Nernst won the Nobel Prize in Chemistry in 1920.

See also **Nernst Effect**; **Nernst Heat Theorem**; **Nernst-Thompson Rule**; and **Thermodynamics**.

J.M.I.

NERNST-THOMPSON RULE. A solvent of high dielectric constant favors dissociation by reducing the electrostatic attraction between positive and negative ions, and conversely a solvent of low dielectric constant has small dissociating influence on an electrolyte.

NERVE BLOCK. See **Anesthetics**.

NEUROREGULATORS. Neuroregulators represent a diverse group of compounds that include both neurotransmitters and neuromodulators. Receptors for neuroregulators on both the cell surface and within the cell represent the molecular targets of the majority of drugs in clinical use. In order to classify an endogenous agent as a neurotransmitter, it must possess a number of general characteristics, which are described. Neurotransmitter receptors are grouped according to sequence homology and structures are given. In many cases human receptors have been cloned.

NEUTRALIZATION. A chemical reaction in which water is formed by mutual interaction of the ions that characterize acids and bases when both are present in an aqueous solution, i.e., $H^+ + OH^- \longrightarrow H_2O$, the remaining product being a salt. R. T. Sanderson states: "An aqueous solution containing an excess of hydronium ions is called acidic. It readily releases protons to electron-donating substances. An aqueous solution containing an excess of hydroxyl ions is called basic. It readily accepts protons from substances that can release then, and is in general an excellent donor. No aqueous solution can contain an excess of both hydronium and hydroxyl ions, because when these ions collide, a proton is immediately transferred from the hydronium to the hydroxyl ion, and both become water molecules."

Neutralization occurs with both (1) $Ca(OH)_2 + H_2SO_4 \longrightarrow CaSO_4 + 2H_2O$; (2) $HCOOH + NaHCO_3 \longrightarrow HCOONa + CO_2 + H_2O$. It should be noted that neutralization can occur without formation of water, as in the reaction $CaO + CO_2 \longrightarrow CaCO_3$. Neutralization does not mean the attaining of pH 7.0; rather it means the equivalence point for and acid-base reaction. When a strong acid reacts with a weak base, the pH will be less than 7.0, and when a strong base reacts with a weak acid, the pH will be greater than 7.0. See also **Acids and Bases**.

NEUTRINO. A neutral particle of very small (presumed zero) rest mass and of spin quantum number $\frac{1}{2}$. This particle was initially postulated to account for the continuous energy distribution of beta particles and to conserve angular momentum in the beta-decay process. Experimental evidence indicates that, for the linear momentum to be conserved in the beta process, there must be a contribution from a departing neutrino. Presumably, a neutrino (or antineutrino) is emitted in every beta transition. The energy of a neutrino emitted in a beta disintegration is assumed equal to the difference between the energy of the particular beta particle and the energy corresponding to the upper limit of the continuous spectrum for that beta transition. The neutrino has also been postulated as one of the particles in pion (π) decay and as two of the particles in muon (μ) decay. These processes, however, lead to two types of neutrinos: an electron-associated neutrino ν_e and a muon-associated neutrino ν_μ. For example, $\pi^+ \to \mu^+ \to \overline{\nu_\mu} + e^+ + \nu_e$ or $\pi^+ \to e^+ + \nu_e$, whereas neutron decay obeys only the process $n \to p^+ + e^- + \overline{\nu_e}$, where the bar over ν indicates an anti-particle. The difference between neutrinos was established at Brookhaven in 1962 when it was shown that a beam of neutrinos from the process $\pi^+ \to \mu^+ + \nu_\mu$ gave rise to the process $\nu_\mu + n \to p + \mu^-$ but not to $\nu_\mu + n \to p + e^-$. There is also a neutrino associated with the tau particle. Because of its properties, the neutrino has negligible interactions with matter and has proved difficult to detect. It was first positively identified experimentally in 1956 by Reines and Cowan, Jr. See also **Particles (Subatomic)**.

The term antineutrino usually denotes an antiparticle whose emission is postulated to accompany radioactive decay by negatron emission, such as, for example, in neutron decay into a proton p^+, negatron e^- and antineutrino $\overline{\nu_e}$, expressed by the equation $n \to p^+ + e^- + \overline{\nu_e}$. Capture of a neutrino by the neutron, $\nu_e + n \to p^+ + e^-$ would be an equally good description of the process. Positron emission is accompanied by a neutrino, as in the decay $^{64}Cu \longrightarrow {}^{64}Ni + e^+ + \nu_e$. Orbital electron capture also involves a neutrino, as for example, $e^- + {}^{64}Cu \longrightarrow {}^{64}Ni + \nu_e$. Since there is no possibility of charge differentiation between the antineutrino and the neutrino, differentiation between these two particles can be made only on the basis of such properties as the sign of the ratio of magnetic moment to angular momentum.

In the past the terms neutrino and antineutrino were sometimes used in reverse sense to that stated above, i.e., the neutrino is said to accompany negatron emission and the antineutrino, positron emission. The preferred usage has been accepted in order to provide conservation of leptons in the conservation laws.

Neutrino Astronomy. For several years, there has been a marked trend in astronomy to expand the use of the electromagnetic spectrum beyond the visual range in investigating the universe. It now appears that, in addition to infrared, ultraviolet, gamma ray, x-ray, and radio astronomy, among others, increasing attention will be given to neutrino astronomy, i.e., the detection and measurement of neutrinos emanating from such celestial bodies as supernovas and x-ray double stars. Traditionally, neutrinos have been created in large accelerators and used for investigating the characteristics of other elementary particles. It is now reasoned that neutrinos entering the earth's atmosphere from celestial distances may furnish new, heretofore unavailable information.

Search for Neutrinos

Certain mysteries continue to surround the neutrino, emphasizing how far physicists still may be from a full comprehension of the complete array of subatomic particles. Numerous detectors in different locations have been constructed for detecting neutrinos, particularly as they emanate from the sun.

The first recorded attempt to construct a neutrino telescope was undertaken by Davis (Brookhaven National Laboratory) in the 1960s. Davis' principal objective was detection of low-energy neutrinos emitted by the sun. These neutrinos are generated deep within the sun as the result of thermonuclear reactions. It has been estimated that nearly 10% of the energy released by the transmutation of hydrogen in the sun is carried away by neutrinos, which have energies ranging from $\frac{1}{2}$ million eV to about 14 million eV. The solar flux of neutrinos is tremendous. It is estimated that 10^{14} solar neutrinos pass through the human body every second. Davis' detector consisted of a large tank containing 610 tons of tetrachloroethylene, C_2Cl_4. Of the chlorine atoms present, 25% are of the isotope chlorine 37. When this atom captures a neutrino, it is transformed to an atom of argon 37.

An early detector was established in the shaft of the Homestake Mine (South Dakota) in 1968. The data gathered did not correspond with the scientists' expectation. The neutron flux measured was less than one-third that predicted. This discrepancy challenged researchers to question perhaps the "established" concepts of particle physics and indeed the manner in which the sun functions.

Some years later, a Japanese-built detector (*Kamiokande II*), designed to detect the more energetic solar-emitted neutrinos (~5 mil electron volts), came up about 50% short of the expected counts, thus reconfirming a shortage of solar neutrons.

Neither of the aforementioned detectors was designed to sense comparatively low-energy (proton-proton) neutrinos, which result from the fusion of two protons.

Subsequently, two additional detectors were built with the objective of seeking lower-energy neutrinos. One of the detectors was located in the Caucasus of the former Soviet Bloc and was named the Soviet-American Gallium Experiment (SAGE). The detector used a gallium metal detector believed to be sensitive to neutrinos, with energy as low as 0.23 mil electron volts. Another similar detector (*Gallox*) was constructed in Italy. At both sites, difficulties with calibration were expected and did occur. Some tenuous observations later were made to suggest a correlation of neutrinos detected with the occurrence of sun spots and with solar acoustic oscillations.

Based upon the foregoing experiences, some researchers observed that the same reluctance to interact with matter is responsible for the neutrino's long range and ability to resist detection. Thus, it was reasoned that an apparatus for detecting neutrinos should be massive and shielded from the interference of other particles and radiation. As a solution to these problems, some researchers proposed a deep underwater muon and neutrino detector (acronym DUMAND).

Fiber optic data cable will stretch from the shore for 30 km to a connector box some 4800 meters below the ocean surface. Strings of nine separate cables will rise vertically about 280 meters above the ocean floor. Each cable, held up by a float, will contain 24 detectors. The apparatus, referred to as a neutrino telescope, will have to pick up at least ten muon events per year from any given 1° patch of sky for the DUMAND scientists to be confident that they have a significant neutrino source, not just a few background pulses from non-neutrino cosmic rays.

Construction of DUMAND, with Japanese and German collaborators, got underway off the west coast of Kona (Hawaii) in 1990 and was expected to be operational within a few years. V. Stenger (University of Hawaii) observes, "The idea of using the ocean floor as a detector actually goes back to the 1960s and people started taking it seriously back in the mid 1970s."

A number of scientists are hopeful that the neutrino telescope will ultimately yield much additional information on neutron stars, supernovas, quasars, etc., which are presumed to be large emitters of neutrinos. Some astronomers estimate that SS 433 puts out 1000 times more energy per second than the brightest stellar object known in the galaxy. Why should such a powerful object have been discovered so recently? The fact is that SS 433 is a comparatively weak source of photons. The accreting matter that gives SS 433 its great power also serves to screen its bright central

region from view. Much remains to be learned concerning SS 433 and perhaps neutrino astronomy may supply some answers at a future date.

Laboratory Experimentation on Neutrinos

During the 1960s, L.M. Lederman, M. Schwartz, and J. Steinberger conducted the well-known two-neutrino experiment, which established a relationship between particles, muon and muon neutrinos, electron and electron neutrino. This later evolved into the standard model of particle physics. The Nobel prize in physics was shared by these researchers in 1988.

Massive Neutrino Proposed. J. Simpson (University of Guelph, On tario) in the late 1980s presented evidence of the existence of a *heavy neutrino* having a mass of 17,000 electron volts (keV, the units of energy that are interchangeable with mass). A renowned neutrino physicist for several years prior, in 1985 Simpson conducted a series of experiments in his laboratory. The objective of his initial experiment was that of measuring the energy of electrons emitted from heavy hydrogen (tritium) in the radioactive process of beta decay. In this process, the energy of the emitted electrons should appear as a spectrum (smooth curve) from zero to a maximum endpoint. However, Simpson noted "occasional" aberrations in the plotted data. This so-called "kink" corresponded with an energy of 17 KeV of the normal plot. This indicated the probable presence of an unknown massive force. In addition to repeated experiments with tritium, Simpson also used Sulfur-35. Simpson then suggested that the aberration, when it occurred, could be attributed to a heavy 17 KeV neutrino.

Simpson's carefully prepared data, when published, attracted wide attention and drew a wide spectrum of professional reactions. Meanwhile, experiments by other laboratories have confirmed Simpson's results. Researchers at the Lawrence Berkeley Laboratory, using Carbon-14, have reported evidence for a 17.2 KeV neutrino in 1.4% of their experiments. Researchers at the Ruder Boskovic Institute in Zagreb (formerly Czechoslovakia), using Iron-55 and Germanium-71, also have found the evidence appearing in 1.5% of their experiments. Thus, confidence in Simpson's claim appeared to be gaining momentum in the early 1990s.

As pointed out by M. Turner (University of Chicago), a massive neutrino would "violate every theoretical prejudice we have in particle physics, astrophysics, and cosmology." J. Bahcall (Institute of Advanced Study at Princeton) observes, "It's a surprise. If it's true, then it's pointing us in a different direction than previous physics suggested."

NEUTRON. The discovery of the neutron by Chadwick in 1932 represented a great step forward in the investigation of nuclei of atoms. Chadwick found that a radiation emitted when α-rays from polonium reacted with beryllium could project protons from a thin sheet of paraffin wax. Although the radiation itself produced no observable ionization when passing through a gas, the protons released from the paraffin were detected in an ionization chamber. Inability to produce ionization was interpreted as a lack of electric charge. From measurements of the ionization from the protons, Chadwick deduced that the so-called beryllium radiation must consist of neutral particles with a mass very nearly equal to that of the proton. He announced the discovery of the neutron, a previously unknown particle. It has been confirmed that the neutron has no charge and a mass of 1.088665 atomic mass units. Thus, it is heavier than the proton by 0.00139 mass unit. The introduction of the neutron into nuclear structure produced a sharp change in previously held concepts. Lacking knowledge of the neutron, masses of atomic nuclei had been attributed solely to protons. The number of protons required on this basis for most nuclei greatly exceeded the known charge number. In an attempt to solve this dilemma, a number of electrons were assigned to each nucleus to adjust the charge number to the proper value. This compromise created an even greater problem, that of accommodating so many electrons in the small space occupied by a nucleus. Bringing the neutron into the picture meant that a nucleus contains only enough protons to equal the charge number, with the rest of the mass contributed by neutrons. No additional electrons were required.

Decay. The neutron in the free state undergoes radioactive decay. Elaborate experiments by Robson were required to identify the products of the decay and to measure the half-life of the neutron. He showed that the neutron emits a β-particle and becomes a proton. The half-life was found to be 12.8 minutes. In stable nuclei, neutrons are stable. In radioactive nuclei, decaying by β-emission, the neutrons decay with a half-life characteristic of the nuclei of which they are a part. See also **Radioactivity**.

Detection. Because it is a neutral particle the neutron is detected by means of a secondary charged particle which it releases in passing through matter or by means of the radioactivity which the neutron can induce in stable elements. Protons may be projected by collisions with neutrons in hydrogenous material and the ionization from the protons can be measured in an ionization chamber, as in the original experiment with neutrons. Secondary charged particles may be the direct result of nuclear disintegration produced by neutrons, as in the case of the reaction $^{10}\text{B} + {}^{1}n \rightarrow {}^{7}\text{Li} + \alpha$. Commonly, the radioactivity induced in a stable element by neutron capture serves to detect neutrons, and this technique is known as the *activated foil method*. Also, fission may be utilized for detection of neutrons by placing fissionable material inside an ionization chamber and observing the ionization generated by the fission fragments.

Energies. The kinetic energy of neutrons has an important bearing on their behavior when interacting with nuclei. These kinetic energies may range from near zero to as much as 50 MeV. It is therefore natural to classify neutrons in terms of energy according to their properties in each range of energy. For example, energies from zero to about 1000 eV are usually called *slow neutrons*. Because they are more readily captured by nuclei than faster neutrons, slow neutrons are responsible for a large number of nuclear transformations. When slow neutrons have velocities in equilibrium with the velocities of thermal agitation of the molecules of the medium in which they are situated, they are called *thermal neutrons*. The distribution of these velocities approaches the Maxwell distribution

$$dn(v) = Av^2 e^{-(Mv^2/2kT)} dv$$

where v is the neutron velocity, M its mass, k is Boltzmann's constant, and T is the absolute temperature. In the slow neutron range of energies, various atomic nuclei show strong absorption (capture) of neutrons at fairly

well-defined energies. Neutrons having energies corresponding to those of the absorption bands are called *resonance neutrons*. Frequently, neutrons with energies greater than 1000 eV and less than 0.5 MeV are termed *intermediate neutrons*. In more general terms, all neutrons with energies greater than 0.5 MeV are called *fast neutrons*. The practical upper limit of neutron energy is set by the devices thus far developed for accelerating charged particles to extremely high energies.

Magnetic Moment and Spin. Alvarez and Bloch succeeded in measuring the moment of the magnetic dipole associated with the known spin of $\frac{1}{2}$ possessed by the neutron. More refined measurements by Cohen, Corngold, and Ramsey of the magnetic moment μn yielded a value of

$$\mu n = 1.913148 \text{ nuclear magnetons}$$

Interactions with Nuclei. Neutrons may be scattered or captured by heavy nuclei. Scattering may be elastic, resulting only in the change of direction of the neutrons, or inelastic, in which the neutron loses part of its energy to the scattering nucleus. Collisions with light nuclei, in the absence of capture, result in communicating considerable fractions of the neutron energy to the target nucleus. A neutron colliding head-on with a proton will give practically all its kinetic energy to the proton. As the mass of the target nucleus increases, the transfer of energy decreases, in accordance with the laws of conservation of energy and momentum. The loss of energy by mechanical impact is utilized in slowing down fast neutrons, a process known as *moderation*. Slow neutrons are most useful, for example, in the production of radioelements from stable elements by neutron capture. A good moderator should have low mass and a small capture cross section. The rate r of capture of neutrons from a neutron flux F (neutrons cm^{-2} sec^{-1}) incident on a layer of matter having N nuclei per square centimeter is given by

$$r = F\sigma N$$

where σ is the complete probability of capture. Replacing r by dN/dt and writing the flux as nv, where n is the number and v is the velocity of the neutrons, we have

$$dN/dt = nv\sigma N$$

which integrated gives

$$N = N_0 e^{-nv\grave{e}t}$$

where N is the number of unchanged nuclei in the target area at time t and N_0 is the number at time $t = 0$. The cross section σ is so named because it has the dimensions of an area. The unit for the cross section is the *barn*, equal to 10^{24} cm^2. When, as is often the case, σ is proportional to $1/v$, the advantage of slow neutrons in capture interactions becomes apparent. When the value of s departs sharply from that predicted by the $1/v$ law, it usually increases over a narrow range of energies, and we have what is called a *resonance*. Slow neutron cross sections are customarily quoted for thermal neutrons at 20°C, corresponding to a value of v of 2200 m/sec. Under these conditions, representative thermal neutron capture cross sections are: boron, 759 barns; cobalt, 38 barns; cadmium, 2450 barns; gadolinium, 46,000 barns; gold, 99.8 barns; helium, 0; lead, 0.170 barn; and oxygen <0.0002 barn.

Additional interactions of neutrons with nuclei include the release of charged particles by neutron-induced nuclear disintegration. Commonly known reactions are $n - p$, $n - d$, and $n - \alpha$. In these cases, the incident neutrons may contribute part of their kinetic energy to the target nucleus to effect the disintegration. Hence, more than mere neutron capture is involved. Then, there is usually a lower threshold for the neutron energy below which the reaction fails to occur. Another important reaction involving neutrons is fission, which may occur under different conditions for either slow or fast neutrons with appropriate fissionable material.

Sources of Neutrons. Any nuclear reaction in which neutrons are released might serve as a source of neutrons. In the initial experiments with neutrons, an α–n reaction was used. Because of the charge on the α-particle, it must have a high kinetic energy to penetrate a nucleus. Thus, polonium α-particles could release neutrons from beryllium. Such a natural source produces relatively few neutrons. The yield of neutrons from charged particle reactions can be increased manyfold by the use of particle accelerators. Here large numbers of charged particles of high energy can be used in the bombardment of the target to release numerous neutrons. Frequently deuterons or protons are used for the bombardment. A far more prolific source is the nuclear reactor. Fission of uranium is usually the source of the neutrons in this case. A nuclear reactor as usually constructed generates neutrons of different energies in various parts of its structure. Neutrons of suitable energy for a given experiment may be brought outside the reactor through channels into appropriate sections of the reactor. See also **Nuclear Power Technology**.

Traditionally, the neutron is regarded as a particle which is a component of nuclei and which exists only briefly in the free state. For many purposes, this view is sufficient. However, it became obvious some years ago from various experiments, for example, in very high energy accelerators, that the neutron must have a complex structure. This view was reinforced by the nature of the decay of the neutron. A ς particle is ejected from the neutron on decay, but it is quite certain that the electron did not exist within the neutron prior to the decay. Rearrangements of an internal structure of the neutron must provide the energy for the formation and ejection of the ς particle. An early theory would have the neutron consist of a proton and a π^- meson bound together so that they oscillate between a completely bound state and a more loosely bound state. This concept might explain the feeble interaction that has also been observed between electrons and neutrons at very short range.

Fermi Age Model. This is a model for the study of the slowing down of neutrons by elastic collisions. It is assumed that the slowing down takes place by a very large number of very small energy changes. Phenomena due to the finite size of the individual losses are ignored. In this model, the word age is somewhat of a misnomer, since its units are those of area rather than time. The name arises because the variable τ, the Fermi age, appears in the Fermi age equation in the same way that time appears in the standard heat-diffusion equation. The equation for the Fermi age in a unit volume of nuclear reactor is $\tau = D\phi/q$, in which D is the diffusion coefficient for fast neutrons, $\phi = nv$ is the fast neutron fluence, and q is the number of neutrons thermalized per second per cubic centimeter. For this purpose fast neutrons are inclusively all neutrons with energies between those acquired at fission and that energy at which they are thermalized.

Ultracold Neutrons. As pointed out by King (Massachusetts Institute of Technology), there is probably as much to be learned between the lowest energy yet reached and zero energy as there is between the highest energy attained and infinite energy. Ultracold neutrons may provide an avenue to very-low-energy research. It should be recalled that a neutron with an energy of 10^{-7} electron volt is at the low end of the energy scale. A neutron has the energy that would be imparted to an electron by a potential difference of one ten-millionth of a volt (0.1 microvolt). As pointed out by Golub et al. in 1979, this is the amount of energy of a particle in a gas whose temperature is one millidegree K. Unlike high-energy particles, ultracold neutrons move at a rate measured in a few meters per second. Golub et al. have proposed that inasmuch as ultracold neutrons cannot penetrate a solid surface, they can be confined in a metal bottle and by storing over long periods, it may be possible to measure the fundamental properties of the neutron.

Outside the nucleus, the neutron is an unstable particle. Free neutrons are rare in nature. By the process of beta decay, the neutron breaks down into a proton, an electron, and a neutrino (a massive particle). For probing atomic and molecular structures, thermal neutrons have traditionally been used. As explained by Golub et al., ultracold neutrons can be employed in a similar way, but their low energy and long wavelength adapt them to the examination of materials on a somewhat larger scale. At the Technical University (Munich), Steyeri and associates have developed a neutron spectrometer. In conventional neutron spectrometers, particles are analyzed by a magnet that bends their trajectories. In an ultracold-neutron spectrometer, the earth's gravitational field is used. In the device, the neutrons enter the spectrometer in a horizontal movement and are accelerated as they fall a fixed distance to a specimen. Those neutrons that rebound from a target are collected by an exit slit of the instrument. An exchange of energy with the specimen is reflected by the maximum height to which the neutrons rebound.

During the past decade, since their detection, much research has been directed toward methods of extracting, storing, and manipulating ultra-cold neutrons. It now appears that the next period will be one of investigating the neutron per se and possibly of using this new knowledge for the study of other systems of particles.

See **Particles (Subatomic)** for more recent views. See also **Proton**.

Glossary of Neutron Terms

Neutrons are designated according to their energies, including the following:

Thermal neutrons, or neutrons in thermal equilibrium with the substance in which they exist; most commonly, neutrons of kinetic energy about 0.025 eV, which is about $\frac{2}{3}$ of the mean kinetic energy of a molecule at 15°C.

Epithermal neutrons, or neutrons having energies just above those of thermal neutrons; the epithermal neutrons energy range is between a few hundredths eV and about 100 eV.

Slow neutrons (a less definite classification), which may mean either neutrons having energies up to about 100 eV, or thermal neutrons.

Intermediate neutrons, which are neutrons having energies in a range that extends roughly from 100 to 100,000 eV. This range is above that of epithermal neutrons and below that of fast neutrons.

Fast neutrons, which are neutrons with energies exceeding 10^5 eV, although sometimes a lower limit is given.

Resonance neutrons may be either of the following: (1) for a specified nuclide or element, neutrons that have energies in the region where the cross section of the nuclide or element is particularly large because of the occurrence of a resonance. For example, cadmium resonance neutrons have energies between 0.05 and about 0.3 eV. (2) Neutrons having kinetic energies in the region of values for which prominent resonances are encountered in many nuclides; loosely, epithermal neutrons.

Prompt neutrons are those neutrons released coincident with a fission process.

Delayed neutrons are those neutrons released subsequently in a fission process, or, more generally, neutrons emitted by excited nuclei formed in any radioactive process (beta disintegration, in all cases so far known). The neutron emission itself is prompt, so that the observed half life is that of the preceding beta emitter. The situation is similar to that involving gamma-ray emission, which is a competing process. Delayed neutron emission is possible only if the excitation energy of the product nucleus exceeds the neutron binding energy for that nucleus. The chemistry of the delayed neutron emitter is that of the beta activity; thus ^{87}Br, ^{137}I, and ^{17}N are delayed neutron precursors, although the neutron emission actually takes place from excited nuclei of the products ^{87}Kr, ^{137}Xe, and ^{17}O.

Neutron cycle is the average life history of a neutron in a nuclear reactor. The gain in the number of neutrons in a reactor during any individual neutron cycle is given by $n(k-1)$, where n is the number of neutrons in the reactor of the beginning of the cycle and k is the multiplication factor.

Neutron excess is the difference between the number of neutrons and the number of protons in an atomic nucleus. This is found by subtracting the atomic number of that nuclide from the neutron number; or by subtracting twice the atomic number from the mass number.

Neutron flux density is the number of neutrons that enter a sphere of unit cross-sectional area per unit of time. This quantity is sometimes defined in terms of a unidirectional beam of neutrons incident perpendicularly upon a unit area, but this definition is less general. It is also sometimes called neutron current density.

Neutron number is the number of neutrons in a nucleus. Its symbol is N. The neutron number for a given nuclide is equal to the difference between the mass number and the atomic number for that nuclide.

NEUTRON ACTIVATION ANALYSIS. This is a method of elemental analysis based upon the quantitative detection of radioactive species produced in samples via nuclear reactions resulting from neutron bombardment of samples. The neutron-induced reactions are of two main types: (1) those induced by very slow (thermal) neutrons, having energies of about 0.025 eV; and (2) those induced by fast neutrons having energies in the range of MeV. The method is used in two different forms. The purely instrumental form is fast and nondestructive and is based upon the quantitative detection of induced gamma-ray emitters by means of multichannel gamma-ray spectrometry. The amount of the element present is usually computed from the photopeak (total absorption peak) height or area of its gamma ray, or one of its principal gamma rays, compared with that of the standard. Where interferences from other induced activities are serious and cannot be removed by decay, spectrum subtraction, or computer solution, one must turn to the radiochemical separation method. Here the activated sample is put into solution and equilibrated chemically with measured amounts (typically 10 milligrams) of added carrier of each of the elements of interest, before chemical separations are carried out. The element to be detected needs then to be recovered in chemically and radiochemically pure form, but it need not be quantitatively recovered, since the carrier recovery is measured and the counting data are then normalized to 100% recovery. This form is slower, but it applies to pure beta emitters, as well as to gamma emitters, and it does eliminate interfering activities.

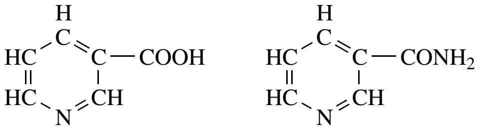
NIACIN. [CAS: 59-67-6]. Sometimes referred to as nicotinic acid or nicotinamide and earlier called the P-P factor, antipellagra factor, antiblacktongue factor, and vitamin B_4, niacin is available in several forms (niacin, niacinamide, niacinamide ascorbate, etc.) for use as a nutrient and dietary supplement. Niacin is frequently identified with the B complex vitamin grouping. Early in the research on niacin, a nutritional niacin deficiency was identified as the cause of pellagra in humans, blacktongue in dogs, and certain forms of dermatosis in humans. Niacin deficiency is also associated with perosis in chickens as well as poor feathering of the birds.

Varying in degree in relationship to the length and severity of diet deficiency of niacin, pellagra is clinically manifested by skin, nervous system, and mental conditions. The disease occurs most frequently among the economically deprived and particularly in areas where the diet may be high in maize (corn) intake. The disease was first described by Gaspar Casal in 1735 and was common in many areas, including Europe, Egypt, Central America, and the southern portion of the United States for many years. The largest outbreak occurred in the United States during the period 1905–1915 and resulted in a high mortality. The medical awareness and understanding of vitamins and dietary deficiencies, coupled with the availability of dietary supplements in staple foods, have resulted in a great lessening in the occurrence of pellagra. Where the disease is found, niacin is a specific for the treatment of acute pellagra. Those afflicted are accustomed to a diet low in protein and made up largely of carbohydrates. Predisposing causes are found idiosyncrasies, chronic alcoholism, and diseases that interfere with the assimilation of a proper diet.

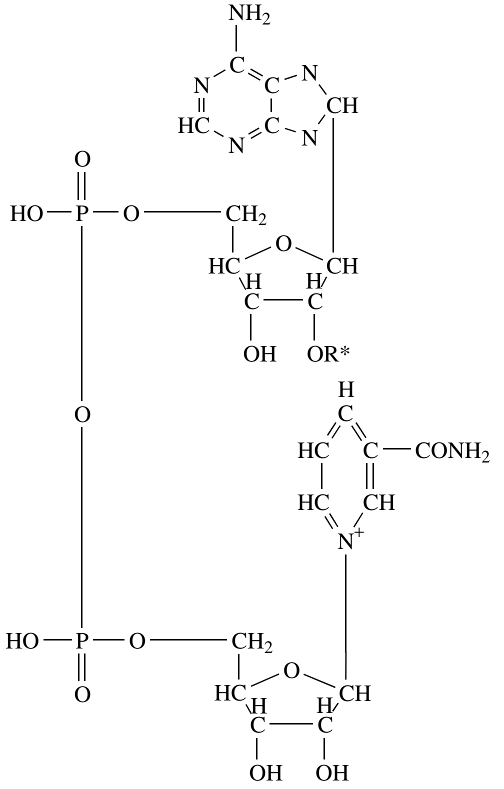
Huber first synthesized nicotinic acid in 1867. In 1914, Funk isolated nicotinic acid from rice polishings. Goldberger, in 1915, demonstrated that pellagra is a nutritional deficiency. In 1917, Chittenden and Underhill demonstrated that canine blacktongue is similar to pellagra. In 1935, Warburg and Christian showed that niacinamide is essential in hydrogen transport as diphosphopyridine nucleotide (DPN). In the following year, Euler et al. isolated DPN and determined its structure. In 1937, Elvhehjem et al. cured blacktongue by administration of niacinamide derived from liver. In the same year, Fouts et al. cured pellagra with niacinamide. In 1947, Handley and Bond established conversion of tryptophan to niacin by animal tissues.

In the physiological system, niacin and related substances maintain nicotinamide adenine dinucleotide (NAD) and nicotinamide adenine dinucleotide phosphate (NADP). Niacin also acts as a hydrogen and electron transfer agent in carbohydrate metabolism; and furnishes coenzymes for dehydrogenase systems. A niacin coenzyme participates in lipid catabolism, oxidative deamination, and photo synthesis.

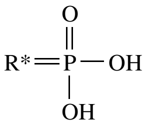
Nicotinic acid can be converted to nicotinamide in the animal body and, in this form, is found as a component of two oxidation-reduction coenzymes, NAD and NADP, as previously mentioned. Structurally, these are:



Nicotinic acid Nicotinamide

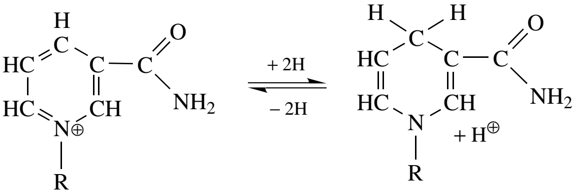


Nicotinamide adenine dinucleotide (NAD) R* = H



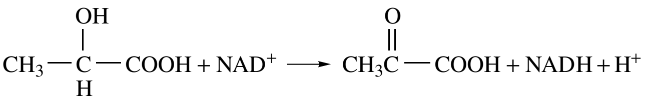
Nicotinamide adenine dinucleotide phosphate (NADP)

The nicotinamide portion of the coenzyme transfers hydrogens by alternating between an oxidized quaternary nitrogen and a reduced tertiary nitrogen as shown by:



NAD (oxidized) NADH + H^+ (reduced)

Enzymes that contain NAD or NADP are usually called dehydrogenases. They participate in many biochemical reactions of lipid, carbohydrate, and protein metabolism. An example of an NAD-requiring system is lactic dehydrogenase which catalyzes the conversion of lactic acid to pyruvic acid. Numerous NAD-dependent enzyme systems are known.



Lactic acid Pyruvic acid

Distribution and Sources. In plants, niacin production sites occur in leaves, germinating seeds, and shoots. In humans, niacin is not available from intestinal bacteria, but some conversion is made from tryptophan which occurs in tissues.

High niacin content (10–100 milligrams/100 grams) Chicken (white meat), groundnut (peanut), halibut, heart (calf), kidney (beef, pork), liver (beef, calf, chicken, pork, sheep), meat extracts, rabbit (white meat), swordfish, tuna, turkey (white meat), yeast

Medium niacin content (1–10 milligrams/100 grams) Almond (dry), asparagus, avocado, barley, bean (kidney, lima, snap, wax), beef, broccoli, cashew, cheeses (camembert, roquefort, Swiss), chestnut, chicken (dark meat), clam, date (dry), duck, fig (dry), fishes (except those listed under "High"), kale, lamb, lentil (dry), maize (corn), molasses, mushroom, oats, oyster, parsley, pea, potato, prune (dry), rice (brown), rye, soybean (dry), shrimp, walnut, wheat, wheat germ

Low niacin content (0.1–1.0 milligram/100 grams) Apple, apricot, banana, beet, beet greens, berries (black-, blue-, cran-, rasp-, straw-), Brussels sprouts, cabbage, carrot, cauliflower, celery, cherry, chicory, coconut, cucumber, currant, dandelion greens, eggs, eggplant, endive, fig, grape, kohlrabi, lettuce, lemon, melons, milk, onion, parsnip, peach, pear, pecan, pepper, pineapple, plum, pumpkin, radish, raisin (dry), rhubarb, spinach, sweet potato, tangerine, tomato, turnip, watercress

Precursors in the biosynthesis of niacin: In animals and bacteria, tryptophan; and in plants, glycerol and succinic acid. Intermediates in the synthesis include kynurenine, hydroxyanthranilic acid, and quinolinic acid. In animals, the niacin storage sites are liver, heart, and muscle. Niacin supplements are prepared commercially by: (1) Hydrolysis of 3-cyanopyridine; or (2) oxidation of nicotine, quinoline, or collidine.

Bioavailability of Niacin. Factors which cause a decrease in niacin availability include: (1) Cooking losses; (2) bound form in corn (maize), greens, and seeds is only partially available; (3) presence of oral antibiotics; (4) diseases which may cause decreased absorption; (5) decrease in tryptophan conversion as in a vitamin B_6 deficiency. Factors that increase availability include: (1) alkali treatment of cereals; (2) storage in liver and possibly in muscle and kidney tissue; and (3) increased intestinal synthesis.

Antagonists of niacin include pyridine-3-sulfonic acid (in bacteria); 3-acetylpyridine, 6-aminonicotinamide, and 5-thiazole carboxamide. Synergists include vitamins B_1, B_2, B_6, B_{12}, and D, pantothenic acid, folic acid, and somatotrophin (growth hormone).

In humans, overdosage of niacin causes a limited toxicity (1 to 4 grams/kilogram) with individual variations in sensitivity.

NICKEL. [CAS: 7440-02-0]. Chemical element, symbol Ni, at. no. 28, at. wt. 58.69, periodic table group 10, mp 1453°C, bp 2732°C, density 8.9 g/cm^3 (solid, 20°C), 9.04 g/cm^3 (single crystal). Elemental nickel has a face-centered cubic crystal structure. Nickel is a silver-white metal, harder than iron, capable of taking a brilliant polish, malleable and ductile, magnetic below approximately 360°C. When compact, nickel is not oxidized on exposure to air at ordinary temperatures. The metal is soluble in HNO_3 (dilute), but becomes passive in concentrated HNO_3. The

metal does not react with alkalis. Finely divided nickel dissolves 17× its own volume of hydrogen at standard conditions. There are five naturally occurring stable isotopes, ^{58}Ni, ^{60}Ni through ^{62}Ni, and ^{64}Ni. Six radioactive isotopes have been identified, ^{56}Ni, ^{57}Ni, ^{59}Ni, ^{63}Ni, ^{65}Ni, and ^{66}Ni. ^{59}Ni has a half-life of 8×10^4 years, and ^{63}Ni has a half-life of 80 years. The half-lives of the remaining radioactive isotopes are relatively short, expressed in hours and days. The element ranks 21st among the elements in terms of abundance in the earth's crust, the estimated average content of igneous rocks being about 0.02%. In terms of cosmic abundance, nickel ranks 28th among the elements. Nickel ranks 40th in terms of concentration in seawater, the estimated content being about 2.5 tons of nickel per cubic mile (540 kilograms per cubic kilometer) of seawater. Awareness of nickel probably dates back to antiquity, but the element was not firmly identified until 1751 when Axel Fredric Cronstedt isolated the metal from the sulfide ore NiAsS.

First ionization potential 7.33 eV, second, 18.13 eV. Oxidation potentials $Ni \longrightarrow Ni^{2+} + 2e^-$, 0.230 V; $Ni^{2+} + 2H_2O \longrightarrow NiO_2 + 4H^+ + 2e^-$, −1.75 V; $Ni + 2OH^- \longrightarrow Ni(OH)_2 + 2e^-$, 0.66 V; $Ni(OH)_2 + 2OH^- \longrightarrow NiO_2 + 2H_2O + 2e^-$, −0.49 V.

Other physical properties of nickel are given under **Chemical Elements**.

In the early 1800s, the principal sources of nickel were in Germany and Scandinavia. Very large deposits of lateritic (oxide or silicate) nickel ore were discovered in New Caledonia in 1865. The sulfide ore deposits were discovered in Sudbury, Ontario in 1883 and, since 1905, have been the major source of the element. The most common ore is pentlandite, $(FeNi)_9S_8$, which contains about 34% nickel. Pentlandite usually occurs with pyrrhotite, an iron-sulfide ore, and chalcopyrite, $CuFeS_2$. See also **Chalcopyrite**; **Pentlandite**; and **Pyrrhotite**. The greatest known reserves of nickel are in Canada and Russia, although significant reserves also occur in Australia, Finland, the Republic of South Africa, and Zimbabwe.

Principal producers and/or exporters of nickel include, in diminishing order, Canada, Russia, the United Kingdom, Norway, and Indonesia. Main consumers are the United States, Japan, the United Kingdom, Norway, Germany, Canada, and France.

After beneficiation of the raw ore to form a sulfide concentrate, the latter is roasted to achieve partial oxidation of iron and partial removal of sulfur. The roasted material then is smelted with a flux to eliminate the rock content. At this point, part of the iron goes into the slag. The remaining material is a copper-bearing nickel-iron matte, made up mainly of the sulfides of these metals. The matte is then treated in a Bessemer converter to achieve further removal of iron and sulfur. After controlled cooling, which assists separation, the Bessemer product is finely ground and subjected to magnetic separation and differential flotation. The separated product is an impure nickel sulfide. The sulfide then is sintered to nickel oxide. This product may be marketed for some applications, but the majority of the oxide is cast into anodes for refining into nickel metal by one of two major processes.

In (1) the electrolytic process, a nickel of 99.9% purity is produced, along with slimes which may contain gold, silver, platinum, palladium, rhodium, iridium, ruthenium, and cobalt, which are subject to further refining and recovery. In (2) the Mond process, the nickel oxide is combined with carbon monoxide to form nickel carbonyl gas, $Ni(CO)_4$. The impurities, including cobalt, are left as a solid residue. Upon further heating of the gas to about 180°C, the nickel carbonyl is decomposed, the freed nickel condensing on nickel shot and the carbon monoxide recycled. The Mond process also makes a nickel of 99.9% purity.

Uses. The three main commercial forms of primary nickel are: (1) electrolytic sheets, (2) pellets resulting from the decomposition of nickel carbonyl, and (3) ferronickel. Traditionally, pellets are favored in Europe, whereas electrolytic nickel is favored in North America. Additional forms of commercial nickel are powder, ingots, shot, and briquettes. Ferronickel, containing 24–48% nickel with the remainder iron, is used mainly in the production of stainless steel. More than half of the nickel produced is used in stainless steels and high-nickel alloys. Additional uses include nickel plating, iron and steel castings, coinage, and copper and brass products.

The main consumer of nickel is austenitic stainless steel, which contains from 3.5 to 22% nickel and 16 to 26% chromium. In these steels, nickel stabilizes the austenite and enhances the ductility of the steel. Nickel, along with chromium, contributes to corrosion resistance. Up to amounts of about 9%, nickel adds strength, hardness, and toughness to many alloy steels. Alloys in the 9% nickel range remain stable at low temperatures and are capable of handling liquefied gases. The lower-nickel steels (0.5 to 0.7%) are ductile, strong, and tough, and find use for many automobile parts, in power machinery, and construction equipment. There are hundreds of nickel-containing alloys, running the gamut from hardenable silver alloy (0.02% Ni) up to malleable nickel (99% Ni).

Wrought Nickel and High-Nickel Alloys. Some of the major nickel alloys, along with wrought nickel, are described in Table 1.

Commercially pure wrought nickel in the form of sheets, wire, and tubing has many uses because of its corrosion resistance. These uses include utensils, food-processing equipment, marine hardware, coinage, and chemical equipment. Electroplated nickel also is used as a protective coating on steel. *Nimonic* alloys, not shown on the table, are based on an 80% Ni, 20% Cr composition. They are high-strength, heat-resistance metals that are age-hardened to increase strength at elevated

TABLE 1. WROUGHT NICKEL AND REPRESENTATIVE NICKEL ALLOYS

Melting range °C	Poisson's ratio
Wrought nickel 99% Ni, 0.25% Cu, 0.15% C	1,435–0.31 1,445
Duranickel 301 93.9% Ni, 0.05% Cu, 0.15% C, 0.15% Fe, 0.5% Ti, 4.5% Al	1,400–0.31 1,440
Monel 400 66.0% Ni, 31.5% Cu, 0.12% C, 1.35% Fe	1,300–0.32 1,350
Hastelloy B 63.5% Ni, 0.05% C, 5.0% Fe, 2.5% Co, 1.0% Cr, 28.0% Mo, 0.3% V	1,320– – 1,460
Hastelloy F 45.5% Ni, 0.05% C, 20.5% Fe, 2.5% Co, 22.0% Cr, 6.5% Mo, 1% W, 2% (Nb + Ta)	1,290–0.305 1,295
Inconel 600 72% Ni, 0.5% Cu, 0.15% C, 8.0% Fe, 15.5% Cr	1,370–0.29 1,425
Incoloy 800 32.5% Ni, 0.75% Cu, 0.10% C, 45.6% Fe, 21.0% Cr	1,355–0.30 1,390
Illium G 56.0% Ni, 6.5% Cu, 22.5% Cr, 6.5% Mo q	1,255–0.29 1,340

Note: Recently introduced new or improved nickel alloys include:

Inconel alloy 625 —Low-cycle fatigue resistance has been increased from 70–80,000 to 110–120,000 psi at 10 cycles. This has been achieved through grain size control and improved product cleanliness. Major applications are bellows and expansion joints.

Inconel alloy 725 —An age-hardenable alloy for deep sour gas well service, combining height strength with the attributes of Inconel alloy 625, such as pitting resistance and stress corrosion cracking resistance to salt, hydrogen sulfide, and sulfur at temperatures up to about 230°C (450°F) and to sulfide stress corrosion cracking.

Inconel alloy 622 —Modified composition and special thermal mechanical processing give this alloy superior thermal stability and resistance to intergranular attack and localized corrosion. The alloy is particularly suited to acidified halide environments, especially those containing oxidizing acids.

Inconel alloy 925 —An age-hardenable nickel-iron-chromium alloy providing high strength up to 540°C (1000°F). Developed for use in gas production applications, such as tubular products, tool joints, and equipment for surface and downhole hardware in gas industry.

Inco alloy 25–6MO —Used for its corrosion resistance in many environments, this is an austenitic nickel-iron-chromium alloy with a substantial (6%) addition of molybdenum. Especially useful for resisting pitting and crevice corrosion in media containing chlorides or other halides. Applications include equipment for handling sulfuric and phosphoric acids, offshore platforms and other marine equipment, and for bleaching circuits in pulp and paper plants.

temperatures—with a useful range of 700–825°C. *Monel* metal (several types) is a high-strength corrosion-resistant alloy available in many wrought and cast forms for use in processing equipment, marine construction, and household appliances. *K Monel* can be heat treated by precipitation hardening to about 2× the strength of annealed *Monel. Hastelloy*-type alloys are well known for their excellent resistance to HCl, H_2SO_4, and other acids. The *Incoloy*-type alloys (35% Ni approximately) are heat-resistant alloys used mainly as castings for furnace parts. The lower-nickel/higher-chromium alloys generally are classified as stainless steels. See also **Iron Metals, Alloys, and Steels**.

Although not of high-tonnage production, several nickel metals serve important uses, such as:

Permalloy, 78.5% Ni, 21.5% Fe; *Hipernik*, 50% Ni, 50% Fe; and *Perminvar*, 45% Ni, 30% Fe, 25% Co—are representative of a group of high-nickel magnetic alloys.

Constantan, 45% Ni, 55% Cu, has high electrical resistivity and a very low temperature coefficient of resistivity. It is extensively used with copper as a thermocouple element.

Nichrome, 80% Ni, 20% Cr (several types with variations of these percentages and additions of other elements, such as silicon in small amounts), is used as resistance wire for heating elements.

Calorite, 65% Ni, 8% Mn, 12% Cr, 15% Fe, also is used in electric heating elements.

Alumel, 94% Ni, 2.5% Mn, 0.5% Fe plus small amounts of other elements, is used in thermocouples

Chromel, 35–60% Ni, 16–19% Cr, generally with the balance Fe, also is used as resistance wire and for thermocouples.

Invar, 36% Ni, 64% Fe, has a very low temperature coefficient of expansion and is used for measuring tapes, instruments, and bimetallic thermostats.

Elinvar, 34% Ni, 57% Fe, 4% Cr, 2% W, has a very low temperature coefficient of elasticity which makes it useful for springs in watches and precision instruments.

There are hundreds of special nickel-bearing alloys of proprietary formulations and tradenames.

Alloy with Memory. In seeking a way to reduce the brittleness of titanium, U.S. Navy researchers serendipitously discovered a nickel-titanium alloy having an amazing memory. Previously cooled clamps made of the alloy (*nitinol*) are flexible and can be placed easily in position. When warmed to a given temperature, the alloy hardware then exerts tremendous pressure. Use of conventional clamps for holding bundles of wires or cables in a ship or aircraft structure requires special tools. For this and other applications in industry and medicine, nitinol has been in demand. The alloy, however, is not easy to produce because only minor variations in composition can affect the "snap back" temperature by several degrees of temperature.

Nickel Powders. The use of nickel in powdered form has increased markedly during the last few years. As shown by Fig. 1, nickel powders are available in several types and are used in a variety of products.

Nickel in Nanometer Materials. Coating a metal with an ultrathin layer of another metal creates properties not found separately in either of the materials. Considerable recent research has been directed toward improving the mechanical properties of bimetallic laminates, sometimes called *composition modulated films*, which have interlayers only a few nanometers thick. Attractive properties also have been found for similar systems, called *nanometer materials*. Nickel has been used in combination with copper, ruthenium, and other metals for producing these new materials.

Production of High-Performance Nickel Alloys. In the production of high-performance alloys, the critical first step of alloying requires sophisticated equipment, stringent controls, and expertise. Several production methods are used.

Air melting in electric-arc or induction furnaces is used for many alloys, sometimes for final alloying, with further refining by argon-oxygen decarburization. Melting in air can result in impurities in some alloys, a problem eliminated by vacuum induction melting, used to produce ingots for direct rolling or for remelting. Remelting is accomplished by two methods, both with precise, computerized control. *Electroslag* remelting uses electrical resistance heating to remelt an ingot (electrode) under molten slag containing fluxes that remove impurities. *Vacuum arc* melting refines the structure of cast electrodes in a contaminant-free chamber. Remelting yields alloys of the highest level of refinement.

(**b**)

Fig. 1. Types of available nickel powders. (**a**) With a surface area of 0.4 m^2/g. this is a spiked nickel powder of single particles 3–7 microns in diameter, with a bulk density of 2 g/cc. The powder is used in both metal and chemical systems for powder metal parts, getters, magnets, electronic strip, flake, and organo-nickel compounds and nickel salts and soaps. (**b**) High-density nickel powder consisting of 8–12 micron semismooth particles, offering mixability with both metallic and nonmetallic powder systems. Applications include welding rods, nickel aluminide, nickel-columbium additives, abradable seals, powder metal parts, carbide binders, and conductive plastics. (**c**) Spherically shaped, high- purity nickel powder, with a surface area of 0.15 m^2/g and a Fisher particle size of 8–9 microns. Applications include friction materials, plasma spraying, metal injection molding, welding electrodes, magnets, cemented carbides, and powder metal nickel steels. Nickel Chemistry and Compounds

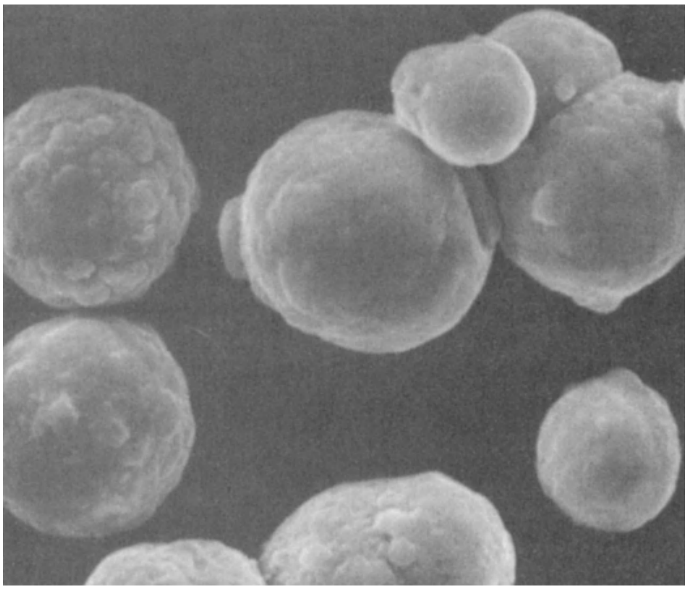
With its $3d^8 4s^2$ electron configuration, nickel forms Ni^{2+} ions. Having a nearly complete $3d$ subshell, nickel does not yield a $3d$ electron as readily as iron and cobalt, and trivalent and tetravalent forms are known only in the hydrated oxides, Ni_2O_3 and NiO_2, and a few complexes.

Nickel(II) oxide, NiO, produced by heating the carbonate, is thermally stable. Higher oxides of nickel, including Ni_2O_3 and NiO_2, are known only as hydrates, being prepared by vigorous oxidation of NiO in alkaline solution.



(c)

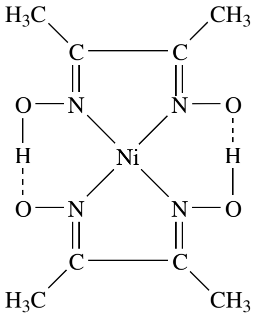
Fig. 1. (*continued*)

Nickel(II) sulfide, precipitated from Ni^{2+} solutions by ammonium sulfide, may show quite a little departure from stoichiometric composition. Like iron(II) and cobalt(II) FeS and CoS, it has in crystal form an electrical conductivity and other properties similar to a metal or alloy. There is no conclusive evidence that Ni_2S_3 can be prepared, but NiS_2 is known and believed to be, like FeS_2, a compound of Ni^{2+} and the S_2^{2-} ion.

All four dihalides of nickel with the common halogens are known: NiF_2, formed by reaction of hydrofluoric acid or nickel(II) chloride or by thermal decomposition of $[Ni(NH_3)_6][BF_4]_2$, is greenish yellow, while the other three dihalides, formed directly from the elements, are green for the chloride, yellow for the bromide, and black for the iodide. In general, anhydrous Ni^{2+} salts are yellow and the ion $Ni(H_2O)_6^{2+}$ in aqueous solution is green.

Other elements with which nickel forms binary compounds, especially at higher temperature, are boron, carbon, nitrogen, silicon, and phosphorus. Like NiO, these compounds may depart slightly or even considerably from daltonide composition, frequently being interstitial compounds, and with higher elements of transition groups 5 and 6, merging into the interstitial compound-solid solution picture which nickel exhibits with the other transition metals.

Divalent nickel forms two main types of complexes. The first consists of complexes of the spin-free ("ionic" or outer orbital) octahedral type (see also **Ligand** for their discussion) in which the ligands are principally H_2O, NH_3, and various amines such as ethylenediamine and its derivates, e.g., $Ni(H_2O)_6^{2+}$, $Ni(NH_3)_6^{2+}$, $Ni(en)_6^{2+}$. These complexes usually have colors toward the high-frequency side of the spectrum, i.e., violet, blue, and green. The other class consists of tetracovalent square complexes with ligands such as CN^-, the dioximes and their derivatives, and other chelates, which usually have colors on the low frequency side of the spectrum, i.e., red, orange, and yellow. The structure of the nickel-dimethylglyoxime complex is



This compound is of interest not only in analysis, but because by limited oxidation with the halogens it yields a unipositive ion containing trivalent nickel and also because the hydrogen bonds formed to the oxygen atoms are among the shortest known. Similarly, the tetracyanide complex of nickel, $Ni(CN)_4^{2-}$, may be reduced by sodium amalgam to give an ion of composition $Ni(CN)_4^{3-}$, or $(NC)_3Ni{-}Ni(CN)_3^{4-}$ containing Ni(I). This latter ion forms a potassium salt of nickel(I) of the formula $K_4Ni_2(CN)_6$ which is reduced in liquid NH_3 by metallic potassium to give the compound $K_4Ni(CN)_4$ in which the nickel has an effective valence of zero. Of course, this zero valence also exists in the carbonyls of nickel (and other elements) which, however, are covalent. $Ni(CO)_4$ is prepared by reaction of carbon monoxide with freshly reduced nickel, which occurs at ordinary temperatures and pressures. As with the carbonyls of other metals, the CO groups may be directly or indirectly, partially or completely, replaced by other groups. Derivatives of trivalent phosphorus form many such compounds of general formula $Ni(CO)\times_{4-x}(PR_3)_x$, where R may be one or more of such groups as F, Cl, Br, I, alkyl, aryl, alkoxy, aryloxy, etc.

See also **Nickel (In Biological Systems)**.

Health and Safety Factors

Eye and Skin Contact. Some nickel salts and aqueous solutions of these salts, e.g., the sulfate and chloride, may cause a primary irritant reaction of the eye and skin. The most common effect of dermal exposure to nickel is allergic contact dermatitis.

Protective equipment and clothing such as face shields and gloves should be worn and safety showers should be available wherever there is a possibility of being splashed or otherwise contacted by nickel containing solutions. If dermatitis should occur, the possibility that it is nickel related should be brought to the attention of a physician.

Inhalation. Nickel carbonyl is an extremely toxic gas. The permissible exposure limit (PEL) in the United States is 1 part per billion (ppb) in air. Nickel carbonyl may form wherever carbon monoxide and finely divided nickel are brought together. Nickel carbonyl should be used in totally enclosed systems or under good local exhaust.

The potential chronic toxicity is of concern. Based on epidemiological and experimental results, the International Agency for Research on Cancer (IARC) http://www.iarc.fr/, has concluded that all nickel compounds are Category 1, i.e., known human carcinogens, and has classified metallic nickel as a Category 2B carcinogen, i.e., possibly carcinogenic to humans.

It is good practice to keep concentrations of airborne nickel in any chemical form as low as possible and certainly below the relevant standard. Local exhaust ventilation is the preferred method, particularly for powders, but personal respirator protection may be employed.

NICKEL (In Biological Systems). Despite its many pharmacological and in vitro actions, convincing evidence showing that nickel is an essential element for some animal species did not appear until the early 1960s. There has been considerable further and more convincing research during the 1970s and early 1980s.

Like most trace elements, nickel can activate various enzymes in vitro, but no enzyme has been shown to require nickel, specifically, to be activated. However, urease has been shown to be a nickel metalloenzyme and has been found to contain 6 to 8 atoms of nickel per mole of enzyme (Fishbein et al., 1976). RNA (ribonucleic acid) preparations from diverse sources consistently contain nickel in concentrations many times higher than those found in native materials from which the RNA is isolated (Wacker-Vallee, 1959; Sunderman, 1965). Nickel may serve to stabilize the ordered structure of RNA. Nickel may have a role in maintaining ribosomal structure (Tal, 1968, 1969). These studies and other information have led to the suggestion that nickel may play a role in nucleic acid and/or protein metabolism.

Nickel also may act to stimulate or inhibit the release of various hormones (Nielsen, 1971, 1972; Dormer et al., 1973; Clay, 1975; Horak-Sunderman, 1975). Nickel has been found to inhibit insulin release from the pancreas (Dormer et al., 1973; Clay, 1975), and stimulates glucagon secretion (Horak-Sunderman, 1975).

Nickel as an essential element in ruminant nutrition has not been proved conclusive as of the early 1980s. However, with nonruminants, some evidence indicates that certain species fed low-nickel diets have a greater infant mortality rate and a general degradation of the reproductive process (Nielsen, 1975; Anke et al., 1973).

Zinc and nickel appear to behave similarly at certain sites in the biological system. Both elements are capable of activating certain enzymes; for example, arginase is an enzyme which can be activated by either element (Parisi-Vallee, 1969). Stimulation of enzyme activity is at a site at which trace element substitutions or interactions may occur. However, some sacrifice of activity usually results when normally occurring metal is replaced by a trace metal. Nucleic acids as well as the ribosomes are likely sites of interaction between nickel and zinc. Both metals are consistently found in high concentrations firmly bound to RNA. It has been suggested that they function in maintaining the structure of RNA, thus preventing conformational changes. Nickel appears to be as effective as zinc at equal concentrations in this respect. Nickel and zinc are also found in ribosomal ash and studies have indicated that both can contribute to ribosomal conformation. The white blood cell is another possible site at which nickel and zinc may interact. Leukocytes are high in zinc and total leukocyte counts as well as differential white cell counts change drastically during a zinc deficiency. The interrelationship between nickel and zinc has been studied in vitro primarily in swine and rats. Their relationship has been studied largely from a substitution standpoint. Nickel appears to substitute for zinc to a certain extent in both species.

Similarly, the relationship between nickel and copper has been under study. One of the major functions of copper is in hemoglobin formation. Hemoglobin and hematocrit values decline rapidly during a copper deficiency. Copper is currently believed to exert its effect on hemoglobin metabolism through ceruloplasmin. Early work also indicated that nickel might be involved in hematopoiesis. Investigators in 1974 found a decreased concentration of copper in the lung and spleen of rats receiving 5 parts per million of nickel in drinking water. High levels of dietary nickel in rats and mice have been reported to decrease the activity of cytochrome oxidase, a copper-containing enzyme.

As pointed out by Eskew, Welch, and Cary in 1983, in contrast with the situation in animals, for which four new essential trace elements were identified in recent years, no new generally essential micronutrient for higher plants has been found since the mid-1950s. When it was found that urease is a nickel-metalloenzyme, this suggested that Ni may play a role in higher plants. Nickel has evidenced a stimulation of growth when urea is the sole source of nitrogen, but has slight or no effect when other nitrogen enrichment sources are used. The aforementioned investigators claim that Ni is essential for nitrogen metabolism in soybeans (*Glycine max* (L.) Merr.), either when nitrogen is furnished as NO_3^- and NH_4^+ or when plants depend upon nitrogen fixation. In experiments, soybean plants deprived of Ni accumulated toxic concentrations of urea (2.5%) in necrotic lesions on their leaflet tips. This occurred regardless of whether the plants were furnished with inorganic N or were dependent on N fixation. Nickel deprivation resulted in delayed nodulation and in a reduction of early growth. The addition of Ni (1 microgram/liter) to the nutrient media prevented urea accumulation, necrosis, and growth reductions. Extrapolating these findings, it is suggested that Ni may be essential for other higher plants.

Toxicity

Nickel contact dermatitis can occur among wearers of nickel-containing jewelry, more common among females than males. This is particularly true of nickel sulfate present in some jewelry. Localization of sites unexpectedly involves the ear lobes, neck, fingers, and wrists. Nickel is a major offender in connection with AECD (allergic eczematous contact dermatitis).

As mentioned earlier, nickel carbonyl is a volatile intermediate in the Mond process for nickel refining. This compound also is used for vapor plating of nickel in the semiconductor industry, and as a catalyst in the chemical and petrochemical industries. The toxicity of the compound has been known for many years. Exposure of laboratory animals to the compound has induced a number of ocular anomalies, including anophthalmia and microphthalmia, and has been shown to be a carcinogenic for rats.

Biochemical Periodic Table—Nickel: http://umbbd.ahc.umn.edu/periodic/elements/ni.html

NICKELINE. A nickel arsenide mineral, NiAs, crystallizes in the hexagonal system but is usually found massive. Color, light copper; hardness, 5.0–5.5; specific gravity, 7.784; luster, metallic; opaque. Found in several European localities and in the Province of Ontario, Canada; in the United States at Franklin, New Jersey, and Silver Cliff, Colorado. It is an ore of nickel.

NICOTINE. See **Alkaloids**.

NINHYDRIN REACTION. See **Amino Acids**.

NIOBIC ACID. Any hydrated form of Nb_2O_5. It forms as a white, insoluble precipitate when a potassium hydrogen sulfate fusion of a niobium compound is leached with hot water or when niobium fluoride solutions are treated with ammonium hydroxide. Soluble in concentrated sulfuric acid, concentrated hydrochloric acid, hydrogen fluoride, and bases. Important in analytical determination of niobium. See also **Niobium**.

NIOBIUM. [CAS: 7440-03-1]. Chemical element, symbol Nb, at. no. 41, at. wt. 92.906, periodic table group 5, mp 2,458–2,468°C, bp 4,742°C, density 8.6 g/cm^3 (20°C). Elemental niobium has a body-centered cubic

crystal structure. The metal has a slightly bluish tinge, is ductile and malleable, and when polished resembles platinum. The metal burns upon being heated in air. There is one natural isotope ^{93}Nb. Seven radioactive isotopes have been identified ^{90}Nb through ^{92}Nb and ^{94}Nb through ^{97}Nb, with a wide range of half-lives. ^{94}Nb has the longest half-life (2×10^4 years). The element was first identified by C. Hatchett in 1801 and was originally called columbium which name persisted for many years. The name still appears widely in the literature, particularly in connection with alloys bearing the element, such as columbium steels.

First ionization potential 6.77 eV; second 13.895 eV; third 24.2 eV. Oxidation potential $Nb \longrightarrow Nb^{3+} + 3e^-$, ca. 1.1 V; $2Nb + 5H_2O \longrightarrow Nb_2O_5 + 10H^+ + 10e^-$, 0.62 V.

Other important physical properties of niobium are given in the Table 1 and under **Chemical Elements**.

Niobium occurs, usually with tantalum, in columbite $Fe(NbO_3)_2$, (80% Nb_2O_5), pyrochlore (50% Nb_2O_5), samarskite (50% Nb_2O_5), chiefly found in western Australia, and South Dakota. Recovered along with tantalum by fusion with potassium bisulfate, and obtained in the residue after subsequent extraction with H_2O. Niobium and tantalum are separated by fractional crystallization of the potassium fluorides, niobium concentrating in the mother liquid and tantalum in the crystals.

The principal uses for the element are in alloys. Niobium also has gained prominence in research as a superconducting material. At the temperatures of liquid helium, niobium becomes a superconductor and, in the form of a fine wire, has been incorporated in a superconducting cell. The element has both size and cost advantages over electronic materials. The alloy Nb_3Sn becomes superconducting at a somewhat higher temperature. Niobium-titanium and niobium-zirconium alloys also have potential as superconductors.

TABLE 1. REPRESENTATIVE PROPERTIES OF REFRACTORY METALS

Property	Tungsten	Tantalum	Molybdenum	Niobium
Density, g/cm^3	19.3	16.6	10.2	8.7
Melting point, °C	3,390–3,420	2,996	2,617	2,458–2,468
Boiling point, °C	5,660	5,325–5,525	4,612	4,742

Phosphoric acid, 85%		N	SL	VS
Concentrated NaOH		R	N	R

N = no appreciable corrosion.
VS = < 0.0005 inch (0.013 millimeter) per year.
SL = 0.0005–0.005 inch (0.013–0.13 millimeter) per year.
S = 0.005–.01 inch (0.13–0.25 millimeter) per year.
R => 0.01 inch (0.25 millimeter) per year.

Alloys. Niobium is used in steel, notably stainless steels, to stabilize the carbon present (as carbide) and for preparing niobium carbide, used for dies and cutting tools. Ferroniobium is a strong carbide-forming material and, when added to 18-8 stainless steel, stabilizes areas that may be heat-affected during welding and thus cause subsequent intergranular corrosion. Niobium steels are used for rotors in gas turbines where temperatures up to 700°C must be withstood. Niobium-base alloys find application in fast reactors. Superalloys for very demanding use, as in military applications contain niobium with cobalt and zirconium. When alloyed with titanium, molybdenum, and tungsten, the elevated-temperature hardness of niobium in enhanced, whereas when alloyed with vanadium and zirconium, the strength of niobium up to temperatures of 500°C is increased. Metallurgically, niobium is attractive because of its density, good workability, retention of tensile strength at high temperatures, and its high melting point. In the temperature range 920–1,200°C, niobium has been found superior to most other metals on a strength-to-weight basis for aerospace applications. In multicomponent alloys, zirconium and hafnium when added with niobium add effectively to strength, even more so than molybdenum or tungsten, but there is some sacrifice in ductility.

In metallurgy, niobium is classified as a refractory metal, along with tungsten, tantalum, and molybdenum. A comparison of the four metals is given in the accompanying table.

Niobium in Tool Steels. In the matrix method of tool-steel development, the composition of the heat-treated matrix determines the steel's initial composition. Carbide volume-fraction requirements then are calculated, based upon historical data, and the carbon content is adjusted accordingly. This approach has been used to design new steels in which niobium is substituted for all or part of the vanadium present as carbides in the heat-treated material. Niobium provides dispersion hardening and grain refinement, and forms carbides that are as hard as vanadium, tungsten, and molybdenum carbides.

Chemistry and Compounds

Elemental niobium is insoluble in HCl or HNO_3, but soluble in hydrofluoric acid or a mixture of hydrofluoric and HNO_3.

As might be expected from its $4d^45s^1$ electron configuration, niobium forms pentavalent compounds. However, the stability of its compounds of lower valence is greater than that of the corresponding tantalum compounds, in keeping with the group 5 position of niobium and tantalum. Nevertheless the similarity of the properties of the compounds of the two metals is so great that special methods are required for their separation, such as solvent extraction of the pentachlorides or chromatographic removal of adsorbed TaF_5 with an ethylmethyl ketone-water system. In addition, divalent and tetravalent compounds are known, and an interstitial, nonstoichiometric hydride.

Niobium forms a divalent oxide, NbO, insoluble in water, but readily soluble in acids or NH_4OH. It also gives by direct combination of the metal on heating with oxygen, the pentoxide, Nb_2O_5, which can be reduced by hydrogen at high temperature to NbO_2, and on heating with magnesium to Nb_2O_3.

Niobium(III) halides are known, notably the chloride, $NiCl_3$, which is of particular interest because its solution has been shown to contain Nb^{3+} ions (in equilibrium with $NbCl_6{}^{3-}$ complex ions).

Tetravalent niobium is believed to occur in the form of $NbOCl_4{}^{2-}$ ions in a solution obtained, with color change, by reduction of HCl solution of $NbCl_5$, and by inference in similarly reduced solutions of the other pentahalides. Tetravalent niobium also is found in the dioxide (see above) and the carbide, NbC.

Four pentahalides of niobium, NbF_5, $NbCl_5$, $NbBr_5$, and NbI_5 have been prepared by heating the pentoxide with carbon in a current of the halogen. They are hydrolyzed in H_2O, and even in concentrated aqueous solution of the respective halogen acids; the Nb^{5+} ion is apparently not present, but rather complex ions such as $[NbOCl_4]^-$ or $[NbOCl_5]^{2-}$. The products of partial hydrolysis of the pentahalides are oxyhalides, such as $NbOF_3$, $NbOCl_3$, and $NbOBr_3$. They are designated in the older literature as columbyl or columboxy compounds. The more stable oxyhalogen compounds of niobium are complexes, such as $NbOF_3 \cdot 3NaF$, $NbOF_3 \cdot ZnO \cdot 6H_2O$, and $NbOF_3 \cdot 2KF \cdot H_2O$.

Further complexes of Nb(V) are formed with oxygen-function compounds, such as *o*-dihydroxybenzene and acetylacetone.

The so-called niobic acid is the hydrated pentoxide, $Nb_2O_5 \cdot xH_2O$, insoluble in H_2O.

The metaniobates of the alkali metals, $MNbO_3$, the orthoniobates M_3NbO_4 and the pyroniobates, $M_4Nb_2O_7$, where M is an alkali metal, can be prepared by various alkali carbonate or hydroxide fusion processes.

Niobium forms a nitride, NbN, and a carbide, NbC.

Niobium forms a diamino compound, $(NH_2)_2NbCl_3$, and an ammine complex, $NbCl_5 \cdot 9NH_3$. It forms two cyclopentadienyl compounds, $(C_5H_5)_2NbBr_3$ and $(C_5H_5)Nb(OH)Br_2$. Its other organometallic compounds are essentially oxygen-functional ones, such as $Nb(OCH)_3)_5$, $Nb(OC_2H_5)_5$, $Nb(O)(OC_5H_{11})_3$, and $Nb(OC_5H_{11})_5$. These compounds are named as substituted niobanes (thus, the last is pentabutoxy niobane) or as alkyl niobate esters.

Health and Safety Factors

Toxicity data on niobium and its compounds are sparse. The most common materials, e.g., niobium concentrates, ferroniobium, niobium metal and niobium alloys, appear to be relatively inert biologically. Limited animal experiments show high toxicity for some salts, which are related to disturbance of enzyme action. Niobium hydride has moderate fibrogenic and general toxic action. Recommended maximum allowable concentrations are 6 mg/m^3. Recommended maximum permissible concentration of Nb in reservoir water is 0.01 mg/L. The threshold for affecting clarity and biological oxygen demand (BOD) is 0.1 mg/L.

Unstable niobium isotopes that are produced in nuclear reactors or similar fission reactions have typical radiation hazards. See also **Radioactivity**.

Fire fighting procedures for niobium and niobium hydride powder, suggest letting the fire burn itself out. Small fires can be controlled by smothering with dry table salt or using Type D dry powder fire-extinguishing material. Under no circumstances should water be used, as a violent explosion may result.

NITER. This potassium nitrate mineral KNO_3 of orthorhombic crystallization usually occurs as thin crusts, or as silky acicular crystals. It has a hardness of 2, and specific gravity of 2.09–2.14, is of white color, translucent with vitreous luster. It occurs as a surface efflorescence, or in soils rich in organic material in arid regions. World occurrences include Spain, Italy, Egypt, Arabia, India, Russia, the western United States, the Republic of South Africa, and Bolivia, South America. Large quantities were recovered from limestone caves in Tennessee, Kentucky, Alabama and Ohio during the Civil War for use in the manufacture of gunpowder. It is used as a source of nitrogen compounds, for explosives and fertilizers.

NITRATION. Nitration is defined in this article as the reaction between a nitration agent and an organic compound that results in one or more nitro ($-NO_2$) groups becoming chemically bonded to an atom in this compound. Nitric acid is used as the nitrating agent to represent *C*-, *O*-, and *N*-nitrations. *O*-Nitrations result in esters. *N*-nitrations are often used as a first step for production of nitramines.

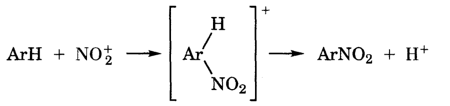
For example, a nitro group is substituted for a hydrogen atom, and water is a by-product. Nitro groups may, however, be substituted for other atoms or groups of atoms. Nitro compounds can also be produced by addition reactions, e.g., the reaction of nitric acid or nitrogen dioxide with unsaturated compounds such as olefins or acetylenes.

Nitrations are highly exothermic, i.e., ca 126 kJ/mol (30 kcal/mol) However, the heat of reaction varies with the hydrocarbon that is nitrated. The mechanism of a nitration depends on the reactants and the operating conditions. The reactions usually are either ionic or free-radical. Ionic nitrations are commonly used for aromatics; many heterocyclics; hydroxyl compounds, e.g., simple alcohols, glycols, glycerol, and cellulose; and amines. Nitration of paraffins, cycloparaffins, and olefins frequently involves a free-radical reaction.

Ionic Nitration Reactions

Acid mixtures containing nitric acid and a strong acid, e.g., sulfuric acid, perchloric acid, selenic acid, hydrofluoric acid, boron trifluoride, or an ion-exchange resin containing sulfonic acid groups, can be used as the nitrating feedstock for ionic nitrations. These strong acids are catalysts that result in the formation of nitronium ions, $NO_2{}^+$. Sulfuric acid is almost always used industrially since it is both effective and relatively inexpensive.

Mechanism. The $NO_2{}^+$ mechanism has been accepted since about 1950 for the nitration of most aromatic hydrocarbons, glycerol, glycols, and numerous other hydrocarbons in which mixed acids or highly concentrated nitric acid are used. The mechanism has been discussed in detail and critically analyzed. $NO_2{}^+$ attacks an aromatic compound (ArH) as follows:



(1)

Nitrosonium ions, NO^+, are, however, the ions employed to start the nitration sequence for easily nitratable aromatic compounds such as phenol.

Kinetics of Aromatic Nitrations. The kinetics of aromatic nitrations are functions of temperature, which affects the kinetic rate constant, and of the compositions of both the acid and hydrocarbon phase. In addition, a larger interfacial area between the two phases increases the rates of nitration since the main reactions occur at or near the interface. Larger interfacial areas are obtained by increased agitation and by the proper choice of the volumetric % acid in the liquid–liquid dispersion. The viscosities and densities of the two phases and the interfacial tension between the phases are important physical properties affecting the interfacial area.

Increased agitation of a given acid–hydrocarbon dispersion results in an increase in interfacial areas owing to a decrease in the average diameter of the dispersed droplets. As the droplets decrease in size, the ease of separation of the two phases, following completion of nitration, also decreases.

Industrial Applications. Significant process changes have occurred in many nitration plants. Continuous-flow units are now widely used in the 1990s, replacing batch nitrations. A well-designed continuous-flow plant often offers all of the following advantages, per unit weight of product, as compared to batch units; increased safety, decreased energy requirements, reduced amounts of undesired by-products, fewer environmental problems, reduced labor requirements, and lower operating expenses.

Many nitrated products are explosives, including DNT, TNT, and nitroglycerine (NG). To minimize the potential for run away reactions and explosions, the compositions of the feed acids and reaction conditions are currently better controlled than formerly. In some processes, 99% or more of the feed HNO_3 reacts. Dispersions (or mixtures) of such a waste acid and the nitration product are relatively safe to handle. Also, centrifugal separators are used in many modern processes to rapidly separate the hydrocarbon and used acid phases. Rapid separation greatly reduces the amounts of nitrated materials in the plant at any given time and reduces undesired reactions of the nitrated products.

Considerable effort has been made to minimize energy requirements in the nitrations plants too.

A significant concern in all nitration plants using mixed acid centers on the disposal method or use for the waste acids. They are sometimes employed for production of superphosphate fertilizers. Processes have also been developed to reconcentrate and recycle the acid.

Nitrations Using N_2O_5. Considerable worldwide interest has occurred in the late 1980s and the early and mid-1990s for nitrations using N_2O_5. Production of nitramines (or *N*-nitrations) is particularly promising, since these compounds are more stable in the presence of N_2O_5–HNO_3 solutions as compared to mixed acids containing H_2SO_4. Good results have been obtained for the production of the high explosives, cyclotetramethylenetetranitramine or HMX and DADN. Another high explosive, polynitrofluorene, has been produced via *C*-nitrations, for the first time. The overall

exothermicities of the reactions are less when N_2O_5 is used, as compared to mixed acids.

Solutions of CH_2Cl_2 and N_2O_5 have only mild nitrating power. Yet some nitrations are rapid: the N_2O_5 reacts on an almost stoichiometric basis, and only minimal residual nitric acid is present upon completion of the nitration. Some nitrations having unique characteristics can be accomplished.

Free-Radical Nitrations of Paraffins

Both vapor-phase and liquid-phase processes are employed to nitrate paraffins, using either HNO_3 or NO_2. The nitrations occur by means of free-radical steps, and sufficiently high temperatures are required to produce free radicals to initiate the reactions steps.

Chemistry. Free-radical nitrations consist of rather complicated nitration and oxidation reactions. When nitric acid is used in vapor-phase nitrations, the main initiating reaction (eq. 2) produces either $\cdot NO_2$ or $\cdot ONO$. Temperatures of $>$ ca350°C are required to obtain a significant amount of initiation, and equation 2 is the rate-controlling step for the overall reaction. Reactions 3 and 4 are chain-propagating steps.

$$HNO_3 \longrightarrow \cdot OH + NO_2 \quad (2)$$

$$RH + \cdot OH \longrightarrow R\cdot + H_2O \quad (3)$$

$$R\cdot + HNO_3 \longrightarrow RNO_2 + \cdot OH \quad (4)$$

When nitrogen dioxide is used, the main reaction steps are as in equations 5 and 6.

$$RH + NO_2 \longrightarrow R\cdot + HNO_2 \longrightarrow R\cdot + \cdot OH + NO \quad (5)$$

$$R\cdot + \cdot NO_2 \longrightarrow RNO_2 \quad (6)$$

An important side reaction in all free-radical nitrations is production, of unstable alkyl nitrites (eq. 7). They decompose to form nitric oxide and alkoxy radicals (eq. 8) which form oxygenated compounds and lower molecular weight alkyl radicals which can form lower molecular weight nitroparaffins by reactions 4 or 6. The oxygenated hydrocarbons often react further to produce carbon oxides and water.

$$R\cdot + \cdot ONO \longrightarrow RONO \quad (7)$$

$$RONO \longrightarrow NO + RO\cdot \quad (8)$$

Processes for Paraffin Nitrations. Propane is thought to be the only paraffin that is commercially nitrated by vapor-phase processes. Temperature control is a primary factor in designing the reactor, and several approaches have been investigated. A spray nitrator in which liquid nitric acid is sprayed into hot propane is used industrially. Relatively small-diameter tubular reactors, fluidized-bed reactors, and molten salt reactors have all been successfully used in laboratory units.

Health and Safety Factors

The danger of an explosion of a nitrated product generally increases as the degree of nitration increases. Nitroaromatics and some polynitrated paraffins are highly toxic when inhaled or when contacted with the skin. All nitrated compounds tend to be highly flammable.

NITRIC ACID. [CAS: 7697-37-2]. This important industrial chemical has been known for at least 1000 years. The acid was known to alchemists as *aqua fortis* (strong water) or *aqua valens* (powerful water). Nitric acid was of particular interest to the early experimenters because of its ability to dissolve a number of metals, including copper and silver. Early chemists were also fascinated by the fact that addition of sal ammoniac (ammonium chloride) gave *aqua regia* (royal water) which dissolves gold as well as silver.

Nitric acid is a colorless liquid, sp. gr. 1.503 (25°C), freezing point −41.6°C, and boiling point 86°C. The 100% acid is not entirely stable and must be prepared from its azeotrope (constant-boiling mixture) by distillation with concentrated sulfuric acid. Reagent grade HNO_3 is a water solution containing about 68% HNO_3 (weight). This strength corresponds to the constant-boiling mixture of the acid with water, which is 68.4% HNO_3 (weight) at atmospheric pressure and boils at 121.9°C. Nitric acid is completely miscible with water. It forms two solid hydrates, $HNO_3 \cdot H_2O$ and $HNO_3 \cdot 2H_2O$, with corresponding melting points of approximately −38 and −18.5°C. Nitric acid is a strong acid and a powerful oxidizer. In dilute solutions, it is almost completely ionized to H^+ and NO_3^- ions and behaves like a strong acid.

With organic compounds, HNO_3 may act as a nitrating agent, as an oxidizing agent, or simply as an acid. The classic example of nitration is its reaction with benzene or toluene in the presence of concentrated H_2SO_4 to form nitrobenzene or nitrotoluene (TNT). An example of oxidation properties is in the oxidation of cyclohexanol by HNO_3 to produce adipic acid, an intermediate of nylon. Behaving like an acid, it forms nitroglycerin by esterification of glycerol in the presence of concentrated sulfuric acid.

An interesting property of HNO_3 is its ability to passivate some metals, such as iron and aluminum. This property is of significant industrial importance, since modern processes for producing the acid depend on it. Modern suitability formulated stainless steel alloys are usefully resistant to nitric acid through a wide range of conditions. The acid's passivity or the metal's resistance to attack is attributed to the formation of a protective oxide layer on the surface of the metal.

Nitric acid is a high tonnage industrial chemical. Much of the production is used in the manufacture of agricultural fertilizers, largely in the form of ammonium nitrate, NH_4NO_3. See also **Fertilizer**. About 15% of the nitric acid produced is used in explosives (nitrates and nitro compounds), and about 10% is consumed by the chemical industry. As the red fuming acid or as nitrogen tetroxide, HNO_3 is used extensively as the oxidizer in propellants for space rockets and missiles.

Production of Nitric Acid

Three commercial methods have been developed for nitric acid production: (1) the reaction between sulfuric acid and sodium nitrate, (2) the thermal combination of oxygen and nitrogen in air, and (3) the catalytic oxidation of ammonia and absorption of the gaseous products in waters. There are numerous variations of these fundamentals processes. The principal process used today is based on the catalytic oxidation of ammonia and absorption of the gaseous products in water. This process was developed by Ostwald (Germany) and based on earlier work of Kuhlmann (France). In the Ostwald process, HNO_3 is produced in a 3-stage operation: (1) Ammonia is oxidized to nitric oxide, (2) the nitric oxide is further oxidized to nitrogen dioxide, and (3) the gases are absorbed in water to yield HNO_3 according to

$$4NH_3 + 5O_2 \longrightarrow 4NO + 6H_2O$$

$$2NO + O_2 \longrightarrow 2NO_2$$

$$3NO_2 + H_2O \longrightarrow 2HNO_3 + NO$$

The nitric oxide formed in the last equation returns to the gas phase, is reoxidized to nitrogen dioxide, and reabsorbed. These reactions are highly exothermic. In actuality, numerous complex reactions occur in addition to the main reactions just outlined.

In a manufacturing plant, air is preheated, mixed with superheated ammonia vapor, and reacted catalytically over a gauze composed of 90% platinum and 10% rhodium at a temperature of 800–960°C and operating pressures between 1 and 8.2 atmospheres. The reaction produces nitrogen dioxide, NO_2 and nitric oxide, NO. The latter is oxidized to NO_2 in the reaction train. The NO_2 actually exists in equilibrium with its dimer, N_2O_4. This equilibrium mixture, sometimes referred to as nitrogen peroxide, is absorbed in water in a cooled absorber tower to form HNO_3 at a strength of 55–60% HNO_3.

Health and Safety Factors

Nitric acid and the oxides of nitrogen found in its fumes are highly toxic and capable of causing severe injury and death. It is corrosive, and can

destroy human tissue. Nitric acid is regulated by OSHA, which lists it as a Process Safety Hazardous Chemical and Air Contaminant. Under SARSH, the EPA lists it as an Extremely Hazardous Substance and Toxic Chemical.

First-aid practices for the treatment of exposure to nitric acid should be obtained from a current version of the Material Safety Data Sheet or other appropriate safety literature.

NITRIDES. At elevated temperatures and pressures, nitrogen combines with most elements to form nitrogen compounds. In the presence of metals and semimetals, it forms nitrides where nitrogen has a nominal valence of −3. Atomic nitrogen, which reacts much more readily with the elements than does molecular nitrogen, forms nitrides with elements that do not react with molecular nitrogen even at very high pressures. The binary compounds of nitrogen may be classified, according to their chemical and physical properties, into four groups: saltlike, metallic, nonmetallic or diamondlike, and volatile nitrides.

Properties

Saltlike Nitrides. The nitrides of the electropositive metals of Group 1 (IA), 2 (IIA), AND 3 (IIIB) form saltlike nitrides having predominantly heteropolar (ionic) bonding and are regarded as derivatives of ammonia. The composition of these nitrides is determined by the valency of the metal. The thermodynamic stability of the saltlike nitrides increases with increasing group number. The saltlike nitrides are generally electrical insulators or ionic conductors. The nitrides of the Group 3 (IIIB) metals are metallic conductors or at least semiconductors, and thus, represent a transition to the metallic nitrides. The saltlike nitrides are characterized by sensitivity to hydrolysis.

Metallic Nitrides. The nitrides of the transition metals of Groups 6 and 7 (IVB–VIIB) are generally termed metallic nitrides because of metallic conductivity, luster, and general metallic behavior. These compounds, characterized by a wide range of homogeneity, high hardness, high melting points, and good corrosion resistance, are grouped with the carbides (qv), borides and silicides as refractory hard metals. Metallic nitrides can be alloyed with other nitrides and carbides of the transition metals to give solid solutions.

Although there are several hundred binary nitrides, only a relative few ternary bimetallic nitrides are known. A group of ternaries of the composition $M_xM'_yN_z$, where M is an alkali, alkaline-earth, or a rare-earth metal and M is a transition or post-transition metal, have been synthesized.

Metallic nitrides are wetted and dissolved by many liquid metals and can be precipitated from metal baths.

Nonmetallic (Diamondlike) Nitrides. The nitrides of some elements of Groups 13 (IIIA) and 14 (IVA) e.g., BN, Si_3N_4, AlN, GaN, and InN, are characterized by predominantly covalent bonding. These are stable chemically, have high degrees of hardness (e.g., cubic BN) and high melting points, and are nonconductive or semiconductive. The structural elements of diamondlike nitrides are tetrahedral, M_4N, which are structurally related to diamond.

Volatile Nitrides. The nitrogen compounds of the nonmetallic elements are generally not very stable. Exceptions are $(SN)_x$, which is polymeric, chemically stable, and has semimetallic properties; and $(PNCl_2)_x$, which has attracted some scientific interest as inorganic rubber. None of the volatile nitrides has obtained any substantial industrial application except ammonia (hydrogen nitride) and nitrogen oxide (oxygen nitride).

Preparation

Nitriding Metals or Metal Hydrides. Metals or metal hydrides may be nitrided using nitrogen or ammonia. Pure metal powders or pure metal hydride powders yield nitride products that are nearly as pure as the precursors.

Metal Oxides. A process based on the reaction of metal oxides rather than more expensive metal powders and nitrogen or ammonia in the presence of carbon is economical and has possibilities for large-scale production. However, the products, which contain oxygen and carbon, are not very pure.

Metal Compounds. Many nitrides, e.g., BN, AlN, TiN, ZrN, HfN, CrN, Re_2N, Fe_2N, Fe_4N, and Cu_3N, may be prepared by the reaction of the corresponding metal halide and ammonia. Nitrides may also be obtained by the reaction of ammonia and oxygen-containing compounds, ammonium-oxo complexes, or oxides and ferrous metal oxides. These nitrides, however, are not very pure and may contain residual oxygen and halogen.

Precipitation from the Gas Phase. The van Arkel gas decomposition process gives especially pure nitrides and nitride films, which under certain conditions may precipitate as single crystals. The nitrides include TiN, ZrN, HfN, VN, NbN, BN, and AlN.

Other Methods of Preparation. The nitrides, Si_3N_4, Ge_3N_4, Zn_3N_2, Cd_3N_2, and Ni_3N, may also be produced by thermal decomposition of the corresponding metal amide of imide. Rb_3N and Cs_3N are obtained by azide decomposition. AlN and Si_3N_4 can be produced by the carbothermal reduction of intercalation compounds, magadiite- and montmorillonite-polyacrylonitrile. Nitrides low in nitrogen can be synthesized from nitrides having a higher nitrogen content by decomposition in a vacuum or by reduction with hydrogen.

The formation of nitrides from gaseous halides, ammonia, and nitrogen (atomic and molecular) in a plasma processing torch is possible by means of a specific type of plasma processing called cathodic arc plasma deposition (CAPD). Plasma nitriding offers several advantages: It is nonpolluting and energy efficiency, provides flexible deposition conditions without sacrifice of quality, minimizes distortion, and is easily applicable to compound film deposition. Ion implantation directly inserts nitrogen into metal surfaces.

Nitride-Containing Layers. The hardening, i.e., increase in nitrogen content, achieved by nitriding special alloy steels is technologically significant in the heat treatment of high quality parts, such as gears. Hardness properties are imparted by the resulting coatings of needle-shaped precipitates of the nitrides and carbonitrides of iron, aluminum, chromium, molybdenum, etc. The hardness of these coatings exceeds that of the precipitation-hardened parts by ca 30%.

In nitriding or carbonitriding of condensed materials, molten cyanides are used at ca 570°C. This method produces fairly thick coatings of nitrides or carbonitrides after ca 1 hr without the risk of distortion during surface hardening.

Wear-resistant layers can be deposited on the surface of nearly every kind of material (e.g., steel, cast iron, and cemented carbides) by a chemical vapor deposition (CVD) process. See also **Thin Films**.

Manufacture and Processing

Nitride Coatings. Carbide tips coated with titanium nitride or titanium carbonitride are usually manufactured by a CVD process using $TiCl_4$, H_4, and N_2 in a hot-wall reactor.

Silicon Nitride. Silicon nitride is manufactured either as a powder as a precursor for the production of hot-pressed parts or as self-bonded, reaction-sintered, silicon nitride parts.

Health and Safety Factors

As a chemical group, toxicity of nitrides generally stems from the possible reactions with water to form toxic fumes (especially ammonia) rather than from the nitride. There are, of course, exceptions: Fine powder or dust of the nitrides of the transition metals can be pyrophoric; nitrides of the actinide metals are carcinogenic.

The diamondlike nitrides, especially as dust, can irritate the lungs or cause scratching of the eyes owing to mechanical means. Nitrides of the 11(IB) and 12(IIB) metals and especially the volatile nitrides have to be handled with extreme care because of their instability and high degree of toxicity.

Uses

Nitrides are used for their high strength and hardness, in nuclear applications, solid electrolytes, refractories, abrasives, coatings and lubrication, catalysis, and electronic and optoelectronic applications.

NITRIDING. Surface hardening of alloy steels by heating the metals to a temperature of 490–650°C in an atmosphere of partially dissociated NH_3 (ammonia). As in cyaniding, hardening results from the formation of nitrides of iron and of certain alloying elements that may be present in the steel. Much longer heating time is required than in carburizing practice, and while the depth of penetration is generally less, the maximum hardness at the surface is higher, 900–1,100 D.P.H. (Vickers Brinell) compared to 800–900 D.P.H. for an average carburized case. Nitriding also differs from carburizing in that the parts are fully heat-treated to develop the required core properties before the nitriding treatment. Because of the comparatively low temperature of the process, distortion and dimensional changes are at a minimum. Nitrided steels have good corrosion-resistance when used for valves, pump parts, shafting, and bearing surfaces operating in steam, crude oil, gasolines, and gaseous products of combustion. The fatigue strength is also improved by nitriding.

Other typical applications are piston pins, crankshafts, cylinder liners, timing gears, gauges, and ball and roller bearing parts.

NITRILE RUBBER. See **Elastomers**.

NITRILES. Nitriles, or organic cyanides, are organic compounds which contain the cyano (i.e., −CN) group. Nitriles are often considered derivatives of carboxylic acids and are named according to the carboxylic acid which is produced upon hydrolysis of the nitrile. For example, cyanomethane (methyl cyanide) is named acetonitrile, because hydrolysis of its cyano group yields acetic acid. Nitriles which contain additional functional groups are typically named as cyano-substituted compounds, (e.g., cyanoacetic acid). Nitriles which contain a hydroxy (−OH) group on the carbon atom that is bonded to the cyano moiety are known as cyanohydrins (qv). Aliphatic nitriles are named as derivatives of the longest carbon chain and the carbon of the nitrile is included.

General Preparations and Chemical Properties

While nitriles may be prepared by several methods, the reaction of alkyl halides with sodium cyanide to produce nitriles (eq. 1) is a general reaction with wide applicability:

$$RX + NaCN \longrightarrow RCN + NaX \qquad (1)$$

where X = Cl, Br, or I. If dimethyl sulfoxide is used as solvent, high yields of nitriles can be obtained with both primary and secondary alkyl chlorides. See also **Sulfoxides**.

Ammoxidation, a vapor-phase reaction of hydrocarbon with ammonia and oxygen (air) (eq. 2), can be used to produce hydrogen cyanide (HCN), acrylonitrile, acetonitrile (as a by-product of acrylonitrile manufacture), methacrylonitrile, benzonitrile, and toluinitriles from methane, propylene, butylene, toluene, and xylenes, respectively. See also **Acrylonitrile**; and **Methacrylic Acid and Derivatives**.

$$RCH_3 + NH_3 + O_2 \xrightarrow{\text{catalyst}} RCN + H_2O \qquad (2)$$

Addition of HCN to unsaturated compounds is often the easiest and most economical method of making organonitriles. However, the addition of HCN to unactivated olefins and the regioselective addition to dienes is best accomplished with a transition metal catalyst.

Chemistry and Uses of Nitriles

As a class of compounds, nitriles have broad commercial utility that includes their use as solvents, feedstocks, pharmaceuticals, catalysts, and pesticides. The versatile reactivity of organonitriles arises both from the reactivity of the C≡N bond, and from the ability of the cyano substituent to activate adjacent bonds, especially C−H bonds. Nitriles can be used to prepare amines, amides, amidines, carboxylic acids and esters, aldehydes, ketones, large-ring cyclic ketones, imines, heterocycles, orthoesters, and other compounds. Some of the more common transformations involve hydrolysis or alcoholysis to produce amides, acids and esters, and hydrogenation to produce amines, which are intermediates for the production of polyurethanes and polyamides.

Acrylonitrile is an important monomer both for plastics and synthetic fibers. Acetonitrile, a by-product of acrylonitrile manufacture, is commercially important for solvent extraction, reaction media, and as an intermediate in the preparation of pharmaceuticals (qv) and other organic chemicals. See also **Extraction (Liquid–Liquid)**. Propionitrile, a by-product of the electrodimerization of acrylonitrile to adiponitrile, is used as a chemical intermediate. Hydrogenation of organonitriles to amines provides important intermediates both for polyurethanes (by way of isocyanates) and polyamides (nylons); adiponitrile is used almost exclusively by the manufacturers in the production of 1,6-diaminohexane (hexamethylenediamine), an intermediate for nylon 6,6. Other nitriles that are produced in thousands of metric tons per year include acetone cyanohydrin, 2-amino-2-methylpropionitrile, and fatty acid nitriles. Acetone cyanohydrin is an intermediate for the preparation of methyl methacrylate and acrylic resins, (e.g., lucite and plexiglas) and for 5,5-dimethylhydantoin, which is used to make commercial water treatment chemicals. 2-Amino-2-methylpropionitrile is an intermediate for the preparation of azobis(isobutyronitrile), which is a widely used polymerization initiator, (e.g., Vazo 64) and in the production of some agrichemicals. Other aminonitriles are unisolated intermediates in the production of chelants such as ethylenediaminetetraacetate (EDTA) and nitrilotriacetate (NTA). The fatty acid nitriles are intermediates in the production of a large variety of commercial amines and amides.

General Health and Safety Factors

As a class of compounds, the two main toxicity concerns for nitriles are acute lethality and osteolathyrsm. Nitriles vary broadly in their ability to cause acute lethality and subtle differences in structure can greatly affect toxic potency. The biochemical basis of their acute toxicity is related to their metabolism in the body.

The propensity of nitriles to release cyanide subsequent to metabolism is the basis of their acute toxicity. Cyanohydrins are acutely toxic because they are unstable and release cyanide quickly. Persons handling nitriles should take precautions to prevent inhalation of fumes or skin contact.

Acetonitrile

[CAS: 75-05-8]. Acetonitrile (methyl cyanide), CH_3CN, is a colorless liquid with a sweet, ethereal odor. It is completely miscible with water and its high dielectric strength and dipole moment make it an excellent solvent for both inorganic and organic compounds including polymers. Many gases also are highly soluble in acetonitrile. It forms low boiling azeotropes with many organics and high boiling azeotropes with BF_3, $SiCl_4$, and $(CH_3)_4Pb$.

Although acetonitrile is one of the more stable nitriles, it undergoes typical nitrile reactions and is used to produce many types of nitrogen-containing compounds.

Most, if not all, of the acetonitrile produced commercially in the United States recently was isolated as a by-product from the manufacture of acrylonitrile by propylene ammoxidation. The acetonitrile is recovered as the water azeotrope, dried, and purified by distillation.

Uses. Because of its good solvency and relatively low boiling point, acetonitrile is used widely as a recoverable reaction medium, particularly for the preparation of pharmaceuticals. Its largest use is for the separation of butadiene from C_4 hydrocarbons by extractive distillation.

Acetonitrile also is used as a catalyst and as an ingredient in transition-metal complex catalysts. There are many uses for it in the photographic industry and for the extraction and refining of copper. It also is used as a reagent for the preparation of a wide variety of compounds.

Adiponitrile

Adiponitrile (hexanedinitrile, dicyanobutane, ADN), $NC(CH_2)_4CN$, is manufactured mainly for use as an intermediate for hexamethylenediamine (1,6-diaminohexane), which is a principal ingredient for nylon-6,6. BASF has announced the development of a process to make caprolactam from adiponitrile. Caprolactam is used to produce nylon-6.

Pure adiponitrile is a colorless liquid and has no distinctive odor. It is soluble in methanol, ethanol, chloroalkanes, and aromatics but has low solubility in carbon disulfide, ethyl ether, and aliphatic hydrocarbons. At 20°C, the solubility of adiponitrile in water is ca 8 wt %; the solubility increases to 35 wt % at 100°C.

Adiponitrile undergoes the typical nitrile reactions, e.g., hydrolysis to adipamide and adipic acid and alcoholysis to substituted amides and esters.

Adiponitrile is made commercially by several different processes utilizing different feedstocks. The reaction of adipic acid with ammonia in either liquid or vapor phase produces adipamide as an intermediate, which is subsequently dehydrated to adiponitrile. The most widely used catalysts are based on phosphorus-containing compounds. Vapor-phase processes involve the use of fixed catalyst beds; whereas, in liquid–gas processes, the catalyst is added to the feed. DuPont currently practices a butadiene-to-adiponitrile route based on direct addition of HCN to butadiene.

Uses. The principal use of adiponitrile is for hydrogenation to hexamethylene diamine leading to nylon-6,6. Adipoquanamine, prepared by the reaction of adiponitrile with dicyandiamide (cyanoguanidine), has typical liquid nitrile properties that suggest its use as an extractant for aromatic hydrocarbons.

α-Aminonitriles

α-Aminonitriles are compounds containing both cyano and amine substituents attached to the same carbon atom. They are versatile synthetic intermediates that are used to make amino acids, agrichemicals, chelants, radical initiators, and water-treatment chemicals. In some cases, aminonitriles produced as intermediates are not isolated, but immediately further reacted, for example by hydrolysis, as is the case in producing ethylenediaminetetraacetate (EDTA) or nitrilotriacetate (NTA). Isolated and commercially available aminonitriles include 2-amino-2-methylpropanenitrile (aminoisobutyronitrile, AN-64), 2-amino-2-methylbutanenitrile (AN-67), 2-amino-2,4-dimethylpentanenitrile (AN-52), and 1-aminocyclohexane carbonitrile (AN-88). The designations in parentheses arise from their identity as intermediates in the production of azo radical initiators.

In 1990, DuPont began practicing a one-step process in which a ketone is treated simultaneously with both HCN and ammonia at 40–60°C. This process (Fig. 1) is both faster and more selective than previous two-step processes.

Physical Properties. α-Aminonitriles are stable at modest temperatures (<70°C) in the absence of water; in the presence of water, they can degrade to their original constituents, i.e., ketone (aldehyde), ammonia and hydrogen cyanide if insufficient ammonia is present. The aminonitriles based on ketones are clear colorless liquids, but sometimes appear yellow to brown depending on the synthetic procedure and the amount of decomposition. They are soluble in polar organic solvents and in aromatic solvents.

Uses. α-Aminonitriles may be hydrolyzed to amino acids, such as is done in producing ethylenediaminetetracetate (EDTA) or nitrilotriacetate (NTA). In these cases, formaldehyde is utilized in place of a ketone in the synthesis. The principal use of the ketone-based aminonitriles is in the production of azobisnitrile radical initiators.

Azobisnitriles

Azobisnitriles are efficient sources of free radicals for vinyl polymerizations and chain reactions, e.g., chlorinations. See also **Initiators (Free-Radical)**; **Initiators (Anionic)**; and **Initiators (Cationic)**. These compounds decompose in a variety of solvents at nearly first-order rates to give free radicals with no evidence of induced chain decomposition. They can be used in bulk, solution, and suspension polymerizations; and because no oxygenated residues are produced, they are suitable for use in pigmented or dyed systems that may be susceptible to oxidative degradation.

The structures of several members of this class of compounds are shown below. They are crystalline solids that are produced by hypochlorite oxidation of α-aminonitriles.

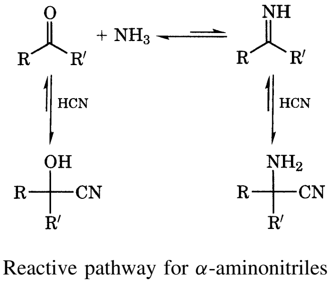

Fig. 1. Reactive pathway for α-aminonitriles synthesis

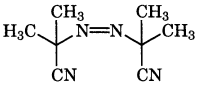
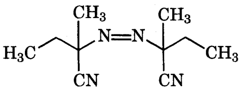
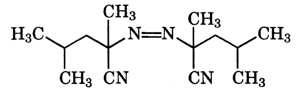


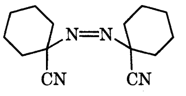
2,2′-Azobis(isobutyronitrile)



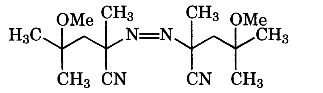
2,2′-Azobis(2-methylbutanenitrile)



2,2′-Azobis(2,4-dimethylpentanenitrile)



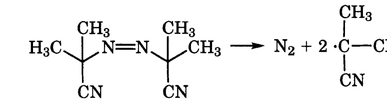
1,1′-Azobis(cyanocyclohexane)



2,2′-Azobis(4-methoxy-2,4-dimethylpentanenitrile)

These compounds are essentially insoluble in water, sparingly soluble in aliphatic hydrocarbons, and soluble in functional compounds and aromatic hydrocarbons.

In solution, the azobisnitriles decompose on heating to form two free radicals with the liberation of nitrogen (eq. 1):



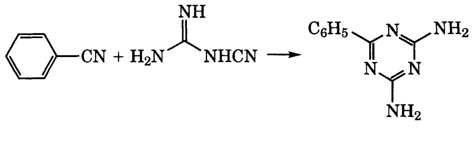
(1)

Uses. The azobisnitriles have been used for bulk, solution, emulsion, and suspension polymerization of all of the common vinyl monomers, including ethylene, styrene vinyl chloride, vinyl acetate, acylonitrile, and methyl methacrylate. The polymerizations of unsaturated polyesters and copolymerizations of vinyl compounds also have been initiated by these compounds.

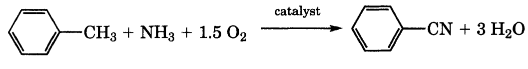
Benzonitrile

[CAS: 100-47-0]. Benzonitrile, C_6H_5CN, is a colorless liquid with a characteristic almondlike odor. It is miscible with acetone, benzene, chloroform, ethyl acetate, ethylene chloride, and other common organic solvents but is immiscible with water at ambient temperatures and soluble to ca 1 wt% at 100°C. It distills at atmospheric pressure without decomposition, but slowly discolors in the presence of light.

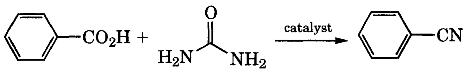
Like acetonitrile, benzonitrile is a powerful solvent for many inorganic and organic materials including some polymers. It can be converted to a large number and variety of derivatives by simple syntheses; e.g., by hydrolysis, it can be converted to either benzoic acid or benzamide. The most important reaction is with dicyandiamide to produce 2,4-diamino-6-phenyl-1,3,5-triazine (benzoguanamine):



Benzonitrile can be produced in high yield by the vapor-phase catalytic ammoxidation of toluene:



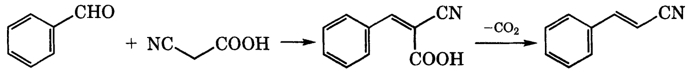
A more recent process involves the reaction of benzoic acid (or substituted benzoic acid) with urea at 220–240°C in the presence of a metallic catalyst.



Uses. The most important commercial use for benzonitrile is the synthesis of benzoguanamine, which is a derivative of melamine and is used in protective coatings and molding resins. See also **Amino Resins**; and **Cyanamides**.

Cyanoacetic Acid and Esters

Cyanoacetic acid, $CNCH_2COOH$, is a strong organic acid with a dissociation constant at 25°C of 3.36×10^3. It is prepared by the reaction of chloroacetic acid with sodium cyanide. It is hygroscopic and highly soluble in alcohols and diethyl ether but insoluble in both aromatic and aliphatic hydrocarbons. It undergoes typical nitrile and acid reactions but the presence of the nitrile and the carboxylic acid on the same carbon cause the hydrogens on C-2 to be readily replaced. The resulting malonic acid derivative decarboxylates to a substituted acrylonitrile:



cinnamonitrile

The methyl and ethyl esters of cyanoacetic acid are slightly soluble in water but are completely miscible in most common organic solvents including aromatic hydrocarbons. The esters, like the parent acid, are highly reactive, particularly in reactions involving the central carbon atom. They are prepared by esterification of cyanoacetic acid and are used principally as chemical intermediates.

Uses. Although cyanoacetic acid can be used in applications requiring strong organic acids, its principal use is in the preparation of malonic esters and other reagents used in the manufacture of pharmaceuticals. See also **Alkaloids**; and **Vitamin**.

Isophthalonitrile

Isophthalonitrile (1,3-dicyanobenzene, IPN), is a white solid which melts at 161°C and sublimes at 265°C. It is slightly soluble in water but readily dissolves in dimethylformamide, *N*-methylpyrrolidinone and hot aromatic solvents. IPN undergoes the reactions expected of an aromatic nitrile. It is prepared by vapor-phase ammoxidation of *meta*-xylene. Its principal use is as an intermediate to amines. As a reagent, IPN can be used to convert aromatic acids to nitriles in near quantitative yields.

2-Methylglutaronitrile

Methylglutaronitrile (2,3-dicyanobutane) MGN, is a by-product of DuPont's adiponitrile process.

Uses. Methylglutaronitrile is readily hydrogenated to give 2-methyl-1,5-pentanediamine (DYTEK A, MPMD), used as a comonomer in polyamide fibers and resins, as a curing agent for epoxy coatings, and as its isocyanate in specialty urethanes. A co-product of the DYTEK A process is 3-methylpiperidine, which can be used to produce vulcanization accelerators for rubber curing.

Pentenenitriles

Pentenenitriles are produced as intermediates and by-products in DuPont's adiponitrile process. 3-Pentenenitrile is the principal product isolated from the isomerization of 2-methyl-3-butenenitrile.

Uses. 3-Pentenenitrile (3PN) is used entirely by the manufacturers to make adiponitrile. *cis*-2-Pentenenitrile (2PN) can be cyclized catalytically at high temperature to produce pyridine, a solvent and agricultural chemical intermediate. 2PN is also used in the manufacture of pentachloropyridine, an intermediate in the insecticide Dursban, and 1,3-pentadiamine, which is used as a curing agent for epoxy coatings and as a chain modifier in polyurethanes.

Fatty Acid Nitriles

Fatty acid nitriles are produced as intermediates for a large variety of amines and amides. See also **Carboxylic Acids**. Fatty acid nitriles are produced from the corresponding acids by a catalytic reaction with ammonia in the liquid phase. They have little use other than as intermediates.

NITRO- AND NITROSO-COMPOUNDS. Nitro-compounds contain the nitro-group ($-NO_2$) attached directly to a carbon atom; nitroso-compounds contain the nitroso-group ($-NO$) similarly attached. A very important member of this group is nitrobenzene, which upon reduction yields a variety of products, important in the synthesis of drugs and dyes. See Table 1.

TABLE 1. REPRESENTATIVE NITRO- AND NITROSO COMPOUNDS

Compound	Formula	Melting point,°C	Boiling point,°C
REPRESENTATIVE NITRO COMPOUNDS			
Nitrobenzene	$C_6H_5 \cdot NO_2$	6	211

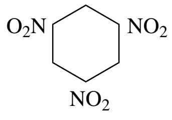
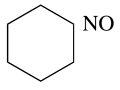
Trinitro-compound

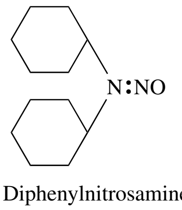


1,3,5-Trinitrobenzene

Nitroso-compounds



Nitrosobenzene



Diphenylnitrosamine

Under the proper conditions of concentration of HNO_3 and of temperature, benzene forms mainly nitrobenzene, nitrobenzene forms mainly 1,3-dinitrobenzene, and 1,3-dinitrobenzene, mainly 1,3,5-trinitrobenzene.

When nitrobenzene is treated (1) with zinc and calcium chloride or ammonium chloride solution, beta-phenylhydroxylamine, C_6H_5NHOH, is formed, and from this by treatment with chromic acid or ferric chloride nitrosobenzene is formed, (2) with tin or iron and HCl, aniline, $C_6H_5NH_2$, is formed and from this by treatment with nitrous acid followed by treatment with stannous chloride plus HCl phenylhydrazine, $C_6H_5NH \cdot NH_2$, is formed.

Mono- or poly-substituted nitro-compounds are changed in whole or in part to the corresponding amino-compounds by proper choice of reducing agent and temperature, e.g., in acid medium 1,3-dinitrobenzene yields 1,3-phenylenediamine, $C_6H_4(NH_2)_2$(1, 3), and with ammonium sulfide yields 3-nitroaniline (1)$H_2NC_6H_4NO_2$(3). When diphenylnitrosamine is reduced, 1,1-diphenylhydrazine, $(C_6H_5)_2N \cdot NH_2$, is formed.

NITROCELLULOSE. See **Cellulose**.

NITROGEN. [CAS: 7727-37-9]. Chemical element, symbol N, at. no. 7, at. wt. 14.0067, periodic table group 15, mp −209.86°C, bp −195.8°C, critical temperature −147.1°C, critical pressure 33.5 atmospheres, density 1.14 g/cm^3 (solid), 1.25057 g/L (0°C, 760 torr), 0.9675 (air = 1.0000). Solid nitrogen has a hexagonal crystal structure. Nitrogen at standard conditions is a colorless, odorless, tasteless gas. The gas is slightly soluble in H_2O (2.35 parts nitrogen in 100 parts H_2O at 0°C), the solubility decreasing with increasing temperature (1.55 parts nitrogen in 100 parts H_2O at 20°C). Nitrogen is slightly soluble in alcohol and is essentially insoluble in most other known liquids. There are two naturally occurring isotopes, ^{14}N and ^{15}N, with ^{14}N by far the most abundant (99.635%). Four radioactive isotopes have been identified, ^{12}N, ^{13}N, ^{16}N, and ^{17}N, all with extremely short half-lives measured in seconds or minutes. In terms of abundance in igneous rocks in the Earth's crust, nitrogen does not appear among the first 37 most abundant elements. In terms of abundance in seawater, nitrogen ranks 16th, with an estimated 2,300 tons of nitrogen per cubic mile of seawater. In terms of cosmic abundance, nitrogen ranks 7th. For comparison, assigning a value of 10,000 to silicon, the figure for nitrogen is 160,000 and that for hydrogen, estimated the most abundant, a figure of 3.5×10^8. Of dry air in the earth's atmosphere, disregarding pollutants, 78.09% is nitrogen by volume and 75.54% by weight. In the atmosphere, the nitrogen is mixed with oxygen, argon, the rare gases, CO_2, and H_2O vapor. Nitrogen was first identified as an element by Daniel Rutherford in 1772. Lavoisier further confirmed Rutherford's findings in 1776. Like oxygen, nitrogen is essential to practically all forms of life, making some of the compounds of this element extremely important as foods and fertilizers. Nitrogen serves the important function of diluent in the earth's atmosphere, controlling natural burning and respiration rates that otherwise would proceed much faster with higher concentrations of oxygen. Nitrogen is an important ingredient of numerous inorganic and organic compounds, including alkaloids, amides, amines, cyanides, cyanogens, diazo compounds, hydrazines, imides, nitrates, nitrides, nitrites, nitriles, oximes, purines, pyridines, and ureas. In terms of high-tonnage production, the nitrogen compound NH_3 (ammonia) ranks first with worldwide production exceeding 50 million tons annually.

First ionization potential 14.84 eV; second, 29.47 eV; third, 47.17 eV; fourth, 73.5 eV; fifth, 97.4 eV. Oxidation potentials $H_2N_2O_2 + 2H_2O \longrightarrow 2HNO_2 + 4H^+ + 4e^-$, −0.80 V; $N_2O_4 + 2H_2O \longrightarrow 2NO_3^- + 4H^+ + 2e^-$, −0.81 V; $HNO_2 + H_2O \longrightarrow NO_3^- + 3H^+ + 2e^-$, −0.94 V; $NO + 2H_2O \longrightarrow NO_3^- + 4H^+ + 3e^-$, −0.96 V; $NO + H_2O \longrightarrow HNO_2 + H^+ + e^-$, −0.99 V; $2NO + 2H_2O \longrightarrow N_2O_4 + 4H^+ + 4e^-$, −1.03 V; $2HNO_2 \longrightarrow N_2O_4 + 2H^+ + 2e^-$, −1.07 V. $N_2O + 3H_2O \longrightarrow 2HNO_2 + 4H^+ + 4e^-$, −1.29 V; $N_2O + H_2O \longrightarrow 2NO + 2H^+ + 2e^-$, −1.59 V; $N_2 + H_2O \longrightarrow N_2O + 2H^+ + 2e^-$, −1.77 V; $N_2O_4 + 4OH^- \longrightarrow 2NO_3^- + 2H_2O + 2e^-$, 0.85 V; $NO + 2OH^- \longrightarrow NO_2^- + H_2O + e^-$, 0.46 V; $N_2O_2^{2-} + 4OH^- \longrightarrow 2NO_2^- + 2H_2O + 4e^-$, 0.18 V; $NO_2^- + 2OH^- \longrightarrow NO_3^- + H_2O + 2e^-$, −0.01 V; $N_2O_2^{2-} \longrightarrow 2NO + 2e^-$ −0.10 V; $N_2O + 6OH^- \longrightarrow 2NO_2^- + 3H_2O + 4e^-$ −0.15 V; $N_2O + 2OH^- \longrightarrow 2NO + H_2O + 2e^-$ −0.76 V. $2NO_2^- \longrightarrow N_2O_4 + 2e^-$ −0.88 V.

Other physical properties of nitrogen are given under **Chemical Elements**

Industrial Nitrogen

Like many of the elements, the compounds of nitrogen by far exceed the use of elemental nitrogen (discounting its important role as diluent in the atmosphere). Industrially, nitrogen gas is produced as a by-product in the liquefaction of air to produce pure oxygen. For some applications, nitrogen provides an excellent inert atmosphere for electric furnace operations and for the gaseous insulation of transformers. An inert atmosphere is required where air must be excluded. Nitrogen is one of the three main gases used for such atmospheres, the other two being carbon monoxide and hydrogen. In providing an inert atmosphere, nitrogen reduces the velocities of reactions, lowers the partial pressure and reduces the flammability of any active gases that may be present. Since commercial nitrogen usually contains traces of oxygen, H_2O vapor, and CO_2, sufficient to cause some oxidation at high temperatures, methane may be added to make the gas fully inert.

Nitrogen gas also is required for nitriding certain alloy steels, but pure gas is not required. The nitrogen is provided by dissociating ammonia at the process temperatures ranging from 475–650°C. Metals treated in this manner are hardened by the formation of nitrides on their surface (casehardening). In cyaniding, iron-base alloys simultaneously absorb carbon and nitrogen by heating the metals in a cyanide salt. Again, the nitrogen is not required in initial gaseous form. See also **Nitriding**. Several powder metallurgy techniques also utilize dissociated NH_3 atmospheres.

Environmental Aspects of Nitrogen

The oxides of nitrogen are among the most critical of air pollutants—both in their effects and in their abatement. These aspects of nitrogen are discussed under **Pollution (Air)**

Chemistry and Compounds

Most of the high-tonnage nitrogen-bearing compounds are described elsewhere in this volume. See also **Ammonia**; **Ammonium Chloride**; **Ammonium Hydroxide**; **Ammonium Nitrate**; **Ammonium Phosphates**; **Ammonium Sulfate**; and **Fertilizer**.

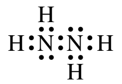
In the laboratory, nitrogen, mixed with argon, neon, krypton, and xenon, is obtained from the air by passing it over heated copper to remove the oxygen, or pure by fractional distillation of liquid air whereby the nitrogen distills off before the oxygen. Pure nitrogen may also be obtained by heating such compounds as ammonium nitrite and ammonium dichromate, and collecting the gas. Mixed with carbon monoxide in producer gas, nitrogen may be utilized without separation by first making methyl alcohol from carbon monoxide and hydrogen and then using hydrogen and nitrogen for ammonia. When nitrogen at low pressure is subjected to the silent electric discharge, activated nitrogen is produced. Activated nitrogen displays a golden yellow afterglow upon cessation of the current, increased by cooling and decreased by heating. This form of nitrogen is very active with phosphorus, with alkali metals (forming azides), with the vapor of zinc, mercury, cadmium, arsenic (forming nitrides), with many metallic chlorides (forming a green fluorescence), and with hydrocarbons (forming hydrocyanic acid and cyanides). The transformation of nitrogen to activated nitrogen is partial, and its return to ordinary nitrogen takes place rapidly, in about one minute.

The metal amides and imides are important in the nitrogen system. The amides of the active metals are produced by (1) reaction of the metal with NH_3, (2) reaction of the metal hydride with NH_3, (3) reaction of the metal nitride with ammonia, (4) reaction with another amide, as $KNH_2 + NaI \longrightarrow NaNH_2 + KI$ (in liquid NH_3). This last method is generally useful for the preparation of the heavy metal amides and imides from halides and binary halogenoids of the heavy metals. Cadmium amide, $Cd(NH_2)_2$ and lead imide, PbNH, for example, are readily prepared in this way. In some cases neither the amide nor the imide is stable, and the reaction proceeds to the nitride.

$$3\ HgBr_2 + 6\ KNH_2NH_3 liq.Hg_3N_2 + 6\ KBr + 4\ NH_3$$

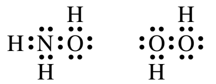
The metal amides and imides are very reactive with oxygen, and are often unstable or even explosive. Some nitrides (e.g., of silver, gold, and mercury) are explosive, but others are stable. The latter may be obtained, (1) by reaction with the metal with nitrogen or ammonia at higher temperatures, e.g., aluminum nitride and magnesium nitride, AlN and Mg_3N_2, (2) by deamination of the metal amide or azide on heating, e.g., Ba_3N_2. The great thermal stability of certain nitrides, e.g., those of boron, silicon and phosphorus, BN, Si_3N_4 and P_3N_5, is attributed to polymerization. Many of the transition metal nitrides are interstitial compounds and are hard and metal-like in their properties.

In the nitrogen system, hydrazine is analogous to hydrogen peroxide in the oxygen system, its structure being



It is readily oxidized, even undergoing auto-oxidation under many conditions, and it is a powerful reducing agent. Like hydrogen peroxide it readily disproportionates (e.g., with a platinum catalyst), giving nitrogen and NH_3. Its reactivity (and other properties) makes it, and its derivative, unsymmetrical dimethylhydrazine, important rocket fuels. It forms addition compounds with many substances, including a monohydrate with H_2O. Hydrazine ($pK_{B1} = 6.04$, $pK_{B2} = 14.88$) forms hydrazinium(1+) compounds, containing the $N_2H_5^+$ ion, analogous to ammonium, and hydrazinium(2+) compounds containing the $N_2H_6^{2+}$ ion.

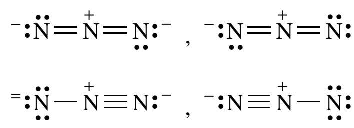
Hydroxylamine is related in its structure both to hydrazine (see formula above) and to hydrogen peroxide.



The chemical properties of hydroxylamine also suggest a compound intermediate between hydrazine and hydrogen peroxide. Its bond lengths are, N–, 1.46 Å, N–H, 1.01 Å, O–H, 0.96 Å, and its angles are H–O–N, 103°, H–N–O, 105°, and H–N–H, 107°. It is a base ($pK_B = 9.02$), forming salts containing the hydroxylammonium ion $HONH_3^+$.

Hydrazoic acid, HN_3, $pK_A = 4.72$, and most of its covalent compounds (including its heavy metal salts) are explosive. It is formed (1) in 90% yield by reaction of sodium amide with nitrous oxide, (2) by reaction of hydrazinium ion with nitrous acid, (3) by oxidation of hydrazinium salts, (4) by reaction of hydrazinium hydrate with nitrogen trichloride (in benzene solution). Hydrazoic acid forms metal azides with the corresponding hydroxides and carbonates. It reacts with HCl to give ammonium chloride and nitrogen, with H_2SO_4 to form hydrazinium acid sulfate, with benzene to form aniline, and it enters into a number of oxidation-reduction reactions.

The azides, except those of mercury(I), Hg(I), thallium(I), Tl(I), copper, Cu, silver, Ag, and lead, Pb, are readily prepared from hydrazoic acid and the oxide or carbonate of the metal, or by metathesis of the metal sulfate with barium azide. They are all thermally unstable, giving nitrogen and free metal or occasionally nitride. The azide ion appears to resonate between four structures:



These structures are in accord with a spacing of 1.15 Å and electronic charges of −0.83, 0.66, and 0.83 on the three nitrogen atoms.

N(I) Compounds. Hydration of nitrogen(I) oxide, N_2O to hyponitrous acid, $H_2N_2O_2$, is not possible. However, the latter decomposes (in three steps) to yield the former, which is thus its anhydride. Spectroscopic studies indicate a linear structure for N_2O, resonating between

However, heat capacity measurements give a higher entropy at low temperatures than spectroscopic studies do, which is explained by a partial randomness of the structure at low temperatures.

Hyponitrous acid ($pK_{A1} = 7.05$, $pK_{A2} = 11.0$) and its salts are obtained by: (1) reduction of sodium nitrite with (a) sodium amalgam, (b) by electrolysis, (c) by stannous or ferrous salts; (2) by reduction of alkyl nitrates; (3) by reduction of hydroxylamine by noble metal oxides; and (4) by reduction of sodium hydroxylamine monosulfonate in alkaline solution.

Explosive salts such as NaNO can be prepared by the reaction of NO and liquid ammonia solutions of alkali metals. The unstable free acid, HNO, is thought to be an intermediate in many redox reactions of nitrogen compounds.

Nitramide, NO_2NH_2, a weak acid ($pK_A = 6.59$), is relatively more stable than its isomer hyponitrous acid.

N(II) Compounds. Nitrogen(II) oxide is formed in many reductions of nitrous acid, but is best prepared pure by reduction with ferrous ions, Fe^{2+}, or iodide ions, I^- It undergoes many types of addition reactions, but its very slight tendency to dimerize and its low reactivity under ordinary conditions suggest that its odd electron lies in an antibonding orbital of very low energy; and the molecular orbital formulation is

$$NO[KK(z\sigma)^2(y\sigma^*)^2(x\sigma)^2(w\pi)^4(v\pi^*)]$$

The nitrosyl compounds can be readily classified on the basis of three modes of reaction of the NO molecule in accordance with the above formulation.

1. It can lose (or partly lose) the odd electron to form an ion of the formula

$$:N\equiv O:^+$$

This formula gives rise to ONF, ONCl and ONBr by direct reaction of NO and the halogen. These are covalent compounds. Such salts as $NOBF_4$, $NOPF_6$, $NOAuF_4$, $NOSO_3F$, and $NOHSO_4$, on the other hand, are ionic. These may be considered the salts of nitrous acid acting as a base, ONOH □ $NO^+ + OH^-$, $pK_B = 18.2$.

2. It can gain an electron to form a negative ion of the formula

$$N\equiv \ddot{O}:^-$$

Thus dry NO reacts with sodium in liquid ammonia to form sodium nitrosyl, NaNO (empirical formula).

3. It can share a pair of electrons to form a coordinate link, as it does in coordination compounds. In most of these, it appears to coordinate as the positive ion, by transfer of an electron to an acceptor metal, which is thereby reduced by 1 unit in oxidation state. This causes, in some cases, the need for placing a negative charge on the metal. To avoid this, Pauling assumed the presence of four bonding electrons, involving structures of the type

$$M=\overset{+}{N}=\ddot{O}:$$

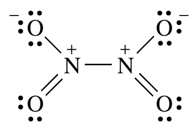
Nitrogen(III) Compounds. Nitrogen(II) oxide, NO, readily enters into equilibrium with NO_2 to form N_2O_3, nitrogen sesquioxide. The latter is unstable even at room temperature and consists of an equilibrium mixture of the three compounds. Its structure appears to be $O{=}N{-}NO_2$. If an equimolar mixture of NO and NO_2 is cooled and condensed, a blue liquid, bp 3.5°C, largely N_2O_3, is obtained. The latter readily combines with H_2O to form nitrous acid, HNO_2 ($pK_A = 3.29$). Nitrous acid is unstable, forming the equilibrium mixture, $3HNO_2$ □ $NO_3^- + 2NO + H_3O^+$, which in concentrated solution or on warming is largely displaced to the right ($K = 39.6$ at 30°C). Moreover, the NO undergoes further reactions, so that the actual system is complex. One of these reactions is: $NO + OH \longrightarrow NO^+ + OH^-$ □ $NO \cdot OH \rightleftharpoons HNO_2$.

The existence of NO^+ and NO^- helps to explain the kinetics of nitrous acid as an oxidizing agent. It oxidizes I^-, Sn^{2+}, Fe^{2+}, Ti^{3+}, $S_2O_3^{2-}$, SO_2, and H_2S. It reacts with NH_3, urea, sulfonates and some other nitrogen compounds to produce nitrogen. With aromatic amines in the cold, it gives diazo compounds, while with secondary amines it gives nitroso compounds. Nitrous acid also functions as a reducing agent, as in the reactions with permanganate and hydrogen peroxide, in which nitrate ion is formed.

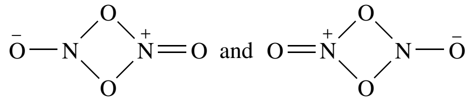
The nitrites vary widely in solubility, those of the alkalies and alkaline earths being very soluble, while those of the heavy metals are only slightly so. Moreover, the latter are relatively unstable, some decomposing at room temperature. The nitrites, like nitrous acid, function either as oxidizing or reducing agents. X-ray and spectroscopic studies give a triangular structure for the nitrite ion, with the N–O bond length 1.13 Å and the O–N–O angle 120–130°. Values of 1.23 Å and 116° have also been reported. Complex ions containing the NO_2 group may be either nitrito complexes (e.g., $Co(NH_3)ONO^{2+}$) or nitro complexes (e.g., $Co(NH_3)NO_2^{2+}$). The former of these two examples readily isomerizes to the latter.

Nitrosyl fluoride, NOF, and nitrosyl chloride, NOCl, are quite stable, but the bromide decomposes at room temperature. They are prepared by direct union of NO and the halogen, among other methods. Three trihalides, NF_3, NCl_3, and NI_3, are known. The first is a colorless stable gas; NCl_3 is a yellow liquid and NI_3, a brown solid; both are explosive. The contrast in stability is attributed to the large amount of ionic resonance energy of the N–F bond, which gives NF_3 a negative heat of formation.

Nitrogen(IV) Compounds. Nitrogen dioxide, NO_2, readily associates to form the tetroxide, N_2O_4, so that at ordinary temperatures and pressures both forms are present in equilibrium. Since nitrogen dioxide has an unpaired electron, it is paramagnetic and colored (red). N_2O_4 is diamagnetic and colorless. As with NO, the odd electron is in an antibonding orbital but of higher energy so that NO_2 is more reactive and more readily undergoes dimerization. The N–O bond length is 1.20 Å and the angle is 132° (electron diffraction). The structure of N_2O_4 is, on the basis of spectral and entropy considerations,



This formula is at variance with Pauling's stability argument, but is supported by Ingold's evidence (Nature, **159**, 743, 1947). Longuet–Higgins has proposed the structures

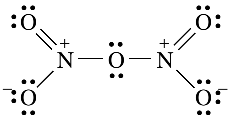


Nitrogen dioxide molecules react with NO to form N_2O_3, in an equilibrium mixture. The equilibrium mixture of NO_2 and N_2O_4 also reacts with water in a series of reactions

$$2\,NO_2 + H_2O \rightleftharpoons H^+ + NO_3^- + HNO_2$$
$$3\,HNO_2 \rightleftharpoons H^+ + NO_3^- + NO + H_2O$$

In warm solution, at high acidity, the second reaction is very rapid. In basic solutions the simple disproportionation $N_2O_4 + 2OH^- \longrightarrow NO_2^- + H_2O$ takes place.

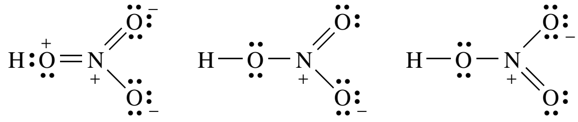
Nitrogen(V) Compounds. Nitrogen(V) oxide, N_2O_5, the anhydride of nitric acid, is a white solid subliming at 32.4°C and 760 mm. It hydrates readily to HNO_3, is a strong oxidizing agent, and decomposes at 20°C slowly into NO_2 and O_2. Its structure in the gas state consists of the molecules



However, x-ray, Raman, and infrared spectra show the crystalline solid to consist of NO_2^+ and NO_3^- ions.

Pure nitric acid, HNO_3, is a colorless liquid boiling with decomposition at 86°C and 760 torr. Upon continued heating it decomposes into NO_2, O_2 and H_2O. It is a fairly strong acid ($K_A = 22$), showing dissociation in concentrated solutions, and the presence of nitryl cation, NO_2^+ (nitronium ion). Solutions of HNO_3 in H_2SO_4 owe many of their properties to ions such as NO_2^+ and NO^+, as well, of course, as to HSO_4^- and oxonium ions.

The properties of HNO_3 are in accordance with resonance between the three electronic structures:



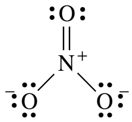
in which the last formula contributes a relatively small proportion to the overall structure. The two N–O bond lengths are 1.22 Å, and N–O–H bond lengths 1.41 Å and 0.96 Å. The N–O–H angle is 90° and the O–N–O angle 130°.

The reactions of nitric acid are of three types: (a) acid-base reactions which are typical of a strong acid; (b) oxidation reactions, such as those with metals and organic materials, the latter often involving carbonization; (c) substitution reactions such as the replacement of $-H$ by $-NO_2$ in aromatic hydrocarbons, to form nitro compounds, or of hydroxyl hydrogen by $-NO_2$ to produce esters of HNO_3.

These esters of nitric acid form one of the two groups of nitrates, the covalent group, which are also exemplified by nitryl hypofluorite and

hypochlorite ($FONO_2$ and $ClONO_2$), often called fluorine and chlorine nitrate. Most nitrates, however, are ionic, e.g., salts of HNO_3. All metal nitrate are soluble in H_2O. Anhydrous metal nitrates, such as $Cu(NO_3)_2$. $Ti(NO_3)_4$, $VO(NO_3)_3$, $CrO_2(NO_3)_2$, $Si(NO_3)_4$, can be made by the action of liquid N_2O_4 on the metal (e.g., Cu) or of $ClONO_2$ on the corresponding chloride (e.g., the other examples given above).

The nitrate ion is considered to resonate between three equivalent structures of the form:



Two nitryl halides, NO_2F and NO_2Cl, are known, as well as nitryl salts, such as NO_2AsF_6, NO_2SbF_6, $(NO_2)_2SiF_6$, NO_2ClO_4, etc. Nitrogen also forms higher oxides, such as NO_3, and possibly NO_4, under action of the electric discharge.

Nitrate Losses from Disturbed Forest Ecosystems

Nutrient losses occur following a forest harvest or other disturbance, whether natural or anthropogenic. Studies have shown a variety of patterns of such losses. Vitousek et al. (1979) report on a systematic examination of nitrogen cycling in disturbed forest ecosystems and show that at least 8 processes, operating in 3 stages in the nitrogen cycle, can delay or prevent solution losses of nitrate from disturbed forests. The study involved 19 forest sites in the United States, including Pack Forest, Findley Lake, and Cascade Head in the northwest; Tesuque Watersheds in the southwest; Lake Monroe in southern Indiana; Coweeta in southwestern North Carolina; and Harvard Forest, Mount Mossilauke, and Cape Cod in the northeastern United States.

The 3 stages and 8 operative processes identified are:

Stage 1. Processes preventing or delaying ammonium accumulation.

(a) Nitrogen immobilization
(b) Ammonium fixation
(c) Ammonia volatilization
(d) Plant nitrogen uptake

Stage 2. Processes preventing or delaying nitrate accumulation.

(e) Lag in nitrification
(f) Denitrification to: $-N_2$, N_2O, or NO_x, $-NH_4$

Stage 3. Processes preventing or delaying nitrate mobility.

(g) Lack of water
(h) Nitrate sorption
(i) Denitrification at depth

The researchers stress that the net effect of all of these processes, except uptake by regrowing vegetation, is insufficient to prevent or delay losses from relatively fertile sites and thus such sites have the potential for very high nitrate losses following disturbance.

Nitrogen Fixation

A positive balance of usable nitrogen on earth depends upon nitrogen fixation which is the process by which atmospheric nitrogen, N_2, is converted either by biological or chemical means to a form of nitrogen, such as ammonia, NH_3, that can be used by plants and other biological agents. Insofar as the total amount of N_2 fixed, the biological processes for converting from N_2 to NH_3 are the most significant. In biological nitrogen fixation, microorganisms, either free-living or in symbiosis with plants (mainly in root nodules), reduce N_2 to NH_3 at atmospheric pressure and within the temperature range of 20–37°C. This natural process is to be contrasted with industrial chemical conversion processes, which may require up to 300 atmospheres of pressure and a reaction temperature range of 200–300°C.

Biological Nitrogen Fixation. The occurrence and importance to soil fertility of biological nitrogen fixation have been known since the early 1800s. The first major finding did not occur until 1960, however, when it was shown that cell-free extracts of the anaerobic bacterium *Clostridium pasteurianum* could be made to fix nitrogen if molecular oxygen, O_2, were rigorously excluded—and also if pyruvic acid, a source of energy and electrons, was supplied. This finding demonstrated that studies no longer were restricted to whole cells, as previously indicated, but that it should be possible to isolate and chemically identify the components of the nitrogen-fixing system.

The first demonstrable product of cell-free N_2 fixation is NH_3, as had been strongly suggested by previous whole-cell studies. Since the reduction of N_2 to $2NH_3$ requires six electrons and since most electron transfer systems known in biochemical pathways involve either a one-or a two-electron transfer, it could be expected that either six one-electron or three two-electron transfer steps would be involved in nitrogen fixation. This would also suggest the existence of nitrogen compounds of valence states (reduction states) intermediate between N_2 and NH_3. However, no such intermediates have been found even in systems using cell-free extracts.

Because of failure to detect intermediates, attention was focused on the mechanism in extracts of *Clostridium pasteurianum* through which electrons were transferred from pyruvic acid to the nitrogen-fixing system. These investigations led to the discovery and isolation of the new electron carrier ferredoxin (Fd) which functioned by accepting electrons released during pyruvate oxidation by enzymes present in the clostridial extracts. The electrons from reduced Fd were transferred to a variety of different acceptors as directed by the cell. For example, some of the electrons from reduced Fd were transferred to hydrogenase, an enzyme which combined the electrons with protons (H^+) to produce molecular hydrogen, H_2, a major by-product of this anaerobe. Other electrons from reduced Fd were transferred via a flavoprotein carrier to nicotinamide adenine dinucleotide phosphate ($NADP^+$) to yield NADPH, a reduced electron carrier shown to be important in the metabolism of all biological agents. It was also found that electrons from Fd were required for nitrogen fixation when pyruvate was present as supporting substrate.

A major finding was that H_2, through hydrogenase, would act as an electron source for reducing ferredoxin. Thus, in these extracts, H_2 could be used to reduce $NADP^+$ to NADPH and NO_{2^-} to NH_3, and Fd was necessary as an intermediary electron carrier. Since Fd is required for pyruvate-supported N_2 fixation, it may be expected that H_2 would support nitrogen fixation, since reduced Fd is readily produced from H_2 in these extracts. Molecular H_2 alone, however, did no support N_2 fixation. This suggested either that a component other than reduced Fd was required, or that H_2, although capable of reducing Fd, was inhibitory to N_2 fixation as prior whole-cell studies had indicated. If an additional component were required, it appeared that it was produced from pyruvic acid, since pyruvic acid supported active N_2 fixation.

Several unsuccessful attempts were made to obtain N_2 fixation in extracts to which H_2, N_2, and one of the other products of pyruvate metabolism, ATP, were added. Active N_2 fixation did occur, however, when another product of pyruvate metabolism, acetyl phosphate, was added in addition to H_2 and N_2. When compounds such as ADP were removed from cell extracts by dialysis, no N_2 fixation occurred unless ADP was added together with phosphate, H_2, and N_2. Acetyl phosphate then was acting as a source of ATP. The reason ATP did not work directly was that a continuous supply of ATP was required, and a high concentration of ATP, if added directly to a cell-free extract, was highly inhibitory to N_2 fixation. In whole cells that are fixing N_2, a continuous supply of ATP is made available during sugar metabolism.

Genetic Manipulation. High on the list of many researcher's agendas for projects using the practical application of recombinant DNA research has been the possible development of a living organism that will produce ammonia—in an effort to lessen dependence upon costly and highly energy-consuming synthetic ammonia fertilizers. However, at symposia held on this topic, these achievements are considered by most researchers as quite long-range. There are fundamental problems difficult to overcome, including: (1) the possibility that increasing biological nitrogen fixation, for which the plant furnishes the energy, can cause a net decrease in crop yields by depriving the plant of nitrogen for the production of certain critical growth elements; and (2) the very rapid-acting inactivation by oxygen of nitrogen-fixation mechanisms. Cloning techniques may be a path toward introducing nitrogen-fixation genes into certain bacteria. One objective is that of developing new forms of bacteria that will enter into symbiotic relationships with crop plants, such as corn (maize) and wheat, that do not possess their own nitrogen fixation symbionts.

In addition to recombinant DNA and molecular cloning techniques, some scientists have combined their research with more conventional genetic techniques. An *E. coli* plasmid capable of carrying nitrogen-fixation genes of *K. pneumoniae* has been developed. Some researchers also believe that nitrogen-fixation genes may be introduced directly into plant cells to result in a plant that requires no nitrogen fertilizer.

In research activities such as these, much knowledge has been gained concerning the energy needs for biological nitrogen fixation. More energy is used than originally contemplated; for example, 20 moles of adenosine triphosphate (ATP) are required to fix one mole of nitrogen. This contributes largely to the first problem mentioned earlier, namely, the great amount of energy required for the plant to fix its own nitrogen, possibly leading to yield reduction.

The well-known nitrogen fixation by rhizobia depends on photosynthesis by the plant. Although the method is essentially impractical, photosynthesis can be increased by blanketing the plant with an atmosphere enriched in carbon dioxide. When this is done in the laboratory, increased legume yields are reported. Some investigators postulate that this effect is the result of a reduction photorespiration, a rather wasteful process in which carbon dioxide gained through photosynthesis is diverted into a series of less productive pathways in the plant. Investigators have also found that 30% of the energy used by the nitrogenase of most rhizobial species goes to producing hydrogen rather than ammonia. Research has also shown that the organisms that perform the nitrogen fixation function in plants are indeed quite diverse in themselves. Thus, new combinations of plants and organisms may increase efficiency in some cases.

As pointed out by Evans-Barber (1977), nitrogen is fixed by a variety of microorganisms in addition to those associated with legumes. Some of these include bacteria located in soils, in decaying wood, and on the surfaces of plant roots. They also include free-living blue-green algae, with fungi, ferns, mosses, liverworts, and higher plants (Hardy-Havelka, 1975). Reviews of numerous nitrogen-fixing organisms are given by Silvester (1976), Dalton (1974), Bond (1974), and Stewart (1974).

Role of Molybdenum in Nitrogen Fixation. Traditionally, molybdenum has been considered a key to the reduction of molecular nitrogen to ammonia by soil- and water-dwelling microorganisms. The metal is believed to be a part of the catalytically active site of nitrogenase, which is the enzyme that accomplishes the reduction. As early as 1980, researchers (North Carolina State University) suggested that the bacterium *Azobacter vinelandii* may have an alternative system for nitrogen fixation, a mechanism that may not require molybdenum. The proposal was regarded with some skepticism until the findings by researchers (Agriculture and Food Research Council Unit of Nitrogen Fixation, University of Sussex, England) in 1985 that confirmed the fact that *A. vinelandii* does have a second fixation system. Mutants of *A. vinelandii* were studied. Genes coding for the nitrogenase proteins were specifically deleted or inactivated. It was found that deletion of all three nitrogenase structural genes did not interfere with the fixation process. However, the process was effective only when molybdenum was not present. It was also found that the “wild” type of bacterium must have Mo in order to reduce nitrogen. Thus, it appears that the alternative mechanism is activated only when the system is subjected to molybdenum starvation. It has been suggested that the alternative system represents an adaptation to molybdenum-poor soils. The extension of these findings to other nitrogen-fixing microorganisms remains to be accomplished. Some further details pertaining to the Sussex investigation are given by Marx (1985).

Madigan (1979) and associates found that photosynthetic purple bacteria can grow with dinitrogen gas as the only source of nitrogen under anaerobic conditions, with light as the energy source. They also found that *Rhodopseudomonas capsula* can fix nitrogen in darkness with alternative energy conversion systems.

Health and Safety Factors

Gaseous nitrogen is nontoxic and nonflammable, but does not support life. Nitrogen should be stored and used only in well-ventilated areas. Special care must be taken entering an enclosed area, which may be enriched in nitrogen.

Liquid nitrogen and its vapor are extremely cold and can rapidly freeze human tissue. Liquid nitrogen spills should be flushed with water to accelerate evaporation. When exposed to liquid nitrogen, carbon steel, rubber, and plastic become embrittled and may fracture under stress. Copper, brass, bronze, Monel, aluminum, and 300 series austenitic stainless steels remain ductile and are acceptable for cryogenic service. Liquid nitrogen in poorly insulated containers can concentrate and condense atmospheric oxygen on the exterior surfaces, which may cause a serious fire hazard. Storage vessels or handling equipment should be provided with multiple pressure relief devices to prevent the buildup of high pressure. A pressure relief valve for primary protection and a frangible disk for secondary protection are commonly provided for on commercial liquid storage vessels.

NITROGEN FIXATION. See **Nitrogen**.

NITROGEN GROUP (The). The elements of group 15 of the periodic classification sometimes are referred to as the Nitrogen Group. In order of increasing atomic number, they are nitrogen, phosphorus, arsenic, antimony, and bismuth. The elements of this group are characterized by the presence of five electrons in an outer shell. The similarities of chemical behavior among the elements of this group are less striking than hold for some of the other groups, e.g., the close parallels of the alkali metals or alkaline earths. Although all of the elements of this group have valences in addition to 5+, all do have the 5+ valence in common. Unlike the

alkali metals or alkaline earths, for example, the elements of the nitrogen group are not so similar chemically that they comprise a separate group in classical qualitative chemical analysis separations. Three of the five, however, antimony, arsenic, and bismuth are members of the second group in terms of qualitative chemical analysis.

NITROGLYCERIN. See **Explosives**.

NOBEL, ALFRED B. (1833–1896). Nobel was a Swedish industrialist and European munitions maker. He was born in Stockholm in 1833. Most of his early education was from tutors and what he learned as he traveled during his teenage years through much of North America and Europe. He learned to speak several languages fluently and studied mechanical engineering.

After his travels, he joined his father's business and worked developing mines, torpedoes, explosives, and other war materials for the Russian czar. The Nobel factory was financially successful until the end of the Crimean War when it fell into bankruptcy. Alfred then went into business with his brother manufacturing drilling tools for oilfields.

In the 1860's Alfred revolutionized the explosives industry by developing the Nobel detonator, a new fuse for nitroglycerin followed by a safe way to handle nitroglycerin by using an organic packing material to reduce its volatility and producing dynamite. In the late 1880's, Nobel produced ballistite, a smokeless powder.

Nobel's inventions brought him a monetary fortune as he controlled most of the explosive manufacturing factories throughout the world. He was, however, disillusioned that his inventions had mostly applications for war. Nobel personally desired world peace. Throughout his life, he had acted in a humanitarian manner. In his will, Nobel directed that the great majority of his estate be used for the purpose of giving yearly prizes to persons whose personal efforts made outstanding contributions to the advancement of physics, chemistry, medicine and physiology, literature, and world peace. The first Nobel Prizes were awarded in 1901 to Wilhelm K. Roentgen (discovery of X-rays in 1895), J.H. van't Hoff (chemical thermodynamics and osmotic pressure), and E.A. von Behring (diphtheria antitoxin). See also **Nobel Prizes**.

NOBELIUM. [CAS: 10028-14-5]. Synthetic radioactive chemical element, symbol No, at. no. 102, at. wt. 254 (mass number of ^{254}No), radioactive metal of the Actinide series, also one of the Transuranium elements. Nobelium has valences of 2^+ and 3^+. In 1957, a group of American, English, and Swedish scientists bombarded a target of several curium isotopes (largely ^{244}Cm) with a beam of ^{13}C ions from the cyclotron at the Nobel Institute for Physics. They obtained a few alpha particles of 8.5 MeV energy and half-life of 10 minutes. This was considered to indicate the presence of element 102 with a probable mass number of 251 or 253. At that time, the element was named nobelium with assignment of the symbol, No. Further experiments at the University of California, however, failed to confirm this discovery. In April 1958, Ghiorso, Sikkeland, Walton, and Seaborg, working with the heavy ion linear accelerator (HILAC) at Berkeley, showed the isotope 102^{254} to be a product of the bombardment of ^{246}Cm with ^{12}C ions. Confirming experiments at Berkeley in 1966 showed the existence of ^{254}No with a 55-second half-life; ^{252}No with a 2.3 second half-life; and ^{257}No with a 23-second half-life. Four other isotopes are now recognized, including ^{255}No with a half-life of 3 minutes.

In 1973, scientists at Oak Ridge National Laboratory and Lawrence Berkeley Laboratory, produced a relatively long-lived isotope of nobelium through the bombardment of ^{248}Cm with ^{18}O ions. A total half-title of 58 ± 5 minutes was computed from the combined data of both laboratories. See also **Chemical Elements**

NOBEL PRIZES. In 1895, the will of Alfred Bernhard Nobel, a successful Swedish industrialist and European munitions maker, directed that the great majority of his estate be invested for the purpose of yielding annual prize money to be awarded to persons who, as the result of their personal efforts, made outstanding contributions to the advancement of science, literature, and peace. Initially, the awards were confined to five domains—Physics, Chemistry, Physiology or Medicine, Literature (of an idealistic tendency), and Peace (to promote the fraternity of nations and the abolition or diminution of standing armies and the formation and increase of peace congresses). In later years, the governors of the fund added Mathematics as a qualifying discipline and, in 1968, a Nobel Prize for the Economic Sciences was established. Although a prize for each of the foregoing categories is awarded each year, it is not mandatory that an award be made for each category every year, a factor determined by the governors of the fund. The will became effective when Nobel died on December 10, 1886, but the first prizes were not awarded until 1901 because of the need for legal clarification of Nobel's wishes as demanded by family members who also were mentioned in the will.

In studying the will, attorneys recognized the possible requirement for splitting a given award among two or even three individuals, but with a maximum of three persons per award. Nobel also mentioned certain criteria for selection of award recipients in each field. In connection with the prize for Physics, Nobel mentioned "discovery" or "invention," whereas the words "discovery" or "improvement" were stipulated concerning the prize for Chemistry. In terms of the prize for Physiology and Medicine, the key word was "discovery." These were guiding factors for application by the governors of the fund, especially during the early years.

If adjusted for inflation over the years, the original fund of 27,716,243 Swedish kroners ($7,427,953) was quite significant, especially when allowing for capital gains through investments realized over subsequent years. Money available for the annual prizes is essentially determined by the annual capital generated by the fund, but with the stipulation that at least 10% of that gain be reinvested each year. It is interesting to note that the honor associated with the prize is never split—that is, a Nobel Laureate is so designated even though a prize may be shared by two or three persons. The original will specified that the Royal Academy of Science (Sweden) select winners in Physics and Chemistry, that the Karolinska Institute of Medicine (Stockholm) make the selections in Physiology and Medicine, and that the Swedish Academy (of Letters) select winners in Literature. A committee of the Norwegian Parliament was specified to select winners of the Peace prize, noting "no consideration whatever be paid to the nationality of the candidates."

Over the years, with the addition of new prize categories, the governors of the Nobel Foundation necessarily have amended certain procedures. The Foundation is governed by a five-person board of control made up of one appointment by the King of Sweden and one each as appointed by the aforementioned organizations (now referred to as Nobel Institutes). Members of the selection board are appointed for a period of $4\frac{1}{2}$ years. The science awards are presented on December 10 (anniversary of Nobel's death) of each year at the Stockholm Concert Hall, with personal felicitation of the King of Sweden. The Peace prize is presented in a formal ceremony in Oslo.

The first Nobel prizes were awarded in 1901 to Wilhelm K. Roentgen (discovery of X-rays in 1895), J.H. van't Hoff (chemical thermodynamics and osmotic pressure), and E.A. von Behring (diphtheria antitoxin). Listings of scores of Nobel prizes awarded over a century of progress can be found

in a number of references, such as "The Information Please Almanac," 45th Edition, 701–709, Houghton Mifflin Company, Boston, Massachusetts. Specific 1992 winners are described in "U.S. Researchers Gather a Bumper Crop of Laurels," Science, 542 (October 23, 1992). An excellent review of the first half-century of the Nobel Foundation is given in an article by George W. Gray, "The Nobel Prizes," *Sci Amer.*, 1 (September 1949).

Although a chronological listing of Nobel prizes in the sciences provides a good source of tracing the progress of science over the years, not all major discoveries and inventions have been so honored. There are several outstanding scientists who have not been included. Traditionally, Nobel prizes are given for achievements that date back a few to several years rather than for discoveries of the immediate past.

NOMENCLATURE. Chemical nomenclature embraces several subcategories; names for chemical elements and compounds; names for classes of compounds and substances, such as mixtures and composites; names for particles, processes and transformations, properties, effects, units of measurements, techniques, instruments and apparatus, and even for theories and concepts. Only the first three are considered to be the heart of chemical nomenclature. The largest part of the subject is the nomenclature of organic compounds, simply because there are so many of them, and of such diverse nature. Concern with chemical nomenclature has grown on a broad international scale as the importance of consistent, uniform nomenclature is increasingly recognized. Various committees, both national and international, are working toward a consistent, systematic nomenclature. Among the areas in which nomenclature plays a key role are patent law, trade and customs regulations, identification of controlled substances, pharmaceutical and health information, and studies of the environment and pollution.

In the United States, the Committee on Nomenclature of the American Chemical Society is the clearinghouse for nomenclature recommendations and adoptions, aided by various divisional nomenclature committees of the Society. Close liaison is maintained with the various nomenclature bodies of the International Union of Pure and Applied Chemistry. Progress is being made not only in improved nomenclature, but also in the extension of nomenclature recommendations to newly developing areas of chemistry.

Important as names are, they cannot serve all purposes. There are other, complementary means of identifying chemical compounds, e.g., structural formulas, notation systems, and registry numbers. None of these are nomenclature, however.

Although symbols are not a part of nomenclature, the two are closely related, and the former have played an extremely important role in chemistry. Because of the difficulty of establishing priority of discovery for most of the elements of atomic number above 100, and because of the need to refer to hypothetical elements with higher atomic numbers, IUPAC has developed interim systematic symbols and names for such elements.

Inorganic Nomenclature

Perhaps no subject in chemistry has undergone less change over the twentieth century than inorganic nomenclature. This longevity attests to the fundamental soundness of the original proposals of Guyton de Morveau that established it, but it also suggests why inconsistencies and confusions have remained as well, which have continued to disconcert chemists. The development of inorganic nomenclature has again accelerated, however, and the inconsistencies are being eliminated.

The System of Guyton de Morveau, Lavoisier, and Co-Workers. The first attempt toward a convenient nomenclature belongs to Guyton de Morveau. His pioneer work led to publication in 1787 of *Methode de Nomenclature Chimique*, written in collaboration with Lavoisier, Berthollet, and Fourcroy, which proved to be a landmark in the development of chemistry.

The fundamental principle of the new nomenclature was that the name of a compound should exhibit the elements involved and their relative proportions, if known. The combinations of oxygen with other elements played a dominant role. Thus, the product of the union of a simple nonmetallic substance with oxygen was called an acid, whereas that of the union of a metal with oxygen was called an oxide. The union of an acid and an oxide produced salt. The acids or oxides were given names in which the generic part was the word "acid" or "oxide" and the specific part was an adjective derived from the name of the other element. The same principle supplied names for sulfides and phosphides.

The names adopted for salts consisted of a generic part derived from the acid and a specific part from the metallic base: The names for salts of acids containing an element in different degrees of oxidation were given different terminations.

Berzelius divided the elements into metalloids (nonmetals) and metals according to their electrochemical character, and the compounds of oxygen with positive elements (metals) into suboxides, oxides and peroxides. His division of the acids according to degree of oxidation has been little altered. He introduced the terms anhydride and amphoteric and designated the chlorides in a manner similar to that used for the oxides.

Established Practice in the English Language. The nearly literal translation of the French terms in English, Russian and other languages resulted in the system whose use has become standard practice in English-speaking as well as other countries. The system has been molded by the fact that elemental composition and valence (or oxidation number) are the principal variables for most inorganic compounds other than the most complex, whereas connectivity and the possibility for isomers have been of little concern.

Modified Forms in Common Use. There are numerous situations in which the foregoing system does not meet all requirements. In the formation of binary compounds, several elements exhibit more than two states of oxidation. One method, recommended by the IUPAC, of handling these situations is the use of prefixes derived from Greek to indicate stoichiometric composition, e.g., titanium dichloride, $TiCl_2$; and dinitrogen oxide (nitrous oxide) N_2O. Other accepted methods of indicating proportions of constituents are the Stock system (oxidation number) and the Ewens-Bassett (charge number) system.

Some elements form acids with more than four oxidation states, requiring other combinations of prefixes and suffixes: $H_4P_2O_6$, intermediate between H_3PO_3 and H_3PO_4, is known as hypophosphoric acid. Here again, the oxidation-number and charge-number systems offer advantages. Ortho-, meta-, and pyro- prefixes or numerical prefixes to denote stages of hydroxylation of acids also find use. In many instances, special names have been created to deal with unusual situations.

Systems of Compounds. The nomenclature system of Guyton de Morveau and co-workers was designed specifically for oxygen compounds. As early as 1826, it became evident that the halogens could play much the same role in many other compounds as oxygen does in the familiar oxygen salts. By 1840, Hare was writing of chloro acids and chloro bases, and recognized classes of salts: oxy-, sulfo- (now called thio-), seleni-, telluri-, chloro-, fluoro-, cyano-, etc. Remsen was a proponent of this system of nomenclature, but it received its fullest treatment from Franklin in connection with his concept of systems of compounds.

The analogies are shown by the following reactions:

$$K_2O + B_2O_3 \longrightarrow K_2O \cdot B_2O_3 \text{ or } KBO_2$$

$$K_2S + B_2S_3 \longrightarrow K_2S \cdot B_2S_3 \text{ or } 2\ KBS_2$$

$$KF + BF_3 \longrightarrow KF \cdot BF_3 \text{ or } KBF_4$$

$$K_3N + BN \longrightarrow K_3N \cdot BN \text{ or } K_3BN_2$$

The products resulting from such reactions should, therefore, have analogous names. If KBO_2 is a borate, then KBS_2 is a thioborate, and KBF_4 is a fluoroborate. Similarly, the replacement of an oxygen atom by a sulfur atom or two fluorine atoms is understandable. However, the relationship of K_3BN_2 is less obvious, until one considers the dehydration and deammoniation schemes:

$$B(OH)_3 \xrightarrow{-H_2O} OBOH$$

$$B(NH_2)_3 \xrightarrow{-NH_3} HNBNH_2$$

His scheme of nomenclature for nitrogen compounds, and the names thio-, chloro-, etc, did become widespread, especially for sulfur and halogen compounds.

Although the foregoing pattern of nomenclature is useful, it does lead to some difficulties. Many quaternary compounds contain oxygen and another electronegative element. In the series M_2CO_3, M_2CO_2S, M_2COS_2, and

M_2CS_3, the names are carbonates, (mono)thiocarbonates, dithiocarbonates, and trithiocarbonates, respectively. However, in practice both the prefixes mon- and tri- are often omitted, and its is uncertain whether the omission signifies the mono- or the completely substituted compound. The situation is somewhat more complicated when oxygen and fluorine are present in the same compound, because one is bivalent and the other univalent, and the coordination number toward fluorine is different from that toward oxygen: H_3PO_4, H_2PO_3F, HPO_2F_2, and HPF_6. Furthermore, investigators have not always been consistent in choosing the same reference state for the names of the oxygen salts and the halogen salts.

Coordination Compounds. The approach of Werner to the problem of naming ternary and higher order compounds is based on an entirely different point of view. By considering all such substances as complex or coordination compounds, he succeeded in making a wide variety of them according to a single general pattern. To designate the oxidation state of the element serving as the center of coordination, Werner chose the characteristic endings suggested by Brauner, but these have been totally superseded by the oxidation-number and charge-number systems.

The Stock Oxidation-Number System. Stock sought to correct many nomenclature difficulties by introducing Roman numerals in parentheses to indicate the state(s) of oxidation.

The oxidation-number system is easily extended to include other coordination compounds. Even substances represented by the formulas $Na_4Ni(CN)_4$ and $K_4Pd(CN)_4$ create no nomenclature problem; they become sodium tetracyanonickelate(0) and potassium tetracyanopalladate(0), respectively.

The Charge-Number (Ewens-Bassett) System. The oxidation state of an atom as expressed by the oxidation number is a formal concept for partitioning the electric charge between atoms in a molecule or chemical structure. For many chemical structures, this formal procedure may lead to representations of charge distribution that are inconsistent with experiment. Therefore, Ewens and Bassett proposed to express only the total charge on an ion without representing valence and its associated arbitrariness of assigning electronic distribution within a given structure, e.g., titanium(2+) chloride for $TiCl_2$; titanium(3+) for $TiCl_3$; potassium tetrachloroplatinate(2−) for K_2PtCl_4; and sodium tetracyanonickelate(4−) for $Na_4Ni(CN)_4$.

International Agreement. The first report of the Commission for the Reform of the Nomenclature of Inorganic Chemistry was written in 1926 by Délépine. Subsequent rules (1940, 1959) were expanded and improved in 1990 to provide the basis for naming inorganic compounds. They retain most of the well established names for binary and pseudobinary compounds and for the oxoacids of the nonmetals and derivatives.

The IUPAC Commission on Nomenclature of Inorganic Chemistry continues its work, which is effectively open-ended. Guidance in the use of the IUPAC rules as well as explanations of their formulation are available. A second volume on nomenclature of inorganic chemistry is in preparation; it will be devoted to specialized areas. Some of the contents have had preliminary publication in the journal, *Pure and Applied Chemistry*, e.g., “Names and Symbols of Transfermium Elements” in 1944.

Organic Nomenclature

Modern organic nomenclature is such that it can be better understood by first tracing how it developed. Organic substances played a minor role in the *Methode de Nomenclature Chimique*. Eighteen organic acids were given their present names (succinic, malic, etc), and several other substances were mentioned, such as alcohol, ether (including esters as well as true ethers), starch, gluten, and camphor. Gaseous hydrocarbons, the only ones included, were lumped together as carbonated hydrogen gas. Thus a few common names were incorporated into the new method, but no systematic organic names were possible because of lack of knowledge. Little else could be done, for the basis for determining elemental composition, as in empirical formulas, did not yet exist.

The practice of assigning ad hoc names to organic compounds was neither avoidable, nor burdensome when only a small number of compounds were recognized. Such ad hoc names are termed “trivial” or “traditional,” to indicate that they contain no encoded structural information. They are useful for common compounds, and many of them are retained to this day, but they are not helpful in understanding chemical relationships. As they proliferated, the number and variety of them became unmanageable. The development of systematic nomenclature was driven by this circumstance, and was made possible by advances in understanding and determining the structure of molecules.

Systematic nomenclature is in essence a scheme for encoding structural information in a name. For organic chemistry, it probably began in 1832, when Justus Liebig’s journal, *Annalen der Chemie*, was born and when Liebig and Woehler published their memorable article on the radical of benzoic acid. This radical (C_6H_5CO in the modern formula) they termed “benzoyl,” thus coining -yl (from the Greek *hyle*, meaning stuff or material), one of the most useful suffixes in chemistry. By radical or compound radical, they meant a group of atoms that remains unaltered in chemical transformations. The word group is used for almost any portion of a molecule considered as a unit for convenience in naming or otherwise. The name ethyl soon followed. These two names, one of an acid group (radical) and the other of a hydrocarbon group (radical), may be regarded as the progenitors of the host of group names used in the 1990s. From them it was an easy step to the combinations of benzoyl chloride, ethyl iodide, ethyl oxide, etc, many of which still survive. These binary names are analogous to the binary inorganic names introduced in 1787.

It was many years before organic nomenclature shook off the influence of electrochemical theory and its binary names. Gradually, as facts accumulated, it became clear that this theory must give way to a unitary conception of the molecule. At the same time, the phenomenon of substitution, or replacement of one atom or group of atoms by another, was recognized to be of central importance. Some binary names are still used, either as a true expression, as for salts, or for convenience, as in ethyl sulfide or acetyl chloride, but for the most part the principle of substitution is used without regard to whether such replacement can actually be effected experimentally. Usually the atom replaced is hydrogen, and the replacement may be indicated by either a prefix or a suffix. Thus, in naming CH_3Cl chloromethane rather than methyl chloride, the replacement of one atom of hydrogen in methane, CH_4, by chlorine is indicated. A third group of names is formed by combining a class name with a specific word, as in ethyl alcohol or benzophenone oxime. Whatever the method or combination of methods used, there must be a name for a parent compound to form a basis for it.

By 1866, it was possible for Hofmann to arrange hydrocarbons in series by their empirical formulas, i.e., methane, CH_4, and methene, CH_2; ethane, C_2H_6, ethene, C_2H_4, and ethine, C_2H_2; propane, C_3H_8, propene, C_3H_6, and propine, C_3H_4; and quartane, C_4H_{10}, quartene, C_4H_8, and quartine, C_4H_6. These are known as the Hofmann-Gerhardt names.

Hofmann’s scheme has been modified by replacing quartane with butane and continuing the homologous series with the Greek forms pentane, hexane, etc, which are still used. For the C_nH_{2n} series, i.e., the olefins, the names methylene, ethylene, propylene, etc, came into use instead of Hofmann’s terms, but the names propene, butene, pentene, etc were revived in the Geneva system and are the preferred terms. For C_2H_2, ethine has never replaced the older term acetylene, but propine, butine, etc, reappeared in the Geneva system. The ending -yne is used, as in propyne, etc, to avoid confusion with the ending -ine of organic bases such as aniline.

The Hofmann-Gerhardt names did not distinguish between isomers. Different methods of distinguishing isomers arose: $CH_3CH_2CH_2CH_3$ became normal butane (abbreviated to *n*-butane), and $CH_3CH(CH_3)_2$ isobutane or trimethylmethane. Of olefins, $CH_2{=}CHCH_2CH_3$ became α-butylene or ethylethylene; $CH_3CH{=}CHCH_3$, β-butylene or symmetrical dimethylethylene; and $CH_2{=}C(CH_3)_2$, isobutylene or unsymmetrical dimethylethylene. It thus becomes evident that as the number of carbon atoms and therefore the number of isomers increases, the coining of such names meets with insuperable difficulties. The situation with regard to hydrocarbons had its parallel in the nomenclature of alcohols and other types of compounds.

The Geneva System. The Geneva Conference was strongly influenced by the need for names that would be suitable for systematic indexing of organic compounds. The groundwork was laid by a French subcommission. One of the chief principles of the system was the selection of the longest straight chain of carbon atoms in the molecule as a parent structure. Thus, the names butane, pentane, etc, would refer to the normal (unbranched) isomers only. The parent hydrocarbon could then be modified by attaching to its name one or more prefixes or suffixes to specify chemically characteristic features commonly termed functional groups. A representative selection is given in Lance 1 when two or more different positions of attachment of a prefixed or suffix exist, a position designator, called a locant, is necessary. These are arabic numerals, set off by hyphens,

TABLE 1. PREFIXES AND SUFFIXES FOR SOME PRINCIPAL FUNCTIONAL GROUPS[a]

Formula	Class name	Prefix	Suffix	Radicofunctional form
$-COOH$	carboxylic acids	carboxy	-carboxylic acid[b] or -oic acid	
$-SO_3H$	sulfonic acids	sulfo	-sulfonic acid	
$-COOR$	esters	alkoxy carbonyl	alkyl -oate or carboxylate[b]	
$-COX$	acid halides	halocarbonyl	-oyl halide or carbonyl halide[b]	
$-CONH_2$	amides	carbamoyl cyano	-amide or carboxamide[b]	
$-CN$	nitriles		-nitrile or -carbonitrile[b]	alkyl[c] cyanide
$-CH{=}O$	aldehydes	formyl	-al or -carbaldehyde[b]	
$-C{=}O$	ketones[d]	oxo	-one	dialkyl[c] ketone
$-OH$	alcohols	hydroxy	-ol	alkyl[c] alcohol
$-SH$	thiols (or mercaptans[e])	sulfanyl (mercapto[e])	-thiol	alkyl mercaptan
$-NH_2$	amines	amino	-amine	
$=NH$	imines	imino	-imine	
$-OR$	ethers	alkoxy or aryloxy		(di)alkyl ether
$-Cl$	chlorides	chloro		alkyl[c] chloride
$-NO_2$	nitro compounds	nitro		
$-SO_2$	sulfones	alkyl[c] sulfonyl		(di)alkyl[c] sulfone

[a] In order of precedence.
[b] The shorter form implies no additional carbon atoms, and is used when the group is part of a chain. The long form implies one more carbon atom than the parent structure, and is used when the group is attached to a ring, or for other reasons is not conveniently named as part of a carbon skeleton.
[c] Or aryl.
[d] Both bonds from the carbonyl group must be to a carbon atom.
[e] Has been widely used, but is no longer officially recommended.

starting with 1 at an end of the chain. Accordingly, $CH_3CH{=}CHCH_3$ became 2-butene, and $CH_3CH_2CHOHCH_2CH_3$ became 3-pentanol. The position of the locants at the beginning or at the end was considered equally acceptable. In the 1990s however, the official IUPAC recommendation is to place the locant immediately before the feature that it locates, as in but-2-ene and pentan-3-ol for the foregoing examples.

The International Union and the Definitive Report. The next important step was the *Definitive Report of the Commission on the Reform of the Nomenclature of Organic Chemistry* in 1930 at a meeting in Liège. This report used the Geneva rules as a basis for modification, and many of the 68 Liège rules deal with topics not touched in the original Geneva report.

An important modification of the Geneva system is that the fundamental chain used as a basis in an aliphatic compound is not necessarily the longest chain in the molecule, but must be the longest chain of those containing the maximum number of occurrences of the principal functional group (Rule 18). This shifts the importance for naming from side chains such as methyl and ethyl to functional groups such as $-COOH$ and $-OH$.

The concept of the principal function raises the question of how priority is determined when two or more different functional groups are present. No arbitrary rule can be entirely satisfactory, but an order has been codified in IUPAC recommendations, and an essentially similar order is used by Chemical Abstracts Service. In general, a higher state of oxidation takes precedence over a lower one (Table 1).

The use of prefixes and suffixes for distinguishing the various radicals, groups, and functions has caused some problems, because some groups, e.g., HS−, have borne more than one name, and some names, e.g., anisyl, have had more than one meaning. The *Definitive Report* included only a limited number of prefixes and suffixes. Chemical Abstracts Service publishes its own lists the most recent version can be found in the comprehensive *Guide to the Use of IUPAC Nomenclature of Organic Compounds*. An important departure from earlier recommendations is that the systematic names of acyl groups derived from carboxylic acids must end in -oyl, common traditional or trivial names, such as acetyl and oxalyl, excepted. The purpose of this rule is to distinguish unambiguously between hydrocarbyl groups and acyl groups. Thus anisyl can only mean methoxyphenyl, whereas anisoyl refers only to methoxybenzoyl.

The ending -yl (or -oyl) is standard for univalent groups (with certain traditional exceptions, such as succinoyl). It may be combined with a sign for unsaturation, as in propenyl, $CH_3CH{=}CH$ thynyl, $CH{\equiv}C-$. The ending -ylene is one device for denoting a bivalent group in which the two free valences are on different atoms, but, with the exception of methylene, $-CH_2-$, and ethylene, $-CH_2CH_2-$, the ending -diyl, with locants as appropriate, is preferred, as in propane-1,3-diyl, $-CH_2CH_2CH_2-$. When the two free valences of a bivalent group form a double bond, the ending is -ylidene, as in ethylidene, $CH_3CH{=}$. For a trivalent group forming a triple bond, the ending is -ylidyne, as in ethylidyne, $CH_3C{\equiv}$.

For indicating the number of groups of the same kind, the prefixes di-, tri-, tetra-, etc are used when the expressions are simple, and bis-, tris-, tetrakis-, etc when they are complex; for example, “dichloro,” but “bis(dimethylamino).” The prefix bi- is used to denote the joining of two groups of the same kind together, as in biphenyl, $C_6H_5{-}C_6H_5$, or the doubling of a compound with loss of two hydrogen atoms, as in biarsine, H_2AsAsH_2.

A historical account of the development of organic nomenclature from the time preceding the Geneva Conference to fairly recent times is available.

The IUPAC Commission on Nomenclature of Organic Chemistry has continuing responsibility for revising and expanding the rules that appeared in the *Definitive Report*.

A considerable number of trivial or semitrivial (traditional) names have been retained by IUPAC for compelling practical reasons; the approved ones are available. A very brief selection is shown in Table 2. Other contributions to organic nomenclature are available.

Biochemical Nomenclature

The IUPAC Commission of Nomenclature of Biological Chemistry was established in 1921, along with the organic and inorganic commissions. It worked actively and closely with the organic commission. Early subjects of

TABLE 2. COMPOUNDS USED AS PARENT STRUCTURES WITH TRIVIAL NAMES

Chemical formula	Name	Systematic equivalents
C_6H_6	benzene	$C_{10}H_6$	naphthalene	C_5H_5N	pyridine	C_4H_4S	thiophene	C_4H_4O	furan	$-COOH$
C_6H_5OH	phenol	benzenol
$C_6H_5NH_2$	aniline	benzenamine
$H_2N{=}NH_2$	hydrazine	diazane
NH_3	ammonia or amine	azane
$HO{=}OH$	hydrogen peroxide	dioxidane
CH_3COCH_3	acetone	propan-2-one
H_2NCONH_2	urea	carbamide

concern were carbohydrates, proteins, enzymes, and fats. More recently, this Commission shared its work with a corresponding Commission of the International Union of Biochemistry, which is not the International Union of Biochemistry and Molecular Biology (IUBMB); this led to the establishment of the Joint Commission on Biochemical Nomenclature (JCBN) in 1964.

The Joint IUPAC/IUBMB Commission has published many recommendations dealing with the nomenclature of natural products. The IUBMB Commission on Nomenclature has also issued a number of recommendations dealing with areas of a more biochemical nature and for naming enzymes.

The presence of many chiral centers in compounds of biochemical significance or natural-product interest has led to the use of stereoparents. These are parent structures having trivial names that imply (without explicitly expressing) a particular steric configuration. Common examples are the names of simple sugars, exemplified by glucose.

Although it is not strictly within the subject of biochemical nomenclature, it is appropriate to mention the existence of standardized generic names for pharmaceutical drugs. Such names are essentially coined, or trivial, names, but often include syllables from the systematic organic names, and endings that reflect a structural class, e.g., -cillin (from penicillin), or an important area of medical application, e.g., -vir (antiviral). Glossaries of these generic names are published periodically and a glossary of United States Approved Names (USAN) is published annually.

Macromolecular Nomenclature

In 1967, the Polymer Nomenclature Committee of the American Chemical Society published proposals for naming linear polymers on the basis of their chemical structure, which were then introduced into *Chemical Abstracts (CA) Indexes* and published in their final form in 1968.

A Macromolecular Division of IUPAC was created in 1967, and it created a permanent Commission on Macromolecular Nomenclature, parallel to the other nomenclature commissions. The Commission over the years has issued recommendations on basic definitions, stereochemical definitions and notations, structure-based nomenclature for regular single-strand organic polymers and regular single-strand and quasi-single-strand inorganic and coordination polymers, source-based nomenclature for polymers and abbreviations for polymers. All of these are collected in a compendium referred to as the IUPAC Purple Book.

Recommendations on additional aspects of macromolecular nomenclature such as that of regular double-strand (ladder and spiro) and irregular single-strand organic polymers continue to be published in *Pure and Applied Chemistry*. Recommendations on naming nonlinear polymers and polymer assemblies (networks, blends, complexes, etc) are expected to be issued in the near future.

Examples of the two macromolecular nomenclature systems are as follows. For source-based names for homopolymers and copolymers: polyacrylonitrile, poly(methyl methacrylate), poly(acrylamide-*co*-vinylpyrrolidinone), polybutadiene-*block*-polystyrene, and poly(propyl methacrylate)-*graft*-poly(1-vinylnaphthalene). Structure-based examples are as follows: poly(oxy-1,4-phenylene) (**1**), poly(oxyethyl-eneoxyterephthaloy) (**2**) and poly[imino(1-oxo-1,6-hexanediyl)] (**3**).

Nomenclature in Other Areas of Chemistry

A number of glossaries of terms and symbols used in the several branches of chemistry have been published. They include physical chemistry, physical-organic chemistry, and chemical terminology (other than nomenclature) treated in its entirety. IUPAC has also issued recommendations in the fields of analytical chemistry, colloid and surface chemistry, ion exchange, and spectroscopy, among others.

NOMENCLATURE (Organic Chemistry). See **Organic Chemistry**.

NONDESTRUCTIVE TESTING (NDT). The examination of materials and objects for the purpose of detecting defects without in any way harming the test object. NDT contrasts vividly with destructive testing methods, which chemically consume or physically damage the test object, rendering it unfit for use. Whereas destructive testing must be confined to statistical sampling procedures, NDT enables 100% on-line inspection if desired. The trend in recent years has been in this direction, with emphasis on automating and increasing the speed of NDT operations. Another significant trend has been that of *testing work in progress*, as contrasted with earlier procedures which concentrated on testing raw materials and final products. In this way, very helpful information for step-by-step quality control can be provided. There remain, of course, numerous examples of where statistical destructive testing is needed—for example, in determining the ultimate compressive and tensile strengths of materials and parts or checking the corrosion resistance of materials. In recent years, it has proven possible to combine the results of NDT with computerized simulation in some instances to predict failure of test objects under certain conditions. For obvious economic reasons, NDT is preferred by manufacturers over destructive testing this accounts for high acceptance and many advancements which have occurred in NDT methods. For research and development applications, nondestructive methods are sometimes referred to as NDE (nondestructive evaluation).

Traditionally, NDT has been associated with metals and materials of construction for finding potentially unsafe conditions, such as cracks, voids, holes, inclusions, and other inconsistencies, as may be found in metal sheets, plates, bars, tubes, castings, forgings, and weldments. Such defects may arise from faulty manufacturing, or from later use, as the result of corrosion, abrasion, vibration, mishandling, and inattention to required maintenance procedures. In recent years, the applications for NDT have broadened to include all manner of materials—films, coatings, polymers, composites, and ceramics as encountered in a wide variety of industries, including numerous uses in the electronics manufacturing industry. Also, NDT is widely used for on-site inspection of large and heavy equipment, which cannot be detached for testing, after installation, but where periodic checks are required. Examples include the inspection of weldments in pipelines, aircraft engines and structural components, military equipment, bridge structures, etc.

During the last half of the 1980s and well into the 1990s, NTD enjoyed the benefits of measurement and computer technologies that contributed immensely to the speed, accuracy, and reliability of NTD, even though instrument costs have risen markedly as a result. However, the ability to make more measurements within shorter periods of time probably has not increased the unit costs proportionately. A number of measurement techniques entirely new to the NDT field have been added to increase the variety of choices.

Radiographic Methods

Radiographic (X- and gamma-ray technology) method using film was one of the earliest NTD schemes used. Although early systems are undergoing modernization, this comparatively simple method still enjoys acceptance for certain applications. This basic technique has taken on a number of new formats.

Film Images. Images made by the traditional film technique are shown in Fig. 1. To reduce costs and meet environmental restrictions, a dry-silver system was introduced in 1991. The system produces a silver-based image without the use of wet chemistry, using photothermographic technology. The image is developed on exposed film by thermal energy rather than by the traditional method of immersing film in a liquid developer and fixer. Three elements required for dry processing are a specially coated film, fluorescent exposing screen, and a thermal processor. The film has a translucent polyester base similar to that of conventional film. Its ultrafine grain produces detailed images of archival quality.

Traditional radiographic methods use two-dimensional film to record the attenuation of X-rays passing through a three-dimensional object. The result is a shadowgraph in which all object features are superposed. To improve the totality of information obtained, backscattering methods were introduced several years ago.

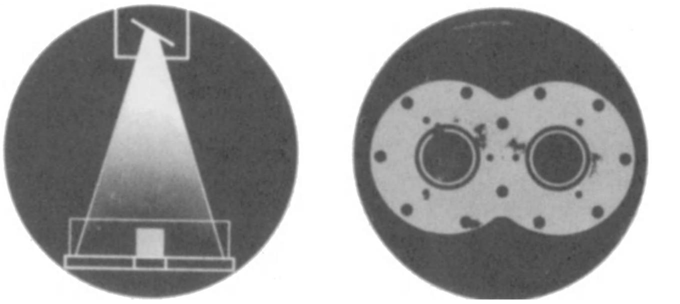

Fig. 1. X-rays or gamma rays are used to create a shadow image of light and dark that reveals any flaws or inclusions in a test part

Principal applications for radiography include the inspection of castings, electrical assemblies, weldments, small, thin, and complex wrought products, some nonmetallics, solid propellant rocket motors, cans or containers, composites, and nuclear reactor fuel rods, among many others.

Chronology of Radiographic Methods. In 1985, researchers at John Hopkins University described a flash X-ray system that uses increased-power X-ray sources to generate very intense short pulses. High-gain X-ray intensifier detectors are used. Exposure times as short as 30 ns are possible and thus microstructural changes due to explosions, heat pulses, and shock waves can be detected. An indirect and direct method are used. In the indirect method, the X-ray diffraction image is converted into a visible light image by a fluorescent screen. The researchers have found that for the indirect method, a multiple-stage image-intensifier system coupled to an external fluorescent screen is the most sensitive and almost instantaneous system. Multiple stages of amplification allow individual X-ray photons to be detected. In more advanced systems, there is inclusion of a microchannel plate where electrons strike the output phosphor and are converted into a strong, visible image.

In the direct method, an X-ray-sensitive vidicon TV camera directly converts the X-ray image into an electronic charge pattern on a photoconductive target, which is read out by a scanning electron beam and displayed visually on a TV monitor.

In addition to testing uses per se, flash-X-ray techniques have been used to study the orientation of single crystals, to study lattice rotation accompanying plastic deformation, to measure the grain boundary migration during recrystallization annealing, and to determine the physical state of exploding materials.

In another technique known as X-ray transmission asymmetric crystal topography, changes in defect structure during polymerization of single crystals have been studied.

Digital Radiography. In this technique, the traditional film is replaced by a linear array of detectors and the X-ray beam is collimated into a fan beam. The object is moved perpendicularly to the detector array, and the attenuated radiation is sampled digitally by the detectors. Data are processed by stored information in the computer's memory to yield a two-dimensional image of the part being inspected.

X-Ray Computed Tomography (CT). In computed tomography, penetrating radiation from many angles is used to reconstruct cross-sectional images of an object. The advantages of CT are exemplified by the inspection of aircraft/aerospace castings for internal defects. Advantages of CT include increased reliability, elimination of unnecessary rejects, and wider use of castings instead of forgings and parts machined from wrought stock. CT has been found to have greater sensitivity (dependent on part size and geometry) than conventional film. CT can spatially define flaw distribution. Aerospace test engineers claim that castings can be measured with an accuracy of better than 0.05 mm (0.002 in), but is adversely affected by the amount of image noise and the edge-detection method used. Computed tomography systems are costly. The general principles of CT are described in article on **X-Ray Scan and Other Medical Imagery**.

Ultrasonic Methods

Typically, ultrasonic images are produced by mechanically scanning an ultrasonic transducer in a raster pattern over an area of a structure and

then displaying the reflected or transmitted energy in a suitable format. Usually, the scan is performed in a tank of water or with some form of squirter nozzle. The liquid medium serves to transmit the ultrasonic energy from the transducer into the test material. Conventionally, the data are displayed as C-scans (a plan view image where a color scale is used to display signal amplitude or depth information) or as B-scans (image of a cross section at one particular location of interest, typically with a color indicating signal amplitude).

As indicated by Fig. 2, there are several testing modes: (1) pulse-echo mode, (2) through-transmission mode, (3) reflector-plate mode, and (4) angle-beam mode.

Sonic (< 0.1 MHz) and ultrasonic (0.1 to 25 MHz) radiation have been used for many years in NDT. In a simple testing scheme, sonic or ultrasonic vibrations are generated and sent by way of a pulse beam through the part to be tested. The beam travels unimpeded through large parts, may be angled for testing sheet stock, and can impact materials immersed in a liquid. Any flaw reflects vibrations back to the instrument, which indicates the location and size of the discontinuity on a CRT (cathode-ray tube). Access is required to only one side of the material being tested. Although energy can be lost from the ultrasonic beam due to geometrical effects, these can be controlled to increase the sensitivity of attenuation measurements. Hence, microstructural alterations, such as microcracks, foreign particles, precipitates, grain boundaries, interphase boundaries, and dislocation defects, can be detected. Research has shown that attenuation measurements have detected microstructural change during fatigue testing, therefore giving early warning to fatigue-induced failure, as well as measuring oxygen content in titanium welds.

Acoustic methods are applicable to numerous kinds of materials. The method can be used, for example, to reveal fiber/matrix bond strength in polymer-matrix composites. In one method (Wan-li Wu, National Institute of Standards and Technology), a continuous wave argon-ion laser is used to heat a very small area of the composite. The resulting thermal expansion between fiber and resin produces a measurable change due to debinding. Conventional methods of evaluating bond strength are time consuming and tedious. Instead of measuring the thermal stress, the laser power level at which debonding occurs is used as the index of debonding stress. Although sonic scanning techniques can be used to detect voids and cracks at interfaces in polymer-matrix composites, they do not measure the strength of interfacial bonds.

As pointed out by D. Sturges (General Electric Aircraft), "Modern ceramic materials offer many attractive physical and mechanical properties for use in a rapidly growing variety of industrial applications. The critical nature of many applications, however, imposes technical challenges in manufacturing and inspection. One nondestructive evaluation (NDE) technique of major relevance to inspecting ceramics is ultrasonic microscopy (also termed acoustic microscopy), that is, the use of tightly-focused, high-frequency sound beams to form images of the point-to-point reaction of a material to periodic stress waves. This technique offers high sensitivity for the detection of small defects, and often is a complementary technique to X-ray inspection."

Computer-assisted ultrasonic microscopy (CAUM) has been of particular significance in the testing of new materials developed for more fuel-efficient engines, wherein one objective is that of maximizing the high thermal efficiency of gas turbine engines by way of incorporating high-temperature ceramic components and exhaust-heat recovery. The object of NDE is that of assuring that ceramic components are free of both surface and internal flows that limit component life. Surface flaws can be generated during production by machining and normal handling.

Penetrant Method. This method does not depend upon radiation interactions with the test object and is essentially noninstrumental. A special penetrant substance is applied freely on the test object and allowed to work into tight cracks. See Fig. 3. The penetrant is removed from all surface areas and the piece is sprayed with a developer. The developer dries to an even white coating, while the penetrant bleeds up from any flaws through the developer, forming bright-red or fluorescent indications on the white surface. The size of the defect is indicated by the richness of color, speed of bleed-out, and dimensions observed.

Because of environmental concerns, a new generation of biodegradable penetrants having sensitivity levels ranging from 1 to 4 has been developed. The new penetrants are water washable and, in most instances, can be directly discharged into sewers. They are free of petroleum-based solutions.

Magnetic-Particle Method. This method makes use of iron powder to reveal the leakage magnetic field created at a flaw or break when any part is magnetized. The familiar horseshoe magnet best illustrates this principle. (1) If a horseshoe magnet is bent into a circle, the field between the ends attracts and holds magnetic iron powder. (2) If a magnet is made completely closed, the field will be contained entirely within the ring and no iron powder will be attracted. (3) However, if the round magnet is cracked, poles are created at the break, and iron powder is instantly attracted to the cracked area to pinpoint the defect. See Fig. 4.

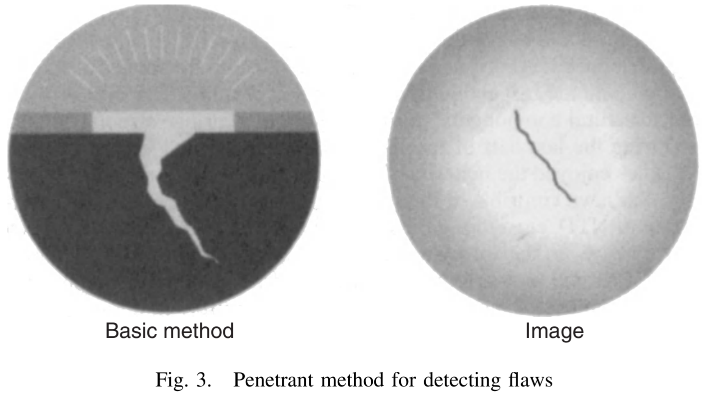

Fig. 3. Penetrant method for detecting flaws

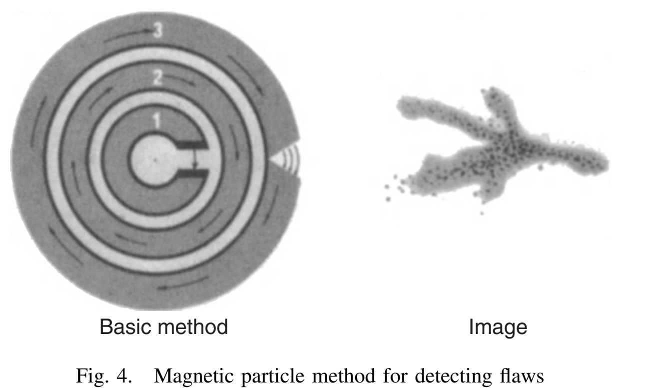

Fig. 4. Magnetic particle method for detecting flaws

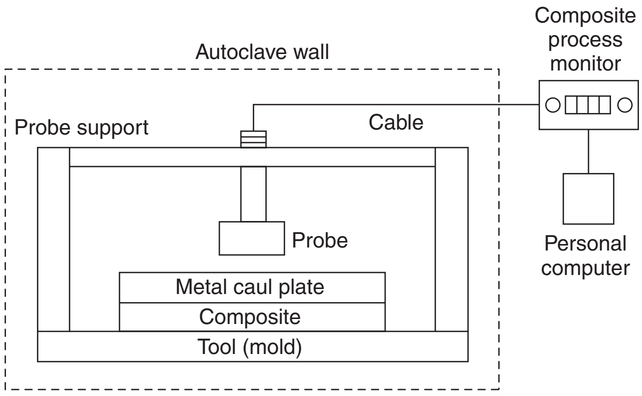

Fig. 5. Use of eddy-current testing for monitoring a composite cure. Typically, eddy-current testing uses an electronic instrument having a small probe on the end of a flexible electrical cable. The probe is placed either against or close to the target. The target must be electrically conductive to allow the generation of eddy currents. The time-variant nature of the probe's magnetic field causes electric currents to flow in the target material. Higher field frequencies or a more electrically conductive material increase the depth of the eddy-current penetration into the material. The concentration of eddy currents near the surface of the material is referred to as the "skin effect." Eddy currents generate their own magnetic field that opposes the probe's magnetic field. Detection circuits in the instrument sense the impedance changes in terms of phase/amplitude changes in probe-coil voltage. (*Suggested by Bar-Cohen and Nguyen*)

Eddy-Current Methods. This is one of the earliest NDT methods and is still used. Basically, this method reveals any differences in electrical impedance between parts to be tested and a reference sample. Parts to be examined are passed through a coil or explored with a probe, and a trace appears on a CRT. Since magnetic and electrical characteristics are closely related to metallurgical quantities, a trace position or pattern or a meter reading clearly shows variations in metal hardness and composition, as well as defects. Both ferrous and nonferrous parts can be tested, and various coils, probes, and detector tips are available.

Aside from more sophisticated electronics, a major contribution to improve eddy-current instrumentation has come from the development of the eddy current resonance digitizing (ECRD) method. With this method, eddy-current instrumentation can separate nonferrous alloys based upon characteristics other than simply their conductivity. See Fig. 5.

NDT Outlook

Improvements in current, established technologies and the introduction of new ways to test materials, nondestructively are expected to continue apac. One promising method is *positron annihilation*. The positron is the antiparticle of the electron; thus a positron/electron pair is unstable and will annihilate. In this process, two gamma rays at approximately 180° to one another are emitted from the center of the mass of the pair. A very slight departure from 180° is directly proportional to the transverse component of the momentum of the pair. The momenta of the electrons involved in such collisions can be calculated from the geometry and intensity of the gamma rays. The dynamics of the electron/positron system underlie the use of the technique for the study of defects in materials.

NORMAL CONCENTRATION. A one normal solution (often abbreviated 1N) contains one gram-equivalent weight of a particular substance dissolved in 1 liter of *solution*. The equivalent weight of a substance may be defined as that weight of the substance that will involve, in a chemical reaction, one atomic weight of hydrogen, or that weight of any other element or portion of a substance, which, in turn, would involve in reaction one atomic weight of hydrogen.

As an example, the chlorine atom of potassium chloride (KCl) also is found in hydrochloric acid (HCl) in combination with one hydrogen atom. Thus, the gram-equivalent weight of KCl is 74.555, which is the same as its gram-molecular weight. A one normal solution of KCl will contain 74.555 grams of the salt per liter of solution.

For a particular solution, the molar and normal concentration are the same only when the gram-molecular and gram-equivalent weights are the same. Sulfuric acid H_2SO_4 represents a case where these values are not the same. This acid contains two active hydrogen ions and, therefore, its gram-equivalent weight is one-half of its gram-molecular weight. Phosphoric acid H_3PO_4 contains three active hydrogen ions. Consequently, the gram-equivalent weight for this acid is one-third that of the gram-molecular weight. Calcium hydroxide $Ca(OH)_2$ contains two active hydroxyl ions, each being equivalent to a hydrogen ion. Therefore, the gram-equivalent weight of $Ca(OH)_2$ is one-half of its gram-molecular weight.

NORRISH, RONALD G. W. (1897–1978). An English physical chemist who was recipient of the Nobel prize in 1967 with Manfred Eigen and George Porter. His analysis of reactions of one ten-billionth of a second were made possible by disturbing the chemical equilibrium with short energy pulses. After receiving a doctorate, he went on the Sorbonne before returning to Cambridge to teach. His career was long and distinguished by many awards.

NORTHRUP, JOHN H. (1891–1987). An American chemist who won a Nobel prize in chemistry in 1946 along with James B. Sumner and Wendell M. Stanley. His work was primarily concerned with isolation and crystallization of enzymes. Many first included the production of the enzyme trypsin in the laboratory and isolation of the first bacterial virus. He was also responsible for producing diphtheria antitoxin in crystalline form. His education was at eastern schools including Harvard, Yale, and Princeton.

NOXIOUS GAS. Any natural or by-product gas or vapor that has specific toxic effects on humans or animals (military poison gases are not included in this group). Examples of noxious gases are ammonia, carbon monoxide, nitrogen oxides, hydrogen sulfide, sulfur dioxide, ozone, fluorine, and vapors evolved by benzene, carbon tetrachloride, and a number of chlorinated hydrocarbons. Gases that act as simple asphyxiants are not classified as noxious. See also **Pollution (Air)**.

NUCLEAR CHEMISTRY. The division of chemistry dealing with changes in or transformations of the atomic nucleus. It includes spontaneous and induced radioactivity, the fission or splitting of nuclei, and their fusion or union; also the properties and behavior of the reaction products and their separation and analysis. The reactions involving nuclei are usually accompanied by large energy changes, far greater than those of chemical reactions; they are carried out in nuclear reactor for electric power production and manufacture of radioactive isotopes for medical use, also (in research work) in cyclotrons. See also **Nuclear Fusion**; **Nuclear Fusion**; **Radiochemistry**; and **Nucleus**

NUCLEAR FISSION. A type of nuclear reaction in which the compound nucleus splits into two nearly equal parts, rather than ejecting one or a few small nuclear particles, as in most nuclear reactions. Our knowledge of nuclear fission dates back to the mid-1930s when Fermi and his coworkers showed that the number of distinctly different radioactive nuclides that could be induced by neutron bombardment of uranium far exceeded the number expected, unless some previously unknown pattern of isomerism could be found. Furthermore, the radiochemical properties of many of these radio-elements different quite markedly from expectations. For example, both Hahn and Strassman in Germany and Curie and Savitch in France found that certain unknown activities, thought to be radioactive radium, always followed the chemically separated barium fraction rather than the radium fraction. Hahn and Strassman found several other similar examples and were able to show that uranium, when bombarded by neutrons, undergoes what then appeared to be a very unusual nuclear reaction in that the products are radio-elements with about half the atomic number of uranium. These findings were interpreted by Meitner and Frisch as the division of an excited nucleus into nuclei of medium mass, a process that was given the name *nuclear fission*.

The first such process to be extensively studied was fission induced in ^{235}U by thermal neutrons (neutrons with energies of about 0.03 eV). This reaction, symbolically represented by the equation

$$^{235}\text{U} + n \longrightarrow {}^{236}\text{U} \longrightarrow \text{fission},$$

produces an unstable system which achieves stability by splitting into two large fragments, not by ejecting one or a few small particles.

An individual fission does not produce a unique pair of fragments, but in a large number of such processes, the mass distribution of the fragments can be predicted with reasonable certainty, leading to predictable fission yields. A fission yield, usually expressed as a percentage, describes that fraction of nuclear fission processes that give rise to a specified nuclide or group of isobars. The yields of single nuclides are known as independent yields and those of a set of isobars as mass yields or chain yields. Since two fragments are produced by each fission, the total of all fission yields for a given fission process is 200%. The fission yield curve is different for each mode of induced fission, the most commonly known one being that for thermal neutron induced fission of ^{235}U, shown in Fig. 1. The chemical characteristics of the two fragments vary within limits, so that many elements are formed. Analysis of the fission products shows that most of them are in two mass groups, a "light" group consisting of elements having mass numbers between 85 and 104, and a "heavy" group consisting of elements having mass numbers between 130 and 149. Fragment mass numbers that have been detected range from around A = 70 to around A = 160. The determination of independent yields is made more difficult

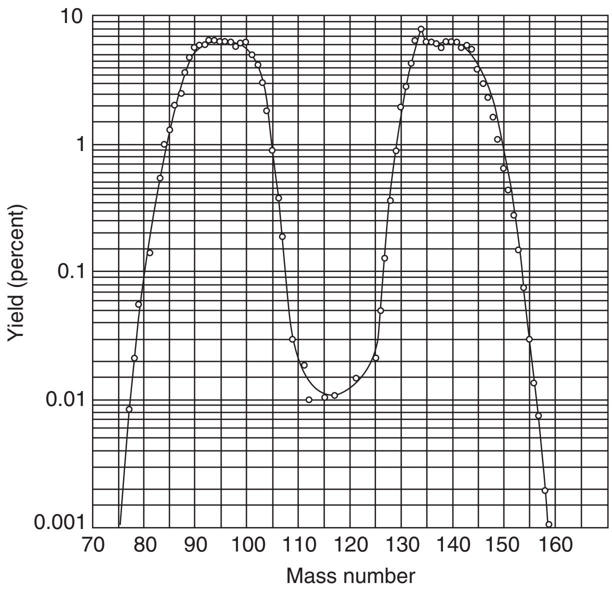

Fig. 1. Mass fission yield curve for $^{235}\text{U} + n$ (thermal)

by the fact that many of the products are highly radioactive and undergo extensive secondary changes, sometimes in extremely short times, a very small fraction of a second.

A most significant aspect of nuclear fission is its great release of energy. The source of this energy is the loss of mass between the initial and final products of the reaction. The total mass of all atoms and nuclear particles produced in a single fission process in less than the original mass of the ^{235}U atom and the neutron that combined with the ^{235}U to induce fission. During fission of ^{235}U, the total energy released because of loss of mass is about 200 MeV. In practical units, the fissioning of 1 gram of ^{235}U yields 24,000 kilowatt-hours of energy.

Another important feature of fission is the presence of neutrons among the reaction products, slightly more than two for each fission of a ^{235}U atom. These neutrons are not an immediate consequence of fission, but are boiled off the original fission products, their release being possible because of the very large amount of available energy. If all these neutrons were captured by other ^{235}U nuclides, the number of available neutrons would multiply by factors of two for every generation of fission processes, a very rapid increase. However, some neutrons escape from the region containing the ^{235}U and others are absorbed in nonfission capture processes. The minimum conditions for a self-sustaining chain reaction is that at least one neutron from each nucleus undergoing fission must cause fission of another nucleus, a multiplication factor of one or greater. Maintenance of a chain reaction is essential to the proper functioning of both nuclear weapons and nuclear reactors.

The probability that fission can occur (generally called the cross section for fission) varies widely among different nuclides. Only a few nuclides, such as ^{235}U, have a high probability of undergoing fission when they capture a neutron. In other nuclides, the probability of fission is generally much smaller. As an example, the cross section as a function of incident neutron energy is shown in Fig. 2 for fission of ^{235}U and of ^{238}U. Although fission can be induced in ^{238}U, such a process is possible only if the incident neutron has an energy greater than 1 MeV, whereas neutrons of any energy can induce fission in ^{235}U. The characteristic double hump yield curve of Fig. 1 (asymmetric fission) is common only for low neutron excitation energy and targets consisting of highly fissile elements. For either higher excitation energies or less fissile elements, such as actinium or radium, symmetric fission becomes much more important, creating a triple humped fission-yield curve, shown in Fig. 3. Slightly fissile elements, such as lead and bismuth, or very high excitation energies further emphasize the symmetric mode of fission, also illustrated in Fig. 3. Nuclear fission may be induced by particles other than neutrons, such as alpha particles and photons. In some nuclides, it also occurs spontaneously, although the probability of such occurrence is so low that it has almost no effect on the radioactive decay characteristic of the nuclide.

Nuclear fission has generally been explained theoretically in terms of the liquid-drop model of the nucleus. In this model, the incident neutron

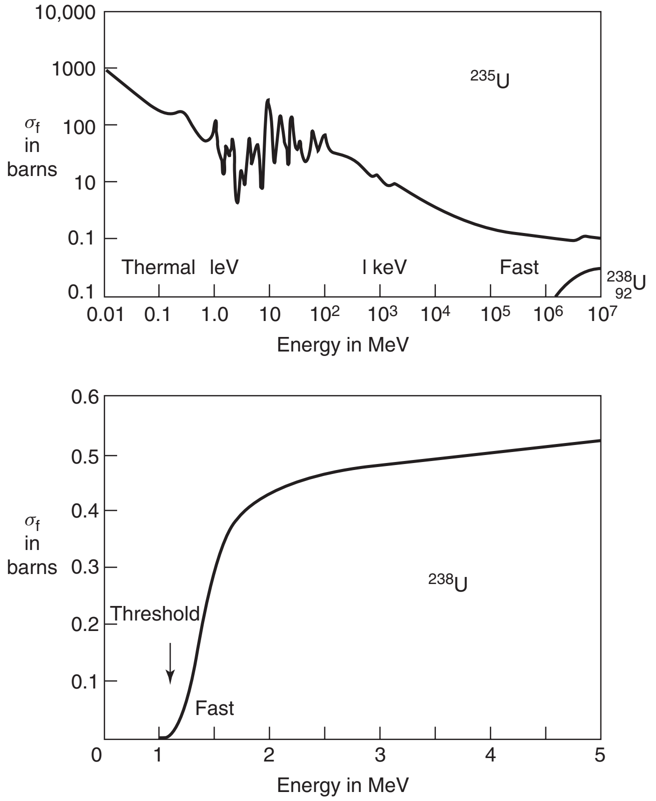

Fig. 2. Fission cross section as function of energy for ^{235}U and ^{238}U

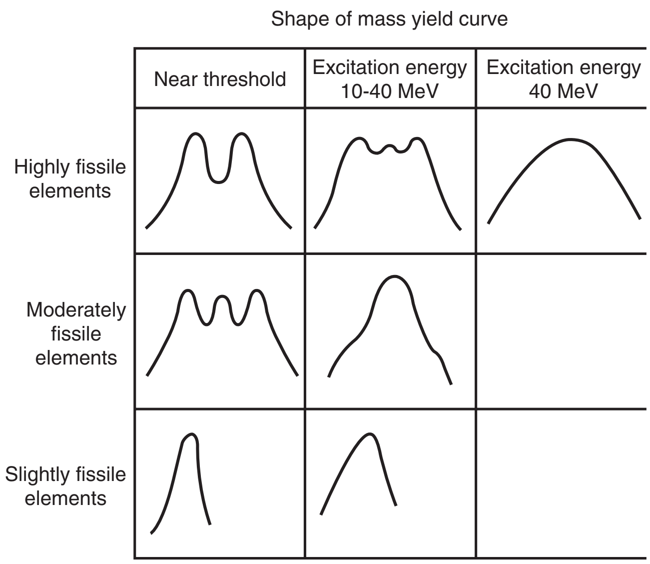

Fig. 3. Mass fission yield curves as function of excitation energy and degree of fission probability

combines with the target nucleus to form a compound nucleus at a high excitation energy. A small part of this excitation energy can be attributed to the kinetic energy of the incident neutron, but most of it usually comes from the binding energy of the incident neutron. This added energy initiates oscillations in the drop, which then sometimes assumes an elongated shape, similar to B in Fig. 4. If oscillations become sufficiently violent that a form similar to D is reached, fissioning (form E) becomes inevitable, since the positive charge at the two ends of the dumbbell-shaped nucleus then produces an electrostatic repulsive force greater than the attractive nuclear force holding the neck of the dumbbell together. The reason for asymmetric fission is not clearly understood. The liquid drop model predicts symmetric fission. Most people believe that asymmetric fission results because of

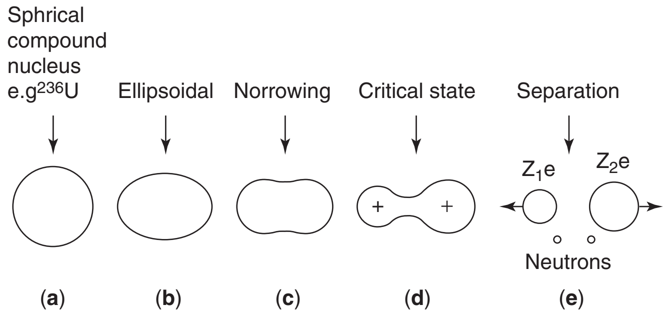

Fig. 4. Fission mechanism according to liquid-drop model of the nucleus

the effects of the closed shells of the nucleus. See also **Nuclear Power Technology**; and **Nuclear Structure**.

NUCLEAR FORCES. Strong, short-range, attractive forces that interact between the individual nucleons of an atomic nucleus. Unfortunately, despite several decades of research, a clear and unambiguous description cannot be given for the forces that hold individual protons and neutrons together in an atomic nucleus. Unlike the electrostatic force that holds electrons in an atom, no equation can be written that completely describes the nature of the force that holds an atomic nucleus together, or the nature of its associated potential energy. A description of the detailed structure of a nucleus cannot, therefore, be derived directly from calculations based on knowledge of nuclear forces. Instead, detailed knowledge of the structure of atomic nuclei has been derived from nuclear models. These models have been constructed by using results from other fields of physical science which display the same or similar characteristics as those observed in nuclear reactions and in radioactive decay. From such analogies, construction of a partial description of nuclear structure and of the nature of nuclear forces has been possible.

Because of the unknown characteristic of nuclear forces, many different suppositions have been made, using available experimental evidence, regarding the nature of the potential energy V of a nuclear particle as a function of its position in the field of a nucleus, or of another nuclear particle. To a first approximation, the nuclear potential is assumed to be spherically symmetric, such as V is a function only of the distance r from the center of the field, thus being the same in all directions, and is representable by a curve as in Fig. 1 curves (a) to (f).

A *potential well* is the name given to a region in which a minimum in the potential is formed; it results from attractive forces. A *potential barrier* is the name given to a region in which there is a maximum in the potential; it results from repulsive forces, either alone or in combination with attractive forces. Some central potentials commonly used as approximations to nuclear potentials are illustrated in the curves. Curve (a) shows a square well potential, which has a constant negative value $-V_0$ for $r \leq r_0$ and zero value for $r \geq r_0$. When this curve represents the potential between two nucleons, r_0 is called the *range of nuclear forces*; when it represents the potential of a nucleus, as this nucleus interacts with an individual nucleon, r_0 is called the *nuclear radius*. Curve (b) shows a square well potential for $r \leq r_0$ with a Coulomb potential resulting from repulsive electrostatic forces, for $r > r_0$. The resulting barrier is called a *Coulomb barrier*, and the maximum energy b is called the barrier height. Such a potential approximates that of a positively charged particle in the field of a nucleus, and is often used in the theory of alpha particle disintegration and nuclear reactions. Curve (c) shows an exponential well, $V = V_0 e^{-r/b}$; curve (d) shows a Gaussian well, $V = V_0 e^{-r/b2}$. Curve (e) shows a Yukawa potential, $V = -(V_0/r)e^{-r/b}$ used in the meson theory of nuclear forces for the interaction between two nucleons; and (f) shows a wine-bottle potential, characterized by a low central elevation. If a high central elevation is present, the resulting barrier is called a *central barrier*, or *repulsive core*.

Although the predominant part of the nuclear potential is the part described above that is derived from the central force produced by the average effects of all other nucleons in the system on the individual nucleon under observation, evidence exists that nonsymmetric tensor and spin-orbit coupling terms must be included in the description of the nuclear potential.

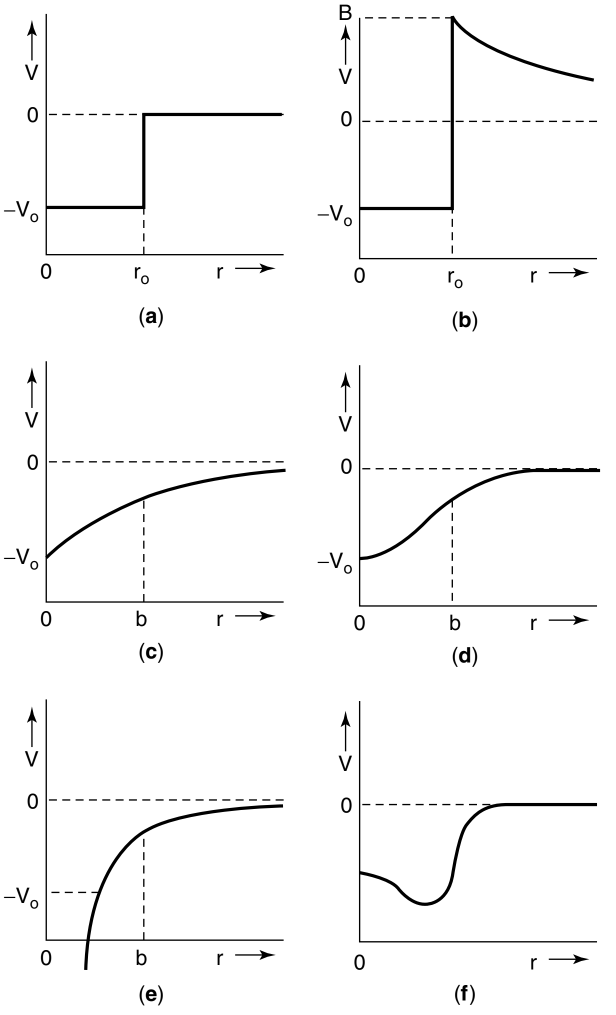

Fig. 1. Potential energy of a nuclear particle versus distance from the center of the field

These are derived from a tensor force resulting from a coupling between individual pairs of nucleons and from the coupling between spin and orbital angular moments of the individual nucleus, as described by the shell model of the nucleus.

A considerable amount of evidence indicates that nuclear forces are charge-independent, i.e., the neutron-neutron, neutron-proton, and proton-proton forces are identical. The meson theory of nuclear forces, originated by Yukawa, postulates the atomic nucleus being held together by an exchange force in which particles, now called mesons, are exchanged between individual nucleons within the nucleus.

C. Sharp Cook
The University of Texas at El Paso

NUCLEAR FUSION. The character of the atomic nucleus is such that the individual nuclear particles are most tightly bound in elements of intermediate atomic number. When energy is sought, attention is focused on the more loosely assembled elements, releasing energy by splitting (*fissioning*) the heavy isotopes, or by joining (*fusing*) the lighter ones. There is less energy release per fusion reaction than there is per fission reaction, but the reactants are more plentiful and, in many respects, easier to handle. A particular fusion reaction is of interest if the power produced can be sufficiently large to offset the power consumed in generating and maintaining the reacting medium, and if the relevant rates can be large enough so that economically interesting regimes are accessible to modern technology. There are over thirty such reactions possible. The most appealing of the fusion reactions as possible routes to fusion energy are (1) those which involve the heavy hydrogen isotopes, deuterium, $^2_1$H or D; and (2) those which involve tritium $^3_1$H or T. These tend to have the largest fusion reaction probability (cross section) at the lowest energies. Deuterium is abundant, naturally occurring and in wide use now as D_2O in heavy-water-moderated reactors. Tritium is a radioactive isotope with a 12.3-year half-life and does not occur in nature. Tritium emits an electron and decays to stable helium-3.

The deuterium (D-D) reaction chain may be represented by:

$$\mathrm{D} + \mathrm{D} \longrightarrow {}^3\mathrm{He} + n + 3.2\ \mathrm{MeV}$$

$$\mathrm{D} + \mathrm{D} \longrightarrow \mathrm{T} + p + 4.0\ \mathrm{MeV}$$

$$\mathrm{D} + \mathrm{T} \longrightarrow {}^4\mathrm{He} + n + 17.6\ \mathrm{MeV}$$

$$\mathrm{D} + {}^3\mathrm{He} \longrightarrow {}^4\mathrm{He} + p + 18.3\ \mathrm{MeV}$$

. . . .

$$6\mathrm{D} \longrightarrow 2{}^4\mathrm{He} + 2p + 2n + 43.1\ \mathrm{MeV}$$

The first two equations represent the fact that the D-D reaction can follow either of two paths, producing tritium and one proton; or helium-3 and one neutron, with equal probability. The products of the first two reactions form the fuel for the third and fourth reactions and are burned with additional deuterium. The net reaction consists of the conversion of six deuterium nuclei into two helium nuclei, two hydrogen nuclei, and two neutrons along with a net energy release of 43.1 MeV. The reaction products—helium, hydrogen, and neutrons—are harmless as contrasted with the myriad fission products obtained in a fission reactor. The neutrons produced may be absorbed in sodium to produce an additional 0.25 MeV per cycle. Therefore, the D-D reaction produces at least 7 MeV per deuterium atom (deuteron) and, with absorption in sodium, more than 10 MeV per fuel atom.

The peak reaction rate coefficient of the D-D reaction is considerably less than that of the deuterium-tritium (D-T) reaction occurring within the (D-D) cycle. Thus, attention tends to focus on the latter. Because tritium does not occur naturally, the reaction must be supplemented by one using lithium to reproduce the tritium fuel:

$$\mathrm{D} + \mathrm{T} \longrightarrow {}^4\ \mathrm{He} + n + 17.6\ \mathrm{MeV}$$

$$n + {}^6\ \mathrm{Li} \longrightarrow {}^4\ \mathrm{He} + \mathrm{T} + 4.8\ \mathrm{MeV}$$

. . . .

$$\mathrm{D} + {}^6\ \mathrm{Li} \longrightarrow 2{}^4\mathrm{He} + 22.4\ \mathrm{MeV}$$

This reaction is tritium-regenerating and produces only helium as a reaction product.

The D-T reactor is technologically more complex than the D-D reactor because of the need to facilitate the second reaction (which takes place outside the plasma) and because very energetic neutrons must be slowed down to allow the reaction with lithium to take place. However, the conditions needed to achieve net power output are less demanding than for the D-D fuel reactor. The D-T reaction will probably be exploited first, but its ultimate, very long term use may be limited by the availability of lithium. See also **Lithium** (**For Thermonuclear Fusion Reactors**).

Fusion reactions can take place only when the nuclei of the fuel atoms are brought into close enough conjunction. The nuclei are positively charged and so repel each other. This repulsion is equivalent to an energy barrier which can be penetrated with reasonable efficiency only if the reacting nuclei have kinetic energy comparable to the barrier height. The level of kinetic energy required depends upon the particular reaction and the desired reaction rate, but in general, plasmas of interest have average energy per particle in excess of 5 keV. A collection of particles with average energy 5 keV has an effective temperature of at least 10^8 degrees Kelvin. At these temperatures, the gas is completely dissociated into its constituent positively charged nuclei and free electrons. The density ranges between 10^{13} to 10^{14} cm^{-3}. The electrical charge density is such that the behavior of the collection of particles is completely dominated by electrostatic and electromagnetic phenomena. Such a charge-dominated collection of ionized matter is known as *plasma*. This plasma at such extremely high temperatures cannot be confined by walls made of materials, known or imagined. But confinement, even for a nanosecond or less, is required if fusion reactions are to occur. Ways to confine the plasma have been researched for 20–30 years by scientists in a number of countries.

After nearly three decades of effort, fusion ignition, that is, the efficient burnup of deuterium and tritium has been accomplished only in one way, namely, the thermonuclear or hydrogen bomb. In this instance, obviously

tremendously greater amounts of energy are released than are required to trigger the fusion reactions. In the case of the hydrogen bomb, an atomic bomb was used to generate the extremely high temperature and the degree of confinement required for hydrogen nuclei to fuse. The methods researched to date for confining the plasma include containment within magnetic fields; inertial confinement methods in which the fuel is pelletized in a special way and fusion reactions are initiated either by laser beams or beams of particles; and by heating the plasma with high-power microwave radiation.

NUCLEAR MAGNETIC MOMENT. An electrically charged particle of finite size that possesses angular momentum, acts like a small magnet and thus possesses a magnetic moment. For atomic nuclei, the magnitude of this moment is within a range of values between zero and a few nuclear magnetons.

NUCLEAR MAGNETIC RESONANCE (NMR) AND MAGNETIC RESONANCE IMAGING (MRI). Since the discovery of electron spin resonance (ESR) by Zavoiski in 1945 and the codiscovery of nuclear magnetic resonance (NMR) in 1946 by Purcell, Pound, and Torrey (Harvard University) and Bloch, Hansen, and Packard (Stanford University), the field of magnetic resonance has reached a high degree of sophistication and versatility.

Soon after its discovery, the principle was applied by physicists to a variety of research programs. Chemists also became interested in NMR because they recognized its potential for elucidating structure and dynamics in pure and applied chemistry. NMR has gained exceptional acceptance over the intervening years as a tool for yielding details of molecular structure, such interests coinciding with other developments in molecular biology. The use of NMR in medical research dates back about 40 years, commencing with proton NMR measurements on cells and organs of both humans and laboratory animals. During the past 20 years, the applications of NMR to clinical medicine have expanded rapidly. NMR permits the analysis of protein structures, for which the former X-ray methods were inadequate. By the late 1980s, the structures of some 50 important proteins had been determined. NMR allows the investigation of proteins and peptides and other macromolecules in an aqueous medium. Consequently, the effects of pH (hydrogen ion concentration) can be observed and the binding of water at the interior and surface of proteins can be determined.

The molecular weights of proteins studied thus far range from about 5000 to 15,000. The use of three-dimensional Fourier transform NMR may ultimately permit the study of macromolecules up to a molecular weight of 40,000.

In analytical chemistry in the early 1990s, NMR was routinely used to study: (1) polymers, polymer networks, and copolymers, and (2) asphalt, bitumens, tars, and pitches, among numerous examples that could be cited.

Commencing with clinical medicine (circa 1981), which led to the development of NMR and magnetic resonance imaging (MRI) for medical research and diagnostics, the medical applications have captured the "headlines," particularly since the early 1990s. It is interesting to note that in 1981 there were only two MRI devices in the United States. By 1987, the installations had reached about 600 in the United States and about 100 MRI facilities in Europe. As of 1994, these Figures expanded into several hundred installations, representing a tremendous investment by the health care field.

Fundamentals of the Technology

Discovery of the principles of ESR and NMR led to the development of several subtechnologies.

Electron Spin Resonance (ESR). Fundamentally, ESR spectrometers consist of three main parts: (1) a magnet with corresponding power supply to provide a steady dc magnetic field at about 3300 G; (2) a microwave bridge capable of producing an oscillating electromagnetic field at a frequency of about 0.5 GHz (X band), which is coupled via waveguide to a high-Q microwave reflection cavity; and (3) the associated signal detection including dc field modulation, amplification, and display systems. See Fig. 1.

Observation of ESR from a particular sample is contingent upon the presence of a macroscopic spin magnetic moment $\overline{\mu}$; i.e., the sample under investigation must contain some minimum number of unpaired electron spins. Upon insertion into the cavity, the sample is subjected to the dc magnetic field H_0, and the unpaired electrons align themselves both parallel

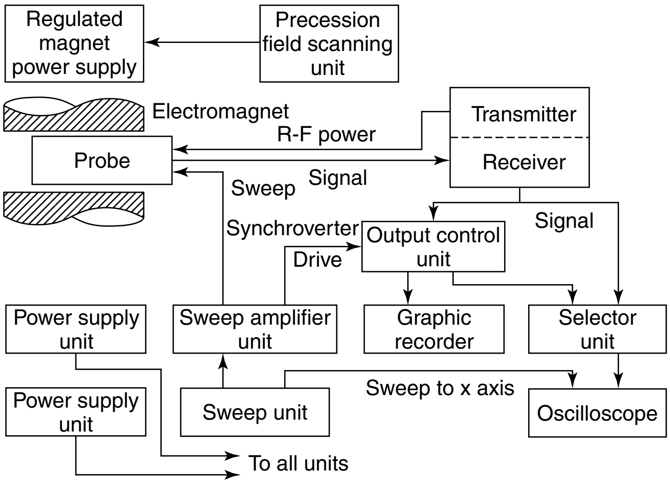

Fig. 1. Schematic of ESR spectrometer

(high energy) and antiparallel (low energy) to H_0. The ratio of the spin populations of the high to low energy states is given by the Botzman distribution, $e^{-hv/kT}$, where hv is the energy difference of the two states. Because of the torque on $\overline{\mu}$ produced by H_0, the spin magnetic moment will precess about H_0, at the Larmor frequency $\omega = \gamma_e H_0$, where γ_e is the gyromagnetic ratio of the electron.

Analysis is accomplished by sweeping the magnetic field until the Larmor frequency of the spin system is identical to the fixed frequency of the oscillating microwave field emanating from the bridge. When the two frequencies are coincident, a net microwave energy will be absorbed by the spin system from the oscillating field because of the excess spin population in the lower energy state. If energy continues to be absorbed, the spin populations will equalize and saturation will occur—no net microwave energy will be absorbed and the signal will disappear. To avoid this situation the spin system interacts with its surroundings (lattice) and transfers the absorbed microwave energy to the lattice in some interval called the spin-lattice relaxation time.

This phenomenon, known as relaxation, acts to restore the spin system to its original Botzman distribution of populations. At equilibrium, microwave energy is being absorbed by the spin system and then transferred to the lattice. This process is monitored via microwave rectification of the reflected cavity signal by a diode detector, preamplification, and lock-in phase detection at the dc field modulation frequency. The signal which appears on the recorder may be a single line from an unpaired electron or a group of lines. The latter are caused by neighboring nuclei with nonzero nuclear spin (hyperfine structure) and by surrounding electric field gradients (quadrupole interactions).

In this manner the unpaired electron spins may be used as a probe for analysis of their immediate microscopic surroundings. Typical instrument sensitivity is such that approximately 10^{-11} mole of a paramagnetic species can be detected, but generally concentrations of 10^{-4} mole give optimum ESR spectra.

Nuclear Magnetic Resonance (NMR). This technique is essentially based on the same principle as ESR, but NMR is capable of detecting nuclei (MHz) instead of electrons (GHz). (Lack of a standardized nomenclature has resulted in numerous modifiers in connection with magnetic resonance instrumentation—electron, proton, nuclear, etc., plus application-related terms, such as silicon-29, oxygen-17, ^{13}C, ^{31}P NMR, etc.)

In nuclear magnetic resonance spectroscopy, a nucleus possessing a magnetic moment when placed in a homogeneous magnetic field will precess about the field axis at a rate which is dependent upon the strength of the field. See Fig. 2. If these nuclei are then brought into contact with an oscillating electromagnetic field of the same frequency as the Larmor precessional frequency of the nuclei, energy will be absorbed by the nuclei spin system from the oscillating ratio frequency field. As stated above, the net energy absorption is proportional to the Botzman distribution of spin populations and the effective nuclear relaxation times.

Different nuclei will have different precessional frequencies and therefore at a particular field will absorb energy at certain characteristic radio frequencies. Also, nuclei of the same nuclear species (such as hydrogen) will absorb energy at slightly different frequencies, dependent

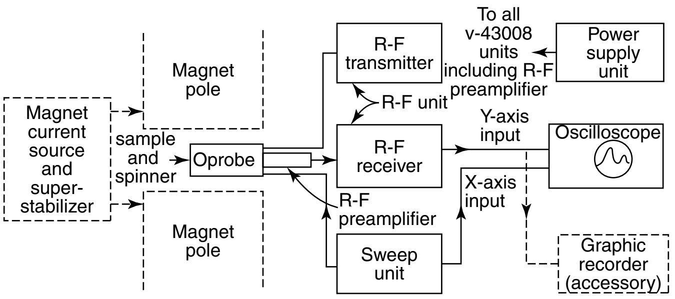

Fig. 2. Schematic of NMR spectrometer

upon their molecular environment. The latter observation makes possible an entire subfield of NMR spectroscopy, termed high-resolution NMR, which is an appropriate method for determining chemical structure and identifying and measuring similar nuclei in two or more different compounds (mixtures).

The major components of a magnetic resonance spectrometer are: (1) a magnet capable of producing a very strong homogeneous field which may be continuously varied over a very small range; (2) a low-power radio frequency oscillator which supplies rf power to a small transmitter coil surrounding the sample; (3) a small receiver coil which also surrounds the sample (but is orthogonal with respect to the transmitter), and feels (4) a sensitive radio receiver (tuned to the same frequency as the transmitter) capable of amplifying any signal which might be induced in the receiver; and (5) a recorder of oscilloscope which can display the resulting spectra.

Various decoupling techniques are used to simplify complex NMR spectra. For example, in a simple two-spin system (homonuclear) giving rise to four NMR lines it is possible to saturate a nucleus at a particular rf frequency and collapse the remaining doublet to a single NMR line. This occurs because the second nucleus sees an averaged interaction from the first rather than two distinct interactions from spins in the high and low energy states. Noise decoupling is predominantly used to decouple different nuclei—for example, hydrogen nuclei C^{13} spectra (heteronuclear). Here the entire hydrogen spectrum is saturated over a range of frequencies (noise) leaving behind the much simplified C^{13} spectrum.

In internuclear double resonance one nuclear line at a given frequency is observed while a second frequency is swept through the remainder of the NMR spectrum. All nuclei which are in some way coupled to the line being observed will enhance or de-enhance the latter as the second frequency passes through the resonance condition. Also, the Fourier transform technique has nicely complimented NMR. Any complex waveform can be converted to a spectrum of frequencies by Fourier transformation.

In NMR, the waveform is a superposition of a set of nuclear precession frequencies with amplitudes decaying due to relaxation and field inhomogeneity. The transformation may be carried out by analog means (spectrum analyzer) or on a small dedicated laboratory computer. The latter appears to be the most convenient solution. Since the free induction decay signal decays with time, whereas the instrumental noise remains constant, the noise content is higher in the tail of the transient signal, and it is possible to improve the overall signal-to-noise ratio by weighting the transient signal with an exponentially decaying function of time. The shorter the time constant of this exponential, the greater the improvement in sensitivity, but this increases the linewidths of the transformed spectrum. The reversal of this procedure can enhance resolution at the cost of sensitivity.

High-Resolution Nuclear Magnetic Resonance of Solids. Important developments in solid-sample NMR techniques of the early 1980s have made NMR of significant interest as a tool for characterizing solid samples—as it has been in the past for the study of liquids. As observed by Maciel, the development of line-narrowing techniques, such as magic-angle spinning (MAS) and high-power decoupling, has led to powerful high-resolution NMR for studying solids. In favorable cases (for example, where high abundances of protons are present) cross polarization (CP) provides a means of circumventing the time hurdle caused by inefficient spin-lattice relaxation in many solids. Combining the CP and MAS approaches for carbon-13 with proton decoupling has become a popular and routine experiment for organic solids. For many nuclides with spin quantum number $1 > \frac{1}{2}$, the central nuclear magnetic resonance transition can be used in high-resolution experiments that involve rapid sample spinning. A continuing stream of other advances in NMR technology bodes well for the characterization of solids by a wide range of nuclides. The complexities of this topic unfortunately are beyond the scope of this encyclopedia.

It is interesting to note that several of the concepts for improving NMR technology, as listed by Levy and Craik, in 1988, already have been partially or fully achieved: (1) two-dimensional Fourier transform (FT NMR); (2) high-resolution NMR in solids; (3) new types of pulse sequences; (4) chemically induced dynamic nuclear polarization; (5) multiple quantum NMR; and (6) NMR imaging (MRI).

Two-Dimensional NMR. Bax and Lerner report on how two-dimensional Fourier transform pulse NMR (2-D FT NMR) has extended the range of applications of NMR spectroscopy into the area of large, complex molecules, such as DNA and proteins. Great spectral simplification can be obtained by spreading the conventional one-dimensional NMR spectrum in two independent frequency dimensions, thus removing spectral overlap, facilitating spectral assignment, and providing additional information. Conformational information related to interproton distances is available from resonance intensities in certain types of two-dimensional experiments. Two-dimensional NMR spectroscopy also has been applied to the study of ^{13}C and ^{15}N to provide connectivity information and greatly improving the sensitivity of these determinations. A traditional NMR spectrum of a sugar and a 2D spectrum are contrasted in Fig. 3.

Correlative spectroscopy (COSY) is an approach that involves correlating groups believed to be coupled to each other and to prove that this coupling does exist. *Spin-echo correlation spectroscopy* (SECSY) is a variation of the COSY technique. Sometimes called *J-resolved spectroscopy*, it is a technique that allows a separation of the chemical shift of a nucleus from the coupling to other nuclei. This simplifies the spectrum and permits one to assign each resonance to a specific nucleus. Sometimes referred to as *nuclear Overhauser effect* (NOESY), this is a technique that makes it possible to determine distances between nonadjacent residues in a peptide chain. Another application, *multiple quantum transitions*, takes advantage of the fact that molecules in a sample are forced to absorb or emit several quanta of energy at one time. For example, the technique can be used to determine which carbon atoms in a molecule are connected to other specific atoms in the molecule.

Magnetic Resonance Imaging (MRI). In 1973, Lauterbur added a new aspect to NMR basics, namely that of image formation based upon NMR

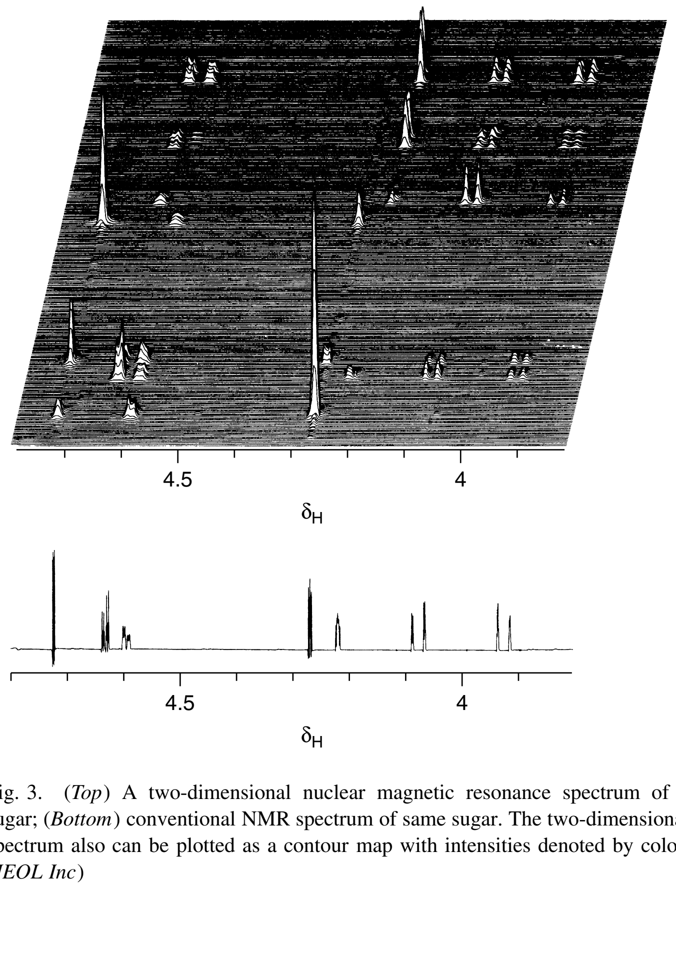

Fig. 3. (*Top*) A two-dimensional nuclear magnetic resonance spectrum of a sugar; (*Bottom*) conventional NMR spectrum of same sugar. The two-dimensional spectrum also can be plotted as a contour map with intensities denoted by color. (*JEOL Inc*)

principles. This led to NMR imaging, now commonly referred to as magnetic resonance imaging (MRI).

The source of the imaging photons is not a Roentgen tube, nor an unstable isotope, nor an electron storage ring, but rather it is a radio transmitter. The commonly referred *radio photon* radiation allows photons to pass into the tissues under study, where they are absorbed by nuclear particles rather than by electrons. The nucleons are momentarily excited by the process and then return to their resting state by emitting photons of the same or nearly the same energy that they had absorbed. Because the nuclei of the different chemical elements absorb radio photons of different frequencies, it is possible to use the method to detect the presence of a single element in a sample. When protons are irradiated by radio photons of a frequency that precisely matches their own precessional frequency, resonance occurs. The resonant frequency (Larmor frequency) is determined by the natural rotational velocity (gyromagnetic ratio) characteristic of each species of atomic nucleus and by the strength of the applied static magnetic field, as expressed by: Larmor frequency =Magnetic field ×Gyromagnetic ratio. See Fig. 4.

Magnetic resonance imaging is well suited for the imaging of soft tissues. It has been found particularly effective in (1) studying skeletal musculature, notably in the male and female pelvic regions, (2) delineating tumor development and assisting in planning surgery or therapy, and (3) precisely locating tumors, particularly in the brain where, with time, the evolution of hematomas can be studied. For clinical work, MRI installations may be used in two staff shifts per day, holidays, and weekends.

The magnetic fields used are usually 1.5 to 2 teslas (15,000 to 20,000 gauss). Barriers to using higher magnetic fields are magnet cost, additional expense for building the site, and notation by some persons (volunteers) to discomfort when over 4 teslas are used, which also causes the patient to move.

In 1986, Fossel and McDonough (Beth Israel Hospital, Boston) proposed that proton NMR spectroscopy of human plasma possibly could be a "potentially valuable approach to the detection of cancer and the monitoring of therapy." Subsequent investigations through 1990 failed to develop a convincing correlation.

Traditional MRI of the human body relies mainly on the detection of the most abundant type of nuclei, the hydrogens in water, and, to some extent, fat.

As pointed out by C. Moonen (National Institutes of Health), "For discrimination of healthy and diseased tissues, adequate contrast is essential. Such contrast depends not only on differences in water concentration, but also on the NMR relaxations, which, in turn, are related to local mobilities and interactions."

Magnetic resonance imaging, in addition to providing detailed information about the macroscopic structure and anatomy, also permits the noninvasive spatial evaluation of various biophysical and biochemical processes in living systems. These include the motion of water in processes, such as vascular flow, capillary flow, diffusion, and exchange. Further, the concentrations of various metabolites can be determined for the assessment of regional regulation of metabolism. In the scholarly Moonen paper, examples are given of flow imaging, diffusion imaging, and the imaging of tissue perfusion, of exchange, and of metabolites. These aspects of MRI imaging sometimes are referred to as *functional MRI.*

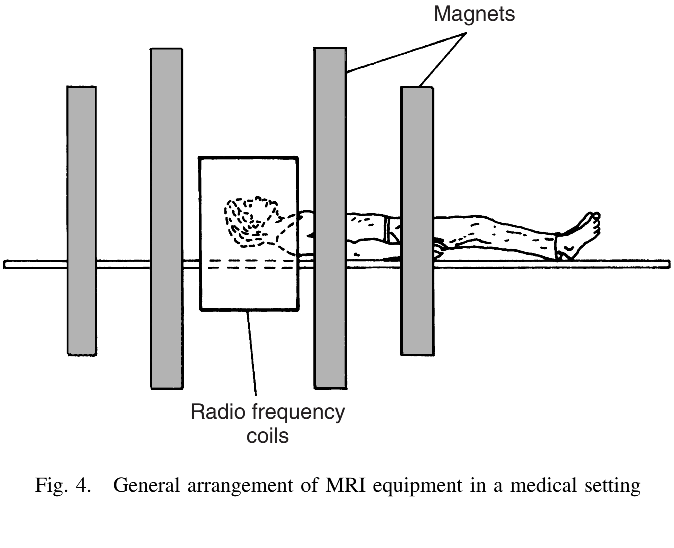

Fig. 4. General arrangement of MRI equipment in a medical setting

Imaging of the central nervous system by MRI technology is of great interest. Advantages of MRI include its sensitivity to soft tissue, the contrast between gray and white matter, the paucity of signals from the skull, and the availability of coronal, sagittal, and transverse sections. The procedure has been used to detect posterior fossa tumors, such as acoustic neuromas, and pituitary and parasellar tumors, orbital tumors, multiple sclerosis, and a number of other lesions in the craniovertebral junction, and of the cord and spine. MRI technology, according to a number of authorities, has large potential for use in *noninvasive* cardiological studies, particularly of blood flow imaging. Contrast agents are not required because nuclei in rapidly flowing blood move out of the volume of interest during the interval required for application of the rf pulse and of gradient magnetic fields. The parameters that influence MRI signals at various flow rates are being studied.

In addition to hydrogen atoms, MRI can create, for example, ^{31}P images which are excellent indicators of energy metabolism. ^{23}Na images reflect extracellular and intracellular fluid fluxes.

Echo-Planar Imaging. A major problem with MRI in the past has been the long data acquisition times (up to several minutes). Consequently, MR images are subject to so-called *motional artifacts*, caused by physiological motions (heartbeat, blood flow, bowel peristalsis, breathing) as well as by voluntary movements in severely ill and uncooperative patients, including children. Echo-planar imaging (EPI) permits faster scan times, thus effectively reducing imaging to a fraction of a second as compared with minutes. Although a technical description of how EPI is implemented is too complex for coverage here, echo-planar imaging uses only one nuclear spin excitation per image.

EPI has broadened the use of MRI to include the evaluation of cardiac function in real time, mapping of organ blood pool and perfusion, functional imaging of the central nervous system, depiction of blood and cerebrospinal fluid flow dynamics, and motion picture imaging of the mobile fetus in utero. EPI also has the practical advantages of increasing patient throughput at a lower cost per MRI examination. With these advantages, it is expected that EPI will become an established tool for early diagnosis of some common and potentially treatable diseases, such as ischemic heart disease and stroke.

Comparison with Ultrasonography. The health care community is aware of the high costs of MRI and continues to seek other techniques that may be effective at lower cost. One such comparison was made in connection with prostate cancer. The approach to treatment varies and depends on the extent of cancer at the time of diagnosis.

In a specific comparative study over a period of 15 months, 230 patients were evaluated with identical imaging techniques. It was found that MRI correctly staged 77% of cases of advanced disease and 57% of cases of localized disease. The corresponding Figures for ultrasonography were 66% and 46%. MRI identified only 60% of all malignant tumors measuring more than 5 mm on pathological analysis, while ultrasonography identified only 59%. The study concluded, "The MRI and ultrasonography equipment is not highly accurate in staging early prostate cancer, mainly because neither technique has the ability to identify microscopic spread of disease."

Superconducting Quantum Interference Device (SQUID). These devices are sensitive detectors of magnetic fields. Low-temperature superconductors have been used in the past to sense weak magnetic signals from the brain for medical diagnosis. Such devices, however, required cooling with liquid helium and thus have resulted in costly, unwieldy apparatus. Research is now underway toward using higher-temperature superconductors, such as $YBa_2Cu_3O_7$. Although the higher-temperature semiconductor still requires refrigeration, this can be accomplished with liquid nitrogen, thus resulting in a less costly, simpler, and more portable detecting device.

NUCLEAR POTENTIAL. The potential energy V of a nuclear particle as a function of its position in the field of a nucleus or of another nuclear particle. A central potential is one that is spherically symmetric, so that V is a function only of the distance r of the particle from the center of force. A noncentral potential, on the other hand, is one that is not spherically symmetrical, or one that depends upon the relative directions of the angular momenta associated with the particle and the center of force, as well as upon the distance r. A negative potential corresponds to an attractive force, while a positive potential corresponds to a repulsive force.

Although the expression can certainly be applied to the problem of nuclear forces, the usual meaning of a nuclear potential refers to the interaction of a nucleon (neutron or proton) with a complex nucleus. Although the potential energy of a single nucleon inside a nucleus is clearly a rapidly varying function of position and time (since it represents the interaction with a large number of closely packed, fast-moving particles), one may nevertheless speak of the average potential energy, and one may regard this as a smoothly varying function. For a neutron, the nuclear potential is essentially negative inside the nucleus, rising rapidly to zero outside the nuclear radius R. For a proton, the long-range electrostatic repulsion must, of course, be added. Owing to the Pauli exclusion principle, and to the exchange nature of nuclear forces, however, such a potential cannot in general be regarded simply as a function of position, $V = V(r)$; it depends in addition upon the momentum of the particle, which in quantum mechanics does not commute with the position. Hence, the potential must be regarded as a nondiagonal matrix operator $V = \langle r|V|r'\rangle$ configuration space, or a similar operator in momentum space.

Although the concept of a nuclear potential in this latter sense cannot be defined in a precise way, it has nevertheless been useful, both qualitatively and quantitatively, in the investigations of nuclear structure and nuclear reactions. It has been of particular usefulness in the optical model of nuclear reactions.

NUCLEAR POWER TECHNOLOGY. After a terse review of the physics and chemistry of nuclear fission and the nature of these reactions, some of the design features and operating parameters of the four families of reactors currently installed are described. These units, some of which are approaching their retirement are, of course, the starting basis for the design of next-generation reactors, which appeared prior to the end of the 20th century. Design improvements that constitute these forthcoming systems are described in terms of their status as of the mid-1990s. The topic of radioactive waste handling is summarized. Based upon available information, nuclear power technology in the United States as well as in Canada, France, Japan, the U.K., and other leading industrialized nations is covered.

The first nuclear power plant was installed at Shippingport, Pennsylvania in 1957 and, after serving as a test facility for several years, was dismantled because of "old age." The plant had a capacity of 60,000 kilowatts. Indeed, the plant was extremely small by comparison with hundreds of units installed today in the United States and other major countries of the world.

NATURE OF NUCLEAR FISSION REACTIONS

The energy of a nuclear fission reaction can be computed from the change in mass between reactants and products according to Einstein's law:

$$\Delta E = \Delta mc^2$$

where E is the energy in ergs, m is mass in grams, and c is the velocity of light in centimeters per second. For example, the mass difference in this equation is $\Delta m = 0.2058$ amu (atomic mass units). Therefore, $\Delta E = 931$ MeV/amu $\times$ 0.2058 amu = 191.6 MeV. The average amount of energy released in the various fission reactions is about 200 MeV (million electron volts). This energy is distributed in the fission process as:

	MeV
Kinetic energy of fission fragments	165
Radioactive-decay energy	23
Kinetic energy of neutrons	5
Prompt gamma-ray energy	7

The energy of a chemical reaction, approximately 3–4 eV, is dramatically lower than that of a nuclear reaction. Hence, the fission of ^{235}U yields 2.5 million times as much energy as the combustion of the same weight of carbon.

The importance of fission in energy (power) production lies in two facts: (1) an exceedingly large amount of energy is released in the fission reaction; and (2) the production of excess neutrons permits a chain reaction. These two circumstances make it possible to design nuclear reactors in which self-sustaining reactions occur with the continuous release of energy. Although described later, it may be pointed out here that nuclear fission is not the only energy-releasing nuclear reaction. The fusion of light nuclides, like hydrogen, into heavier elements is also an energy-producing process.

The heat generated in nuclear power plants is transferred to a working fluid and from this point on the nuclear power plant and the conventional fossil-fueled power plant are essentially similar.

Fission Reaction. In nuclear fission, the nucleus of a heavy atom is split into two or more fragments. The reaction is initiated by the absorption of a neutron. A typical reaction is

$$^{235}_{92}\mathrm{U} + ^{1}_{0}n \longrightarrow ^{137}_{56}\mathrm{Ba} + ^{97}_{36}\mathrm{Kr} + 2^{1}_{0}n + \Delta E$$

In this reaction, a ^{235}U atom absorbs one neutron, becomes unstable, and subsequently fissions into two fission fragments plus two neutrons. This is just one of the many ways in which ^{235}U might fission. The number of neutrons produced in a fission reaction is usually 2 or 3. The excess neutrons produced by the fission reaction provide the means of self-sustaining the chain reaction. Nuclides including ^{233}U, ^{235}U, and ^{239}Pu, which are fissionable by neutrons of all energies, are termed fissile nuclides.

Nuclear Fuels. There are two broad categories of nuclear fuels: (1) the fissile nuclides previously mentioned; and (2) the fissionable nuclides,

^{232}Th (thorium) and ^{238}U. Thermal reactors use fissile nuclides as fuel, while fast reactors are designed to burn fissionable materials. In fast reactors, only a small portion of the ^{232}Th and ^{238}U are fissioned directly. A larger portion of these materials is converted into ^{235}U and ^{239}Pu, respectively, through neutron absorption. Thus, this type of reactor not only consumes fuel, but also produces (breeds) new fuel material. Hence, the term *breeder reactor* is used for reactors designed to take advantage of this phenomenon. Breeding is possible in thermal reactors also, but to a lesser extent. The fuel material in a fast reactor must contain a significant amount (about 10%) of one of the fissile materials. The remainder of the fuel must have a high mass number in order to avoid slowing down the neutrons. The natural reserves of fissionable materials are more than 100 times greater than the reserves of fissile materials. Consequently, from the viewpoint of utilization of available energy resources, fast reactors are of great importance. Breeder reactors are described later.

Moderators. The most important slow-down mechanism is elastic scattering on elements of low mass number. Materials like light and heavy water, beryllium oxide, and graphite are used to slow down, or *thermalize* the neutrons to an energy of about 0.025 eV. As neutrons collide with the nuclei of these atoms, their kinetic energy and speed are gradually reduced until thermal equilibrium is achieved with the reactor structure. The fewer such collisions before deceleration is complete, the less chance of ^{238}U atoms absorbing neutrons.

Critical Mass. Thermal neutrons, which move like atoms in a low-pressure gas, diffuse throughout the reactor. They must be absorbed by a nucleus of the reactor structure, in which case they merely make that nucleus radioactive. Or, they may strike a fissionable atom of ^{235}U, causing fission and, in turn, releasing more neutrons to maintain the reaction. Should the number of neutrons absorbed by the moderator and ^{238}U be greater than about 1.5 excess neutrons emitted from each fission, the chain reaction will not be maintained. Therefore, the reactor core must be designed so that the mass of fuel will be just sufficient to ensure one neutron from each fission causing fission in another atom. A mass and configuration of fissionable material in which this occurs is termed the *critical mass*—or a reactor in which this condition is achieved is said to have "gone critical."

To measure a chain reaction, a multiplication factor k is used to indicate the ratio of neutrons in one generation to those in the preceding generation. Thus, in a constant chain reaction where the total number of neutrons neither increases nor decreases, the heat output is constant and $k = 1$. Should k rise above unity, the rate of fission, and hence the rate of heat productivity, steadily rises. This is so even if k is held constant at its new value. Here lies one *major difference between nuclear reactors and conventional steam generators*. In the latter, heat output is proportional to firing rate. If the firing rate is increased, the steam output is increased; but it remains constant at its new level. In a nuclear reactor, an increase in k results in continuously rising heat output. Only by returning the rate of neutron production to its original ratio can heat output be maintained at its new level.

Reactivity Control. Absorption of excess neutrons, above those needed to maintain a constant reactivity level, provides close control over the degree of reactivity. This is accomplished by inserting materials having a high neutron-capture rate into the core. Control rods of special alloy metals are moved into and out of the cores as required. To start the reactor from shutdown (black start), control rods are partially withdrawn until k becomes greater than one. Neutron flux and heat output grow until the desired level is reached. At this point, control-rod movement is quickly reversed to keep k at unity. The reactor is shut down by inserting the rods to their full extent. In this position, the rods absorb more than 1.5 excess neutrons per fission and the chain reaction quickly stops. Heat production continues for a time, but is usually dissipated by an auxiliary cooling system.

It is interesting to contrast a nuclear power reactor and a nuclear bomb. The designer of a nuclear fission bomb seeks to release as much fission energy as possible within the shortest possible time (milliseconds). Thus, a bomb is designed to favor *prompt neutrons*. By contrast, the normal operating mode of a nuclear power reactor is one in which prompt neutrons alone cannot sustain a chain reaction, but prompt neutrons together with delayed neutrons can. Only the delayed neutrons are controllable. A power reactor is designed to release fission energy *slowly and smoothly* and in just the right amounts to convert water into steam. Whereas the "fuel" in a bomb is used up essentially in an instant, in a power reactor the energy release is spread over months and years. It has been agreed by physicists for many years that it is physically impossible for a power reactor to explode in the manner of an atomic bomb.

TYPES AND MAJOR CHARACTERISTICS OF NUCLEAR POWER REACTORS

In order, the following types of nuclear fission reactors are described in this section: (1) light water reactors, (a) pressurized water reactors, (b) boiling-water reactors; (2) high-temperature gas-cooled reactors; (3) heavy water reactors; and (4) fast breeder reactors. Military reactors are not described.

Contemporary Light-Water Reactors (LWRs)[1]

These reactors are of two principal designs: (1) *pressurized water reactors* (PWR), and (2) *boiling-water reactors* (BWR). In a PWR, heat generated in the nuclear core is removed by water (reactor coolant) circulating at high pressure through the primary circuit. The water in the primary circuit both cools and moderates the reactor. Heat is transferred from the primary to the secondary system in a heat exchanger, or boiler, thereby generating steam in the secondary system. The BWR differs from the PWR primarily in that boiling takes place in the reactor itself. Comparable steam temperatures are possible at pressures of about 1000 pounds per square inch (6.9 mPa) as contrasted with 2000 psi (13.8 mPa) for pressurized reactors.

Contemporary Boiling Water Reactor (BWR)

Aside from its heat source, the boiling water reactor (BWR) generation cycle is substantially similar to that found in fossil-fueled power plants. One of the first BWRs was the Vallecitos BWR, a 1000 psi (6.9 mPa) reactor which powered a 5 MW electric generator and provided power to the Pacific Gas & Electric Company grid through 1963. Power output capabilities have increased many times during the intervening years as shown by tabular summaries given later in this entry.

The direct-cycle boiling water reactor nuclear system (Fig. 1) is a steam generating system consisting of a nuclear core and an internal structure assembled within a pressure vessel, auxiliary systems to accommodate the operational and safeguard requirements of the nuclear reactor, and necessary controls and instrumentation. Water is circulated through the reactor core producing saturated steam which is separated from the recirculation water, dried in the top of the vessel, and directed to the steam turbine-generator. The turbine employs a conventional regenerative cycle with condenser de-aeration and condensate demineralization. The direct-cycle system is used because of its inherently simple design, contributing to reliability and availability.

The steam from a BWR is, of course, radioactive. The radioactivity is primarily ^{16}N, a very short-lived nitrogen isotope (7 seconds half-life) so that the radioactivity of the steam system exists only during power generation. Extensive generating experience has demonstrated that shutdown maintenance on a BWR turbine, condensate, and feedwater components can be performed essentially as a fossil-fuel plant.

The reactor core, the source of nuclear heat, consists of fuel assemblies and control rods contained within the reactor vessel and cooled by the recirculating water system. A 1,220-MWe BWR/6 core consists of 732 fuel assemblies and 177 control rods, forming a core array 16 feet (4.8 meters) in diameter and 14 feet (4.2 meters) high. The power level is maintained or adjusted by positioning control rods up and down within the core. The BWR core power level is further adjustable by changing the recirculation flow rate without changing control rod position, a feature that contributes to excellent load-following capability.

The BWR is the only light water reactor system that employs bottom-entry control rods. From the very first BWRs, bottom-entry control rods have been used because reactivity and moderator density is highest in the lower part of the core. They provide optimum power shaping characteristics for the type of core where moderator density is varied as a function of power level. Bottom-entry and bottom-mounted control rod drives also allow refueling without removal of rods and drives, and allow drive testing with an open vessel prior to initial fuel loading, or at each refueling operation. The hydraulic system, using reactor system pressure, provides rod insertion forces that are greater than gravity or mechanical systems.

The BWR requires substantially lower primary coolant flow through the core than pressurized water reactors. The core flow of a BWR is the sum of the feedwater flow and the recirculation flow, which is typical

[1] In nuclear power technology, ordinary water, in contrast with *heavy water*, is termed *light water*.

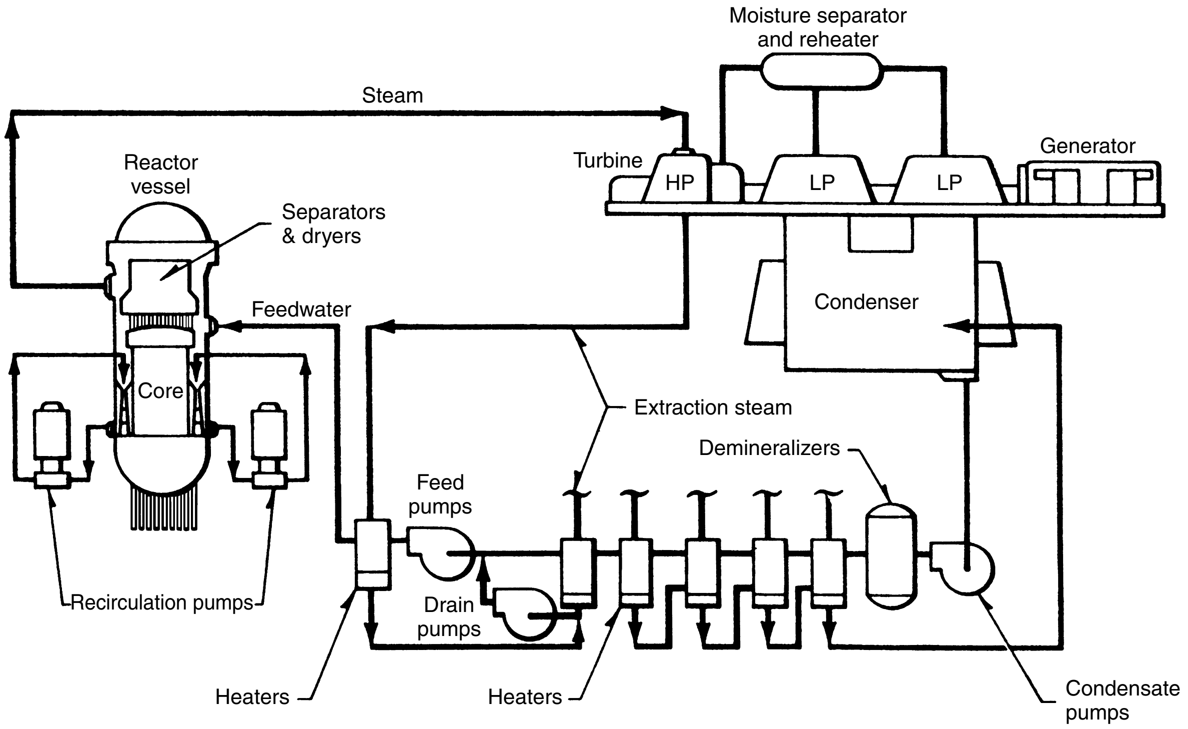

Fig. 1. Contemporary direct-cycle reactor system used in boiling water reactor. (*General Electric*)

of any boiler. Unique to the BWR is the application of jet pumps inside the reactor vessel. See Fig. 2. The jet pumps deliver their driving force from the external recirculation pumps and generate about two-thirds of the recirculation flow within the reactor vessel. The jet pumps also contribute to the inherent safety of the BWR design under loss-of-coolant emergency conditions because they continue to provide internal circulation with one or both external recirculation loops out of service. The BWR can deliver about one-third power through this natural jet pump circulation mode, a vital capability in effecting a "black start" (a fully fresh start-up of a reactor) of the plant without external power.

The BWR operates at constant pressure and maintains constant steam pressure similar to most fossil-fueled boilers. The BWR primary system operates at pressure about one-half that of a pressurized water reactor primary system, while producing steam of equal pressure and quality.

The integration of the turbine pressure regulator and control system with the reactor water recirculation flow control system permits automated

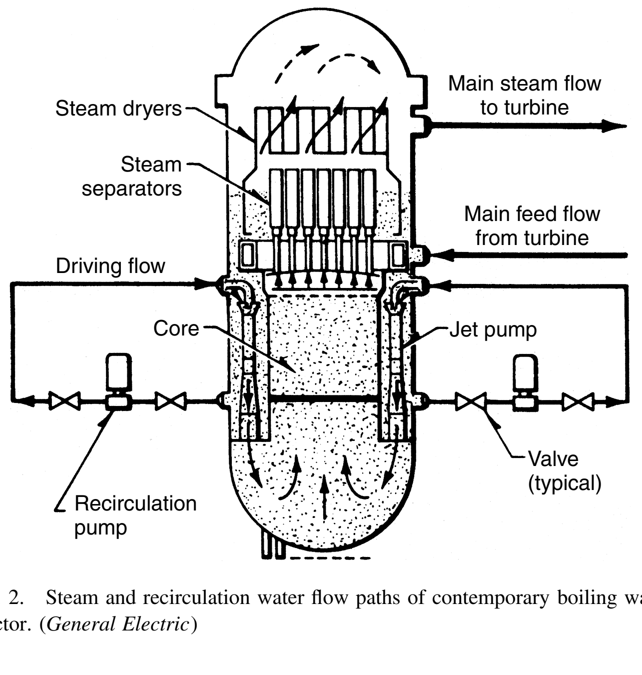

Fig. 2. Steam and recirculation water flow paths of contemporary boiling water reactor. (*General Electric*)

changes in steam flow to accommodate varying load demands on the turbine. Power changes of up to 25% can be accomplished automatically by recirculation flow control alone, at rate of 15% per minute increasing and 60% per minute decreasing. This provides a load-following capability that can track rapid changes in power demand.

Nuclear Boiler Assembly. This assembly consists of the equipment and instrumentation necessary to produce, contain, and control the steam required by the turbine-generator. The principal components of the nuclear boiler are: (1) reactor vessel and internals—reactor pressure vessel, jet pumps for reactor water circulation, steam separators and dryers, and core support structure; (2) reactor water recirculation system—pumps, valves, and piping used in providing and controlling core flow; (3) main steam lines—main steam safety and relief valves, piping, and pipe supports from reactor pressure vessel up to and including the isolation valves outside of the primary containment barrier; (4) control rod drive system—control rods, control rod drive mechanisms and hydraulic system for insertion and withdrawal of the control rods; and (5) nuclear fuel and in-core instrumentation.

Reactor Assembly. This assembly (Fig. 3) consists of the reactor vessel, its internal components of the core, shroud, top guide assembly, core plate assembly, steam separator and dryer assemblies and jet pumps. Also included in the reactor assembly are the control rods, control rod drive housings and the control rod drives.

Each fuel assembly that makes up the core rests on an orificed fuel support mounted on top of the control rod guide tubes. Each guide tube, with its fuel support piece, bears the weight of four assemblies and is supported by a control rod drive penetration nozzle in the bottom head of the reactor vessel. The core plate provides lateral guidance at the top of each control rod guide tube. The top guide provides lateral support for the top of each fuel assembly.

Control rods occupy alternate spaces between fuel assemblies and may be withdrawn into the guide tubes below the core during plant operation. The rods are coupled to control rod drives mounted within housings welded to the bottom head of the reactor vessel. The bottom-entry drives do not interfere with refueling operations. A flanged joint is provided at the bottom of each housing for ease of removal and maintenance of the rod drive assembly.

Except for the Zircaloy in the reactor core, the reactor internals are stainless steel or other common corrosion-resistant alloys. The reactor vessel is a pressure vessel with a single full-diameter removable head. The base material of the vessel is low alloy steel, which is clad on the

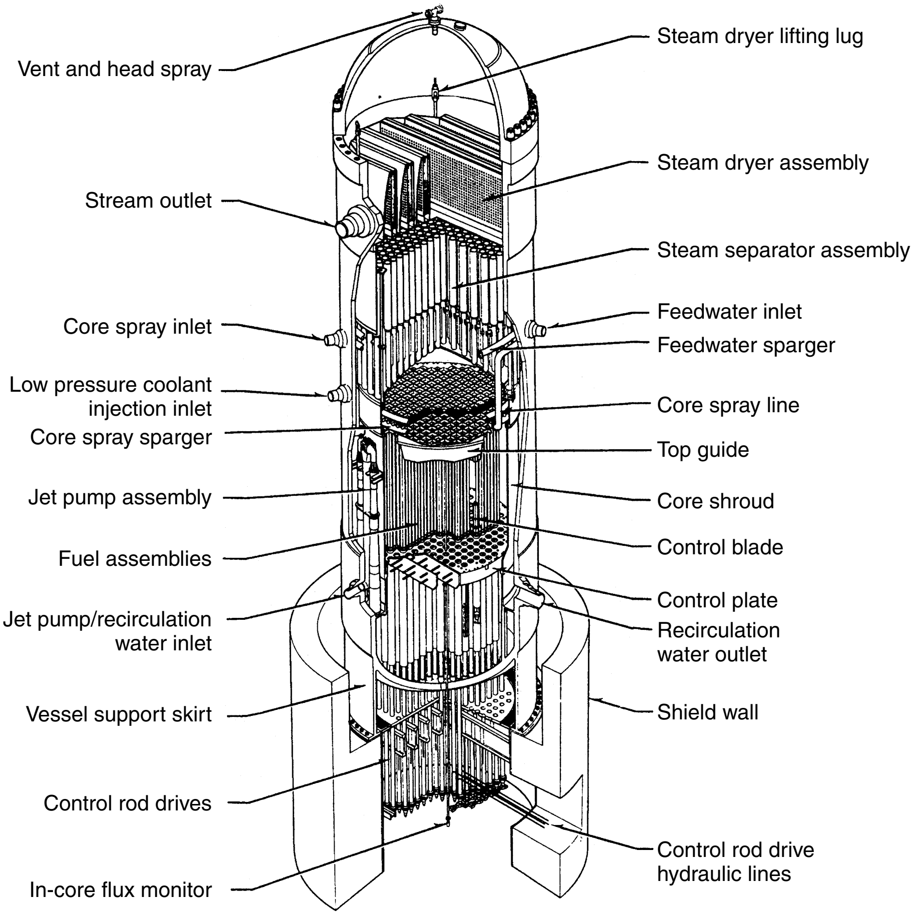

Fig. 3. Reactor assembly of contemporary boiling water reactor. (*General Electric*)

interior, except for nozzles with stainless steel weld overlay to provide the necessary resistance to corrosion.

The shroud is a cylindrical, stainless steel structure that surrounds the core and provides a barrier to separate the upward flow through the core from the downward flow in the annulus. Two ring spargers, one for low pressure core sprays and the other for high pressure core spray are mounted inside the core shroud in the space between the top of the core and steam separator base. The core spray ring spargers are provided with spray nozzles for the injection of cooling water under emergency conditions. A nozzle for the emergency injection of neutron absorber (sodium pentaborate) solution is mounted below the core in the region of the recirculation inlet plenum.

The steam separator assembly consists of a domed base, on top of which is welded an array of standpipes with a 3-stage separator located at the top of each standpipe. The steam separator assembly rests on the top flange of the core shroud and forms the cover of the core discharge plenum region. In each separator, the steam-water mixture rising through the standpipe impinges on vanes which give the mixture a spin to establish a vortex wherein the centrifugal forces separate the water from the steam in each of three stages. Steam leaves the separator at the top and passes into the wet steam plenum below the dryer. The separated water exits from the lower end of each stage of the separator and enters the pool that surrounds the standpipes to join the downcomer annulus flow.

The steam dryer assembly is mounted in the reactor vessel above the separator assembly and forms the top and sides of the wet steam plenum. Vertical guides on the inside of the vessel provide alignment for the dryer assembly during installation. The dryer assembly is supported by pads extending inward from the vessel wall and is held down in position during operation by the vessel head. These vanes are attached to a top- and bottom-supporting member forming a rigid, integral unit. Moisture is removed and carried by a system of troughs and drains to the pool surrounding the separators and then into the recirculation downcomer annulus between the core shroud and reactor vessel wall.

Control Rod Drive System. Positive core reactivity control is maintained by the use of movable control rods interspersed throughout the core. These control rods thus control the overall reactor power level and provide the principal means of quickly and safely shutting down the reactor. The rods are vertically moved by hydraulically actuated, locking piston type drive mechanisms. The drive mechanisms perform both a positioning and latching function, and a scram function with the latter overriding any other signal (scram signifies prompt shutdown).

Core Configuration. The reactor core of the BWR is arranged as an upright cylinder containing a large number of fuel assemblies and located within the reactor vessel. The coolant flows upward through the core. The plan of a typical core arrangement of a large BWR is shown in Fig. 4. The lattice configuration is shown in Fig. 5.

Fuel Rod. A fuel rod consists of uranium dioxide (UO_2) pellets and a Zircaloy-2 cladding tube. The UO_2 pellets are manufactured by compacting and sintering UO_2 powder into cylindrical pellets and grinding to size. The immersion density of the pellets is approximately 95% of theoretical UO_2 density. A fuel rod is made by stacking pellets into a cladding tube that is evacuated, back-filled with helium to atmospheric pressure, and sealed by welding Zircaloy end plugs in each end of the tube. The pellets are stacked to an active height of 148 inches (376 centimeters) with the top 12 inches (30.5 centimeters) of tube available as a fission gas plenum. A plenum spring is provided in the plenum space to exert a downward force on the pellets, the spring keeping the pellets in place during the pre-irradiation handling of the fuel bundle.

Fuel Bundle. Each fuel bundle contains 63 fuel rods, which are spaced and supported in a square (8×8) array by a lower and upper tie plate. Three types of rods are used in a fuel bundle: (1) tie rods; (2) a water rod; and (3) standard fuel rods. The third and sixth fuel rods along each outer edge of a bundle are tie rods. The eight tie rods in each bundle have threaded-end plugs, which screw into the lower tie plate casting. A stainless steel hexagonal nut and locking tab is installed on the upper end plug to hold the assembly together. The water rod not only serves as a spacer support rod, but also provides a source of moderator material near the center of the fuel bundle. This flattens the neutron flux across the bundle,

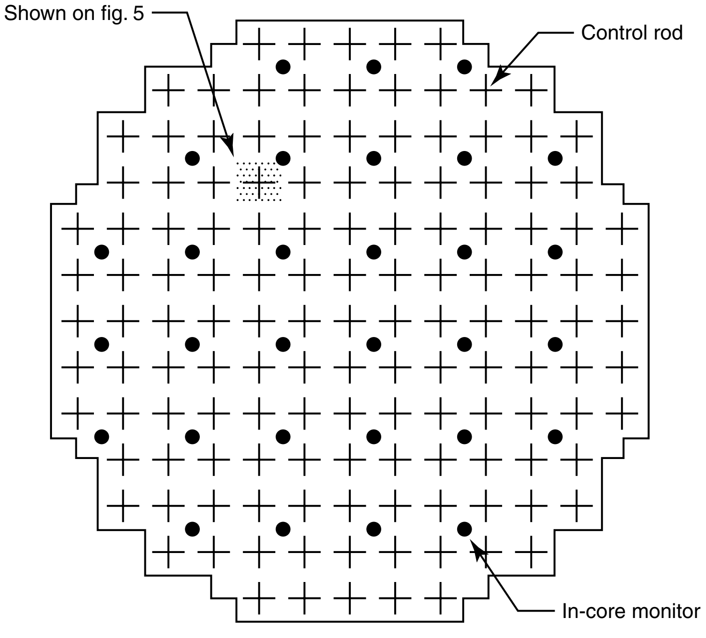

Fig. 4. Typical core arrangement in contemporary boiling water reactor. (*General Electric*)

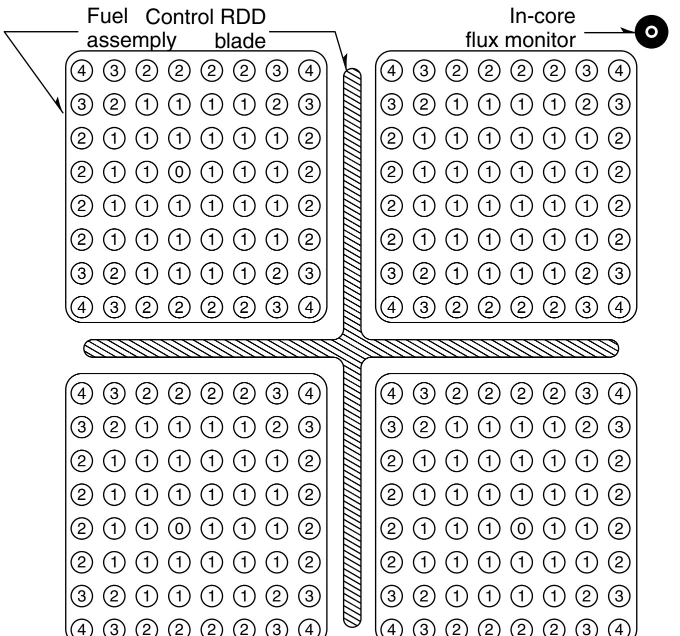

Fig. 5. Core lattice arrangement in contemporary boiling water reactor. (*General Electric*)

and leads to lower local peaking factors and better utilization of uranium in the interior rods of the fuel assembly.

The initial core will contain fuel assemblies having a common average enrichment ranging from approximately 1.6% (weight) of ^{235}U to 2.2%, depending upon initial cycle requirements. Each assembly will contain different enrichment rods. Selected rods in each assembly will, in addition, be blended with gadolinium burnable poison. The reload fuel will also contain four different enrichment rods with an average enrichment in the range of 2.4 to 2.8%. Different ^{235}U enrichments are used in fuel assemblies to reduce the local power peaking. Low enrichment rods are used in the corner rods and in the rods nearer the water gaps; higher enrichment uranium is used in the central part of the fuel bundle.

Fuel Channel. A fuel channel encloses the fuel bundle. The combination of a fuel bundle and a fuel channel is called a fuel assembly. See Fig. 6.

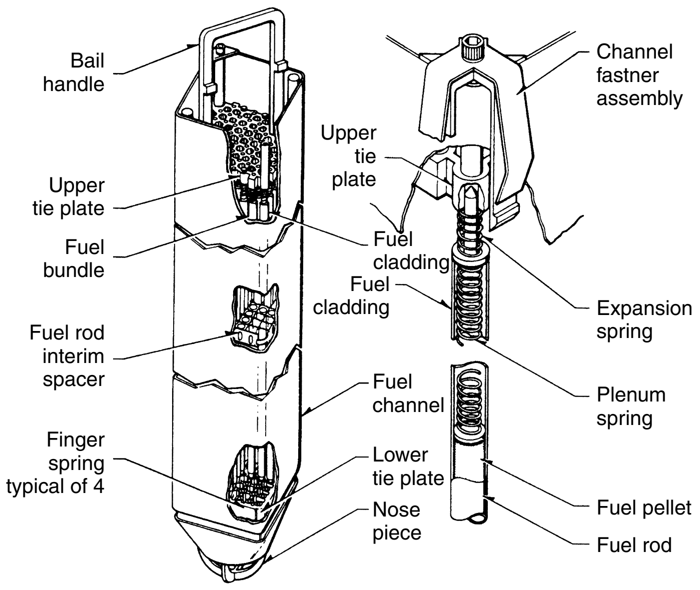

Fig. 6. Fuel assembly of contemporary boiling water reactor. (*General Electric*)

The channel is a square-shaped tube fabricated from Zircaloy 4. The outer dimensions are 5.518 inches (14 centimeters) by 5.518 inches (14 centimeters) by 166.9 inches (424 centimeters) long. The reusable channel makes a sliding seal fit on the lower tie plate surface. It is attached to the upper tie plate by the channel fastener assembly, consisting of a spring and a guide, and a cap screw secured by a lock washer. The fuel channels direct the core coolant flow through each fuel bundle and also serve to guide the control rods.

Neutron Sources. Several antimony-beryllium start-up sources are located within the core. They are positioned vertically in the reactor by "fit up" in a slot (or pin) in the upper grid and a hole in the lower core support plate. The active portion of each source consists of a beryllium sleeve enclosing two antimony-gamma sources. The resulting neutron emission strength is sufficient to provide indication on the source range neutron detectors for all reactivity conditions equivalent to the condition of all rods inserted prior to initial operation. The active source material is entirely enclosed in a stainless steel cladding with an outside diameter of approximately 0.7 inch (1.8 centimeter). The source is cooled by natural circulation of the core leakage flow in the annulus between the beryllium sleeve and the antimony-gamma sources.

Core Design Margins. The reactor core is designed to operate at rated power with sufficient design margin to accommodate changes in reactor operations and reactor transients without damage to the core. In order to accomplish this objective, the core is designed, under the most limiting operating conditions and at 100% rated power, to meet the following bases. (1) The maximum linear heat generation rate, in any part of the core, is always less than 13.4 kW/foot (43.97 kW/meter). (2) The minimum ratio between critical heat flux and fuel operating heat flux, in any part of the core, is always greater than 1.9.

Power Distribution. The design power distribution is divided for convenience into several components: (1) relative assembly power; (2) local; and (3) axial. The relative assembly power peaking factor is the maximum fuel assembly average power divided by the reactor core average assembly power. The local power peaking factor is the maximum fuel rod average heat flux in an assembly divided by the assembly average fuel rod heat influx. The axial power peaking factor is the maximum heat flux of a fuel rod divided by the average heat flux in that rod. Peaking factors vary throughout an operating cycle, even at steady-state full-power operation, since they are affected by withdrawal of control rods to compensate for fuel burnup. The design peaking factors represent the values of the most limiting power distribution that will exist in the core throughout its life.

Because of the presence of steam voids in the upper part of the core, there is a natural characteristic for a BWR to have the axial power peak in the lower part of the core. During the early part of an operating cycle, bottom-entry control rods permit a partial reduction of this axial peaking by locating a larger fraction of the control rods in the lower part of the

core. At the end of an operating cycle, the higher accumulated exposure and greater depletion of the fuel in the lower part of the core reduces the axial peaking. The operating procedure is to locate control rods so that the reactor operates with approximately the same axial power shape throughout an operating cycle.

Reactivity Control. The movable boron-carbide control rods are sufficient to provide reactivity control from the cold shutdown condition to the full-load condition. Supplementary reactivity control in the form of solid burnable poison is used only to provide reactivity compensation for fuel burnup or depletion effects. The movable control rod system is capable of bringing the reactor to the subcritical when the reactor is an ambient temperature (cold), zero power, zero xenon, and with the strongest control rod fully withdrawn from the core. In order to provide greater assurance that this condition can be met in the operating reactor, the core is designed to obtain a reactivity of less than 0.99, or a 1% margin on the "stuck rod" condition. See Fig. 7.

Reactor Auxiliary Systems include: (1) a reactor water cleanup system for maintaining high reactor water quality by removing fission products, corrosion products, and other soluble and insoluble impurities; (2) a fuel and containment pool cooling and cleanup system—a system which accommodates the beta and gamma radiation heating from the fission products that remain in the spent fuel, as well as drywell heat transferred to the upper containment pool; (3) a closed cooling water system for reactor service consisting of a separate, force circulation loop; (4) emergency equipment cooling system; (5) standby liquid control system; (6) reactor core isolation cooling system; (7) emergency core cooling system; (8) high-pressure core spray system; and (9) residual heat removal system.

Contemporary Pressurized Water Reactor (PWR)

In a typical pressurized water reactor (PWR), heat generated in the nuclear core is removed by water (reactor coolant) circulating at high pressure through the primary circuit. The water in the primary circuit cools and moderates the reactor. The heat is transferred from the primary to the secondary system in a heat exchanger, or boiler, thereby generating steam in the secondary system. The steam produced in the steam generator, a tube-and-shell heat exchanger, is at a lower pressure and temperature than the primary coolant. Therefore, the secondary portion of the cycle is similar to that of the moderate-pressure fossil-fueled plant. In contrast, in boiling-water or direct-cycle systems, steam is generated in the core and is delivered directly to the steam turbine.

The similarities of basic pressurized water reactor design from one manufacturer to the next are more striking than the differences. Therefore, the description of one particular configuration (Combustion Engineering, Inc.) can suffice to convey the general operating principles. The major components of a PWR are: (1) the reactor vessel which contains the oxide fuel core, core intervals, control element assemblies, and in-core instruments; (2) the electrically-heated pressurizer; (3) the electric-motor-driven primary coolant pumps; and (4) the U-tube type steam generators. See Fig. 8. The primary coolant system layout can be fitted into a variety of containment types and concepts. A prestressed cylindrical containment is common. Figure 9 shows the arrangement in a spherical containment. This type of building lends itself to separation of safeguards equipment, steam lines, and emergency power supplies.

Steam Generators. The basic geometry is shown in Fig. 10. With the nuclear steam supply system operating at 3,817 MW, two steam generators produce a total of 17.18×10^6 pounds (7.89×10^6 kilograms) of steam per hour at 1,070 psia (72.8 atmospheres). The steam generators are constructed, using carbon steel pressure-containing members and Inconel-600 tubes. The tube-sheet is clad by weld deposit for maximum strength; tongue and groove construction of the divider plate places no stress on the tube-sheet cladding. Fusion welding of the end of each tube to the tube-sheet primary cladding provides an effective seal for leakage control, and "expanding" (explosively expanding) the tubes in the full length of the tube-sheet eliminates corrosion-prone crevices. An economizer section on the units improves heat transfer by preheating the incoming feedwater, using the low (primary side) temperature heat transfer area of the U-tubes. Multiple feed nozzles allow the economizer flow distribution to be optimized for each power level.

Reactor Coolant Pumps. As indicated by Fig. 8, four reactor coolant pumps are used, two for each steam generator. The pumps are vertical, single-bottom-suction, horizontal-discharge, motor-driven centrifugal units. The pump impeller is keyed and locked to its shaft. A complex system of

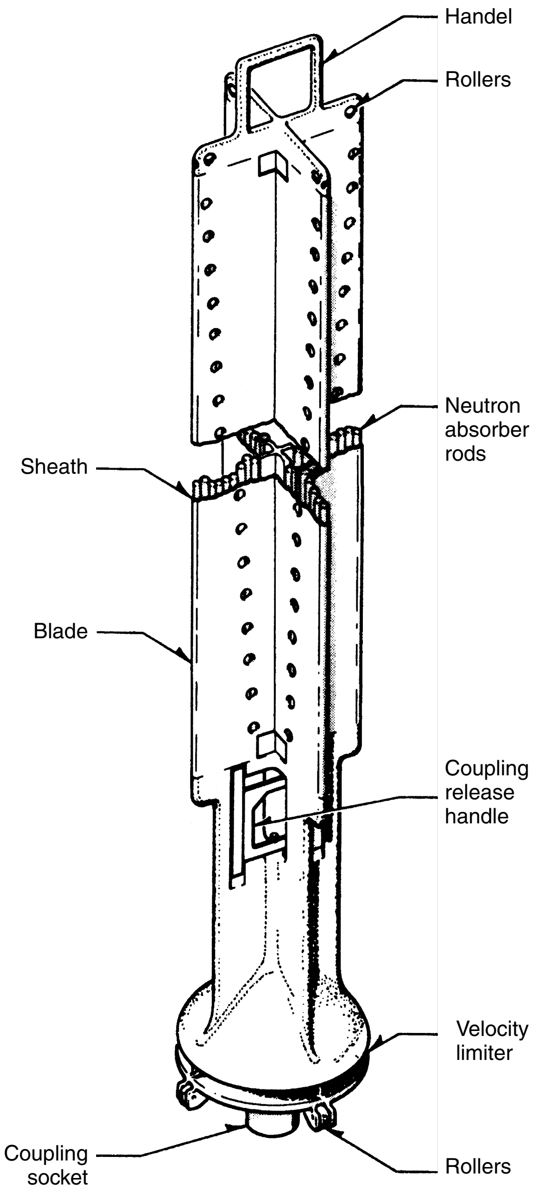

Fig. 7. Control rod used in contemporary boiling water reactor. The cruciform control rods contain 76 stainless steel tubes (19 tubes in each wing of the cross). These tubes are filled with boron carbide powder compacted to approximately 65% of theoretical density. The tubes are seal-welded with end plugs on either end. The individual tubes act as pressure vessels to contain the helium gas released by the boron-neutron capture reaction. The control rods have an active length of 144 inches (365.8 centimeters) of boron carbide, a span of 9.75 inches (24.8 centimeters), and an overall length of 173.75 inches (441.3 centimeters). The control rods can be positioned at 6-inch (15-centimeter) steps and have a nominal withdrawal and insertion speed of 3 inches (7.5 centimeters) per second. Control rods are cooled by the core leakage (bypass) flow. In addition to satisfying initial control effectiveness requirements, it is expected that the control rods will have an average lifetime of approximately 15 full-power years. (*General Electric*)

seals is used to prevent any leakage. The motors are designed to start and accelerate to speed under full load with a drop to 80% of normal rated voltage at the motor terminals. Each motor is provided with an anti-reverse rotation device. Each reactor coolant pump is provided with four vertical support columns, four horizontal support columns, and one vertical snubber. The structural columns provide support for the pumps during normal operation, earthquake conditions, and any hypothetical loss-of-coolant accident in either the pump suction or discharge line.

Pressurizer. The pressurizer is a cylindrical pressure vessel, vertically mounted and bottom supported. Energy to the water is supplied by replaceable direct-immersion electric heaters, which are inserted from the bottom head of the pressurizer. Nozzles are provided for spray, surge,

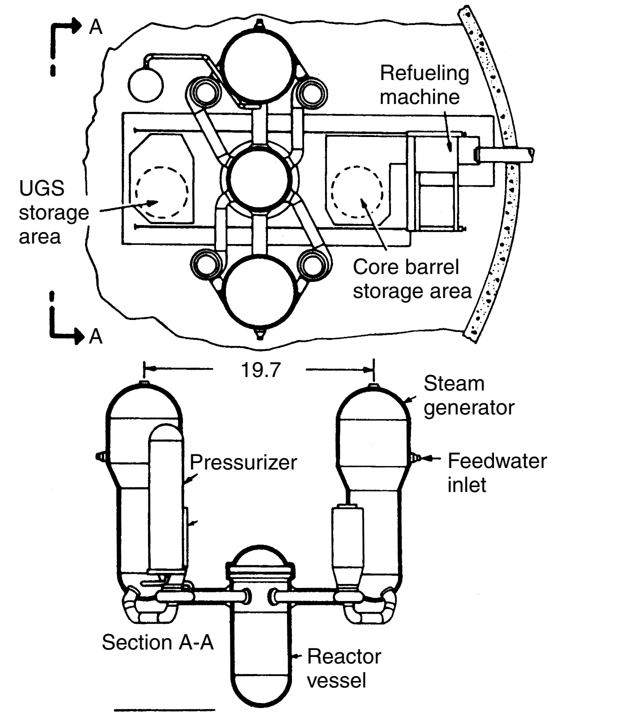

Fig. 8. Nuclear steam supply system for contemporary pressurized water reactor. (*Combustion Engineering*)

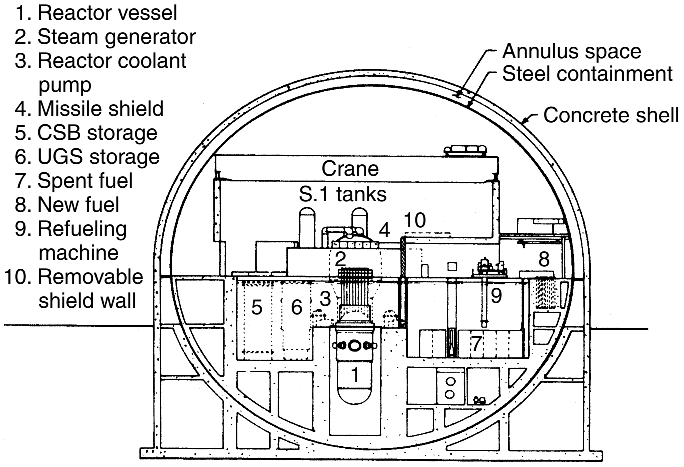

Fig. 9. Spherical containment for contemporary pressurized water reactor. (*Combustion Engineering*)

relief, and instrumentation connections. The pressurizer maintains reactor coolant system operating pressure and, in conjunction with the chemical and volume control system, compensates for changes in reactor coolant volume during load changes, heat-up, and cool-down. During full-power operation, the pressurizer is about $\frac{1}{3}$ full of saturated steam.

Reactor Vessel. This vessel is designed to contain the fuel bundles, the control element assembles, and the internal structures necessary for support of the core. The reactor is a stainless clad, thick-walled, carbon steel pressure vessel comprised of a cylinder with two hemispherical heads. The lower head is integrally welded to the vessel shell and contains in-core instrumentation nozzles. The upper closure head, containing the control element drive mechanism nozzles, is attached to the vessel by means of a bolted flange, thus permitting the head to be removed to provide access to the reactor internals. The head flange is drilled to match the vessel flange stud bolt locations.

The vessel flange is a forged ring with a machined ledge on the inside surface to support the core support barrel. The flange is drilled and tapped to receive the closure studs and is machined to provide a mating surface for the reactor vessel closure seals. Sealing is accomplished by using two

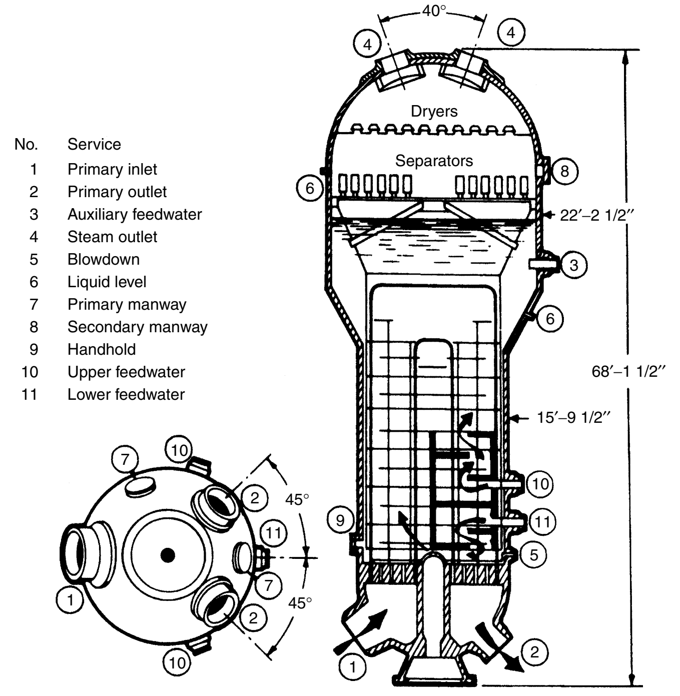

Fig. 10. Steam generator for contemporary pressurized water reactor. (*Combustion Engineering*)

silver-plated, NiCrFe-alloy, self-energizing O-rings. The space between the two rings is monitored to detect any inner-ring coolant leakage. The inlet and outlet nozzles are located radially on a common plane below the vessel flange. Extra thickness in the vessel course provides the reinforcement required for the nozzles. Snubbers built into the lower portion of the vessel shell limit the amplitude of any displacement of the core support barrel. Core stops are also built into the reactor vessel to limit the downward displacement of the core support barrel.

Cladding for the reactor vessel is a continuous integral surface of corrosion-resistant material, having $\frac{7}{32}$-inch (0.56 centimeter) nominal thickness, and a $\frac{1}{8}$-inch minimum thickness. The reactor vessel is supported by four vertical columns located under the vessel inlet nozzles. These columns are designed to flex in the direction of horizontal thermal expansion and thus allow unrestrained heat-up and cool-down. The columns also act as a hold-down device for the vessel. The supports are designed to accept normal loads and seismic and pipe rupture accident loads.

The reactor arrangement is shown in Fig. 11. The barrel-calandria guide structure is a rugged (3-inches thick, barrel section) unit that can withstand and protect all control element fingers from the combined effects of seismic and blowdown loads that may result from a loss-of-cooling accident. The calandria structure fits over the control element guide tubes of the fuel assemblies, aligning all fuel assemblies, and laterally restraining the top ends of the fuel assemblies. With the upper guide structure in place, a continuous guide tube for each control finger is formed, extending from the top of the tube-sheet to the bottom of the fuel assembly. Because of this feature, which isolates every control finger from the coolant crossflow, flexibility is obtained in the number of control fingers that can be attached to one control assembly, i.e., one control element assembly can serve more than one fuel assembly.

Severe emergency core cooling system criteria require that the builders of water reactors increase the linear feet of fuel in the reactor core for the same power in order to reduce LOCA (loss-of-cooling accident) fuel temperatures. In the unit described here, an assembly with a 16 × 16 fuel rod array of smaller diameter rods is used in the same assembly envelope that was occupied by a 14 × 14 assembly in earlier designs. This results in a maximum linear heat rate decrease in the assembly of about 25%.

As shown in Fig. 12, the active core is made up of 241 fuel assemblies, all of which are mechanically identical. As indicated by Fig. 13, each fuel assembly contains 236 Zircaloy-clad, UO_2 fuel rods retained in a structure consisting of Zircaloy spacer grids welded at about 15-inch (38.1-centimeter) intervals to five Zircaloy control element assembly guide tubes which, in turn, are mechanically fastened at each end to stainless

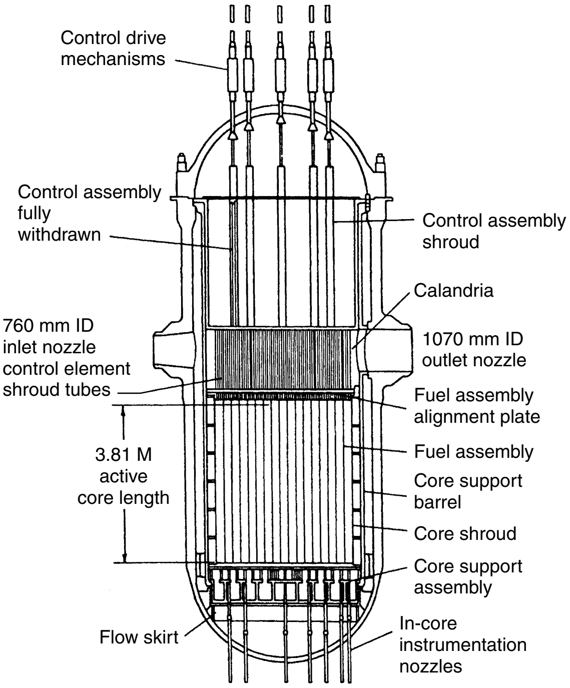

Fig. 11. Reactor arrangement in contemporary pressurized water reactor

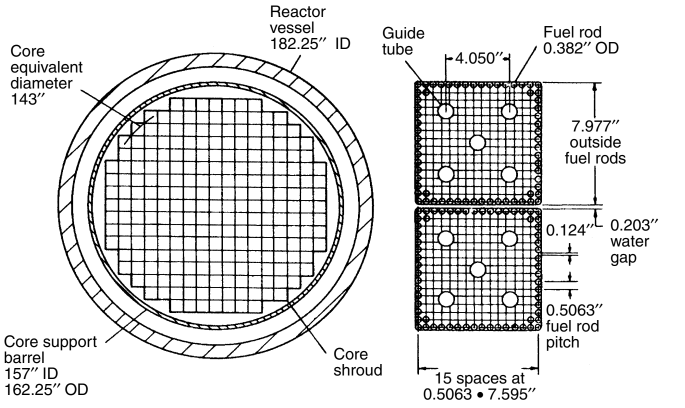

Fig. 12. Reactor core cross section of contemporary pressurized water reactor with 241 fuel assemblies. (*Combustion Engineering*)

steel end fittings. The overall length of the fuel assembly is about 177 inches (450 centimeters) and the cross section is about 8 inches (20.3 centimeters) by 8 inches (20.3 centimeters). Each fuel assembly weighs about 1,450 pounds (657.7 kilograms). With reference to Fig. 13, fuel rods, consisting of uranium dioxide (UO_2) pellets of low enrichment canned in thin-walled Zircaloy-4 tubing, are designed to achieve average burnups of about 33,000 MWD/MTU (thermal megawatt days/metric tons of uranium) and peak burnups of about 50,000 MWD/MTU. The design factors limiting burnup of the fuel are the effects on the clad of volumetric changes of the fuel pellet and fission gas release.

As indicated in Fig. 13, the fuel rod consists essentially of 0.325-inch (0.82-centimeter) diameter, 0.390-inch long UO_2 pellets canned in a 0.382-inch (0.97-centimeter) outside diameter Zircaloy-4 tube. The high density fuel pellets are dished at both ends to allow for axial differential thermal expansion and fuel volumetric growth with burnup.

The control element assemblies consist of an assembly of 4, 8, or 12 fingers approximately 0.8-inch (2-centimeter) outside diameter and arranged as shown in Fig. 14. The use of cruciform control rods, as in boiling water and early pressurized water reactors, necessitates large water gaps between the fuel assemblies to ensure that the control rods will scram (prompt shutdown) satisfactorily. These gaps cause peaking of the power in fuel rods adjacent to the water channel compared to fuel rods some distance from the channel.

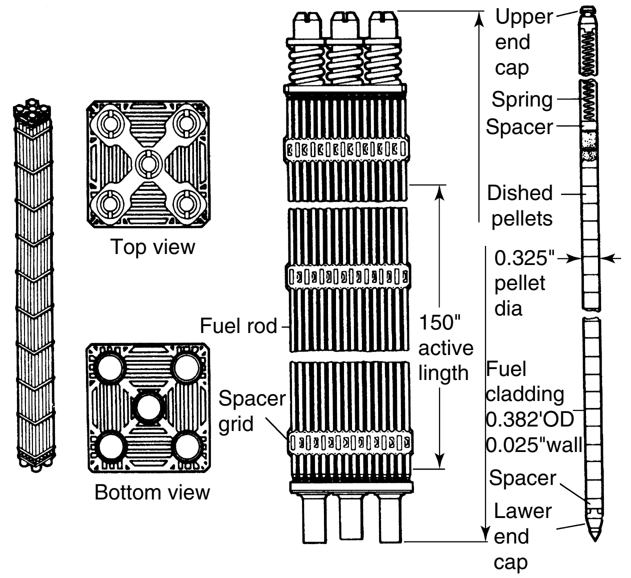

Fig. 13. Fuel assembly used in contemporary pressurized water reactor

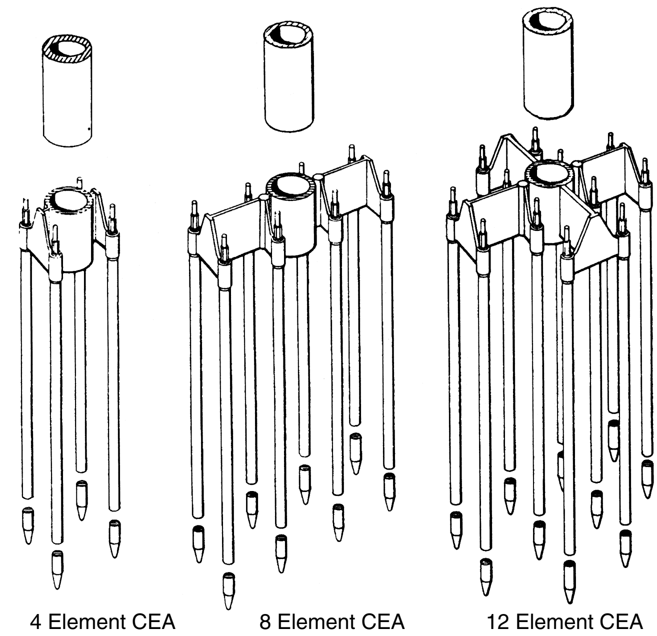

Fig. 14. Four 8- and 12-element control element assemblies. (*Combustion Engineering*)

A five-hole assembly design was evolved from consideration of the lower peaking effect of smaller (removal of one fuel rod) water holes versus the mechanical advantages of larger (four fuel rods removed) water holes. The larger water holes allowed the use of rugged, 0.9-inch (2.3-centimeter) outside diameter by 0.035-inch (0.89-centimeter) thick Zircaloy guide tubes for the fuel assembly structure. These water holes are distributed relatively uniformly in the reactor core when placed in the 16×16 fuel rod lattice. The particular arrangement of water holes was selected in consideration of the water gap between fuel assemblies; the effect of the central water hole in the fuel assembly is balanced by the water gap between fuel assemblies. The mechanical simplicity and ruggedness outweigh the advantage of obtaining a small decrease in local peaking by using very small fingers. The slightly higher peaking associated with the design can be compensated, to a large extent, by varying the enrichment of the fuel in the rods adjacent to the control channel and/or by using water displacers in local hot spots.

The control element assembly, shown in Fig. 15, consists of 0.8-inch (2-centimeter) outside diameter Inconel tubes containing boron carbide pellets as the neutron absorbing material. A gas plenum is provided in order to limit the maximum stress due to generation of internal gas pressure.

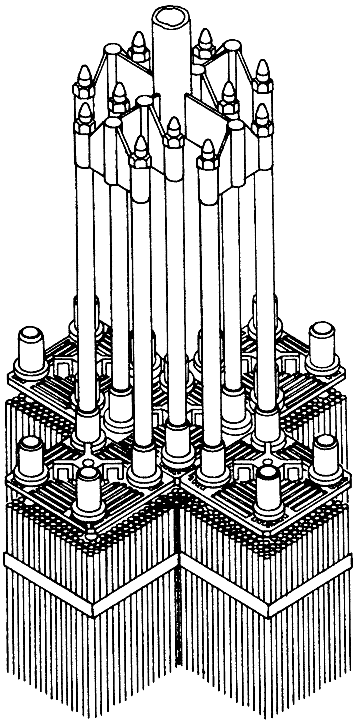

Fig. 15. Control element assembly and fuel for contemporary pressurized water reactor

The individual control fingers are attached mechanically and locked to the various spider assemblies. This allows for simplifications in manufacture, shipping, and assembly of the control element assembly. Because all fingers are removable and replaceable, servicing and disposal problems are decreased. It is intended that the spider assembly and its extension shaft be reused whenever possible.

Design of the upper guide structure permits flexibility in the number of control fingers that can be attached to one control assembly. The standard pattern of control assemblies is shown in Fig. 16. In the standard design, power changes at close to full power, shaping of the radial power distribution, and control of the axial power distribution are best handled by the low worth 4-finger control element assembly entering a single fuel assembly. Shutdown reactivity control in the peripheral region of the core is handled by the 8-finger control element assembly and in the central region of the core it is handled by the 12-finger control element assembly. The need for the two types of shutdown control element assemblies is to obtain "stuck rod worths" in the high reactivity fuel on the periphery of the core which are about equal to the control element assembly control worth in the lower reactivity central zone of the core.

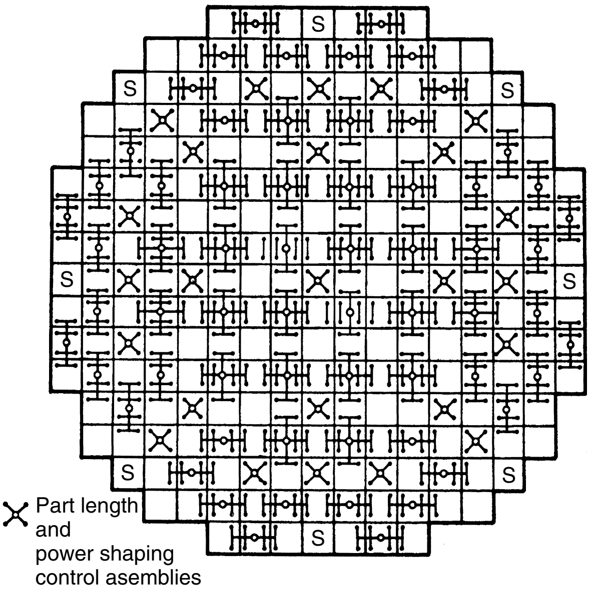

Fig. 16. Standard pattern of control assemblies in contemporary pressurized water reactor core. The pattern provides more-than-sufficient control for self-generated plutonium recycle. For complete open-market plutonium recycle, 4-element control assemblies are added in positions marked S

Instrumentation. The large size of present water reactors and the nuclear effects which can occur, such as xenon redistribution, stuck rods, and reactivity anomalies require that emphasis be placed on instrumentation and control systems if high plant availability is to be maintained, while providing the necessary protection due to abnormal occurrences. Because there are many reactivity effects that can produce changes in the reactor power distribution, more reliable operation can be obtained by on-line monitoring of the reactor. This is best achieved with in-core instrumentation. The system described here has provision for up to 61 in-core instrument (ICI) assemblies, which enter from the bottom of the reactor vessel. Radial distribution of the ICI is such that every type of fuel assembly, rodded and unrodded, is instrumented, assuming symmetrical core power distribution. Five sets of four symmetrically located ICI assemblies are included to monitor core power tilts. Also, every instrumented fuel assembly is either immediately adjacent to or diagonally adjacent to an instrumented fuel assembly to obtain good radial coverage of the core. Each of the ICI assemblies contains five self-powered fixed detectors distributed axially along the length of the core, a thermocouple at the end of the assembly to monitor outlet temperature, and a dry-well instrument tube which can accommodate a movable detector. This allows for high measurement accuracy of the on-line fixed detector.

The continuous monitoring and processing of the data from over 300 fixed detectors by the core monitoring computer provides the operator with information on core power distribution, maximum linear heat rate in the fuel, departure from nucleate boiling ratio, and fuel exposure. These data can then be used to obtain improved maneuvering of core power using the relative low worth 4-finger control element assemblies for power changes and power distribution control.

High-Temperature Gas-cooled Reactor (HTGR)

Although there have been comparatively few gas-cooled reactors installed for generating commercial nuclear electric power, the concept has a number of operating advantages over light-water reactors and could play an important role in the reactor designs for the next century.

The high-temperature gas-cooled reactor (HTGR) is a thermal reactor that produces desired steam conditions. Helium is used as the coolant. Graphite, with its superior high-temperature properties, is used as the moderator and structural material. The fuel is a mixture of enriched uranium and thorium in the form of carbide particles clad with ceramic coatings.

The high-temperature conditions and high thermal efficiency (approximately 39%) of the (HTGR) result in high performance. The amount of cooling water required to carry away the waste heat is significantly less than in a light-water reactor (LWR). The use of thorium in the fuel cycle decreases fuel cost, improves the conservation of fuel, and adds the large deposits of thorium to available fuel reserves. The HTGR has significant environmental advantages, including: (1) lower thermal discharge because of its high efficiency; (2) low release of radioactive waste because of the high-integrity fuel and the inert coolant; and (3) low consumption of raw materials because of high efficiency and use of thorium in the fuel cycle.

High operating temperatures at moderate pressures are achieved through the use of helium as the coolant. Helium is attractive as a coolant because it: (1) is chemically inert; (2) absorbs essentially no neutrons; and (3) makes no contributions to the reactivity of the system. Carbon dioxide also has been used as a coolant.

Graphite is used as the moderator and core structural material because of (1) excellent mechanical strength at high temperatures; (2) very low neutron-capture cross section; (3) good thermal conductivity; and (4) high specific heat. Graphite has a long history of use in thermal reactors. Because of low neutron-capture cross section, no neutrons are lost within the core through absorption in metallic fuel cladding or structural supports. Graphite also is well suited to high-temperature operations, increasing in strength with temperature up to a point (2,482°C) well beyond the operating range of the HTGR.

The use of the thorium-uranium fuel cycle in the HTGR provides improved core performance over the plutonium/uranium low-enrichment

cycle used in LWRs. The principal reason for this is that fissile ^{233}U produced from neutrons captured in thorium during reactor operation is neutronically a better fuel than ^{239}Pu, produced from ^{238}U in the low-enrichment cycle. The excellent neutronic characteristics of the graphite-moderated thorium/uranium cycle leads directly to high conversion ratios and low fuel inventories. Reduced ^{235}U inventories and make-up requirements spell reduced sensitivity to uranium prices.

Early Development of the HTGR

Work on the gas-cooled reactor has been underway essentially since the dawning of the nuclear power industry. The earliest developments were in Britain and France, at which time carbon dioxide gas was used as the coolant. In 1965, Britain opted for an advanced gas-cooled reactor (AGR). In 1969, France swung away from the HTGR (because of high construction costs) and targeted to the employment of more LWRs as well as commencing a concerted effort to develop a fast breeder type reactor. West Germany has been active in the development and testing of HTGRs since the early 1960s, but only recently (late 1980s) have the Germans indicated serious efforts toward commercialization of the HTGR. In the United States, a HTGR was installed at Peach Bottom, Pennsylvania, commencing commercial operation in 1974. As of the late 1980s, only one other HTGR was installed in the United States, the Fort St. Vrain plant near Denver, Colorado.

A simplified flow diagram of this station, which generates 842 MW (thermal) to achieve a net output of 330 MW (electrical), is given in Fig. 17. The helium coolant, at a pressure of about 700 psi (47.6 atmospheres), flows downward through the reactor core, where it is heated to 777°C. The coolant flow can be trimmed by the use of orifice valves located at the top of the core that are integral with the control rod drive mechanisms. From the reactor core, the coolant flows through the steam generators. After passing through the steam generators, the helium is returned to the core at a temperature of about 404°C by four steam-turbine-driven helium circulators. Two identical loops are used, each including a six-module steam generator and two helium circulators. Each loop contributes half of the total output of the nuclear steam supply system, which produces steam at 2,400 psig (163.3 atmospheres) and 538°C with single reheat to 538°C. The helium circulators are driven by the exhaust steam from the high-pressure turbine. This steam is then reheated and returned to the intermediate-pressure turbine. The circulators are also equipped with a Pelton water wheel drive so that they may be driven using the boiler feed pumps for emergency conditions.

The general reactor arrangement is shown in Fig. 18. The prestressed concrete reactor vessel (PCRV) is 31 feet in internal diameter with a 75-foot (23 meters) internal height. The upper and lower heads are nominally 15 feet (4.5 meters) thick, and the walls have a nominal thickness of 9 feet (2.7 meters). Thus, the PCRV provides the dual function of containing the coolant at operating pressure and also providing radiological shielding.

Reactor Core. The HTGR fuel element is a graphite block, hexagonal in cross section and having a grid of longitudinal fuel holes and coolant channels. The fuel element blocks are stacked in columns of eight blocks each and grouped into fuel regions consisting of a central column surrounded by six columns. Each region rests on a large core support block which, in turn, rests on graphite posts standing on the liner of the central cavity. Hexagonal graphite reflector elements are located above, below, and around the active core. These elements are surrounded by permanent side-reflector blocks to give the entire assembly a circular configuration. The fuel holes contain a rod consisting of ceramic-coated fuel particles in a graphite matrix. The coatings, applied by pyrolitic techniques, are multilayered to ensure a high degree of fission-product confinement. A porous interlayer, or buffer zone, accommodates the expansion of the irradiated fuel and provides storage space for gaseous fission products. The outer layer acts as a fission-product retention barrier and provides structural strength. In effect, the particle coating functions as a miniature spherical pressure vessel.

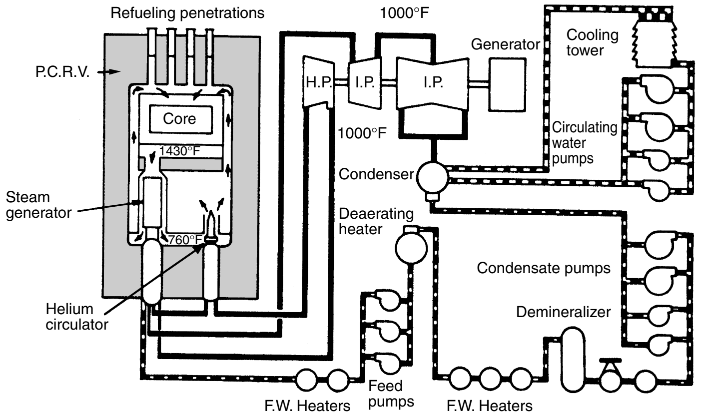

Fig. 17. Simplified flow diagram of Fort St. Vrain Nuclear Generating Station. (*GA Technologies*)

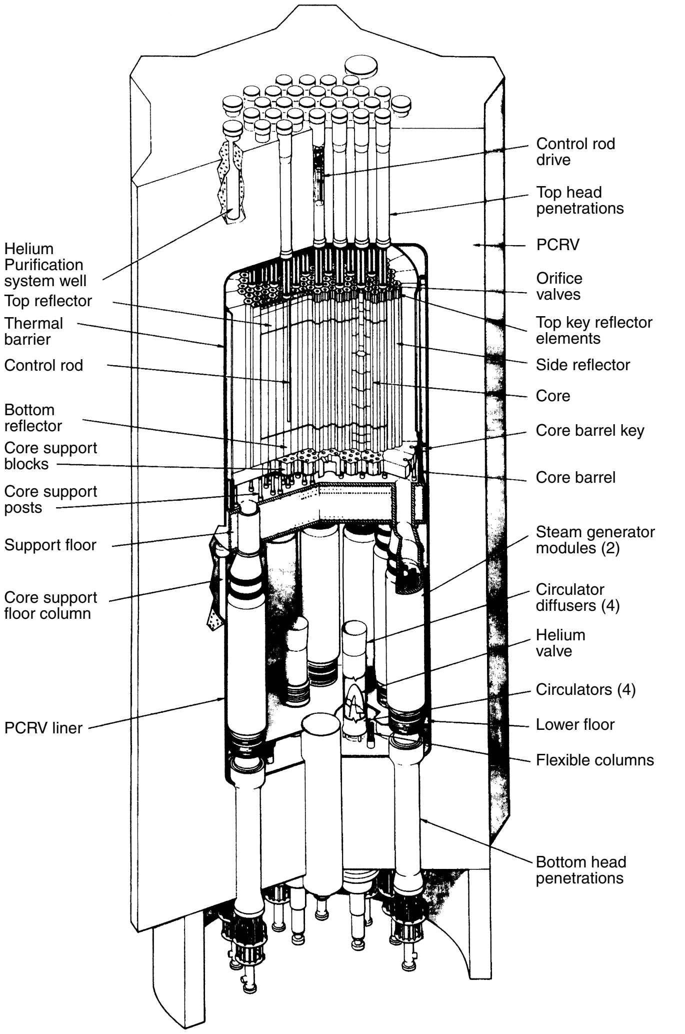

Fig. 18. General reactor arrangement of Fort St. Vrain high-temperature gas-cooled reactor. (*GA Technologies*)

To achieve a fuel management scheme with the lowest fuel cycle cost consistent with the current thermal and material performance limits, the following parameters are selected: (1) a fuel cycle incorporating uranium/thorium; (2) a fuel lifetime of four years; (3) an average power density of 8.4 W/cm^3; and (4) a refueling frequency of once a year.

The reactor is controlled by two control rods located in each refueling region. All control rod pairs have scram (quick shutdown) capability and are driven by gravity. A backup reserve shutdown system is included. This consists of boronated graphite pellets that can be introduced from hoppers located in each refueling penetration into the core via the cylindrical channels in the central fuel element of each refueling region.

Safeguard Systems. The design of HTGR incorporates many inherent safety features and a number of engineered safeguards. The inherent safety characteristics include negative power and temperature coefficients, assured by the thorium content of the fuel. In addition, the high heat capacity of the large mass of graphite ensures that any core temperature transient resulting from reactivity insertions or interruptions in cooling will be

slow and readily controllable. This important safety feature eliminates the need for an emergency core cooling system. Only a residual heat removal system is required for the long-term decay heat, and control of the HTGR is inherently easier than in reactors in which the coolant functions as the moderator. The uranium/thorium fuel contained in the ceramic-coated particles is not susceptible to sudden release of the stored-up fission products as a result of melting. Since the entire primary coolant system is contained within the PCRV, external piping, which might be subject to sudden rupture, is eliminated. Structural strength and integrity of the PCRV is enhanced by the redundant reinforcing steel and prestressed wire tendons. At the maximum credible pressure, the prestressing elements are not stressed above levels experienced during their initial tensioning. As a result, sudden loss of coolant due to prestress failure is not credible.

Second-Generation HTGRs

In addition to upgrading the HTGR at the Fort St. Vrain nuclear power station, efforts have been underway for several years to make both larger and smaller gas-cooled high-temperature reactors. Smaller, modular units could provide the flexibility needed by the public utilities as they plan their expansions for projected increases in electricity requirements. Inherent safety, already a feature of the HTGR, would be enhanced because of the smaller size and low power density of modular units. For example, it is estimated that the power density of a modular gas-cooled reactor would be only 3 kW/liter, as compared with 6 kW/liter for a large reactor and 100 kW/liter for a conventional pressurized-water reactor (PWR) as previously described.

In the new designs, if coolant were lost, the nuclear chain reaction would be terminated by the reactor's negative temperature coefficient after a modest temperature rise. Core diameter of the modular units would be limited so that decay heat could be conducted and radiated to the environment without overheating the fuel to the point where fission products might escape. Thus, inherent safety would be realized without operator or mechanical device intervention.

Large Commercial HTGRs[2]

Following construction of the Fort St. Vrain facility, the HTGR was marketed commercially in direct competition with large pressurized water reactors (PWRs) and boiling water reactors (BWRs). Between 1971 and 1975, ten such reactors were ordered by U.S. utilities. The designs of the commercial HTGR were similar to Fort St. Vrain in that they used the graphite based core structure, helium coolant, prestressed concrete reactor vessel (PCRV) and superheated steam cycle. However, the designs differed in that power outputs were significantly larger and the reactor system was rearranged to accommodate the larger-size components.

The large HTGRs had power ratings of 2000 and 3000 MWt which corresponded to net electrical outputs of 770 and 1160 MWe, respectively. An example of the rearranged reactor system is shown in Fig. 19. A multi-cavity PCRV was used to enclose the reactor system instead of the single-cavity PCRV used in Fort St. Vrain. This was a major advancement in PCRV technology and necessitated the development of a circumferential wire-wrap prestressing system instead of circumferential tendons, although the longitudinal tendons were retained. The sizes of the multi-cavity PCRV were approximately 100 feet (30 m) high by 120 feet (36 m) in diameter for the 3000 MWt plant and 100 feet (30 m) high by 105 feet (32 m) in diameter for the 2000 MWt plant.

The graphite reactor core was located in the central cavity of the PCRV. The steam generators and steam-driven main helium circulators were located in vertical cavities arranged around the periphery of the core. The 2000 MWt system had four steam generator-circulator side cavities while the 3000 MWt unit had six such cavities. The hot primary coolant helium (1366°F; 741°C) exiting from the bottom of the core collected in the lower core plenum from which it was distributed to the steam generators through the lower cross-ducts. The circulators, located above the steam generators, returned the cool helium (710°F; 377°C) through the upper cross-ducts to the upper core plenum. The helium in the upper plenum then flowed down through the core where it was heated.

Another feature of the large HTGRs was the core auxiliary cooling system which provided an independent means of core afterheat removal in the event that the main coolant loops (i.e., steam generators and steam-driven circulators) were shut down. The core auxiliary cooling system consisted of two redundant cooling loops, each capable of removing 100% of the afterheat, for the 2000 MWt plant and three redundant cooling loops, each capable of removing 50% of the decay heat, for the 3000 MWt plant. Each loop contained a motor-driven circulator and water-cooled heat exchanger and circulated flow through the core just at the main loops. Shutoff valves were located in both auxiliary and main loops to assure that helium would not bypass the core through the one system while the other system was in operation.

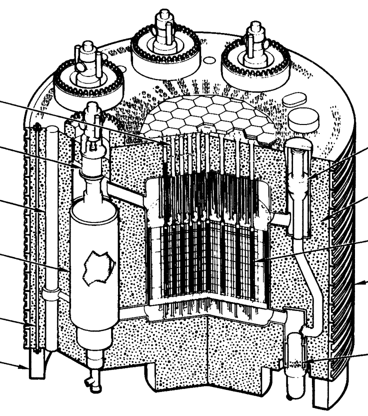

Fig. 19. Integrated HTGR nuclear steam system (1170 to 3360 MW thermal). (*GA Technologies*)

All ten large commercial HTGRs were ordered during the early 1970s as an indirect consequence of the energy crisis brought about by the oil embargo; all were cancelled by 1976. The combination of the recession plus new emphasis on conservation brought about a rapid reduction in electric energy demand which, in turn, resulted in cancellation of over 100 nuclear power plant orders, including the large HTGRs.

Small Modular HTGRs

In the early 1980s, the major influence on new designs was the renewed emphasis on safety brought about by the accident at the Three Mile Island nuclear plant. The experience from licensing and operation of nuclear plants during the 1970s indicated a need to reduce design complexity and develop passive approaches to reactor safety rather than rely on complex emergency safety systems. HTGR designers in the United States and Europe determined that a substantial reduction in plant size could enable the HTGR to be entirely inherently safe by virtue of the high temperature structural integrity of the graphite core and ceramic coated fuel. This means that a small HTGR would not require any active safety equipment or any action by the operator in order to prevent release of radioactivity for any accident condition.

A major concern with reducing plant size was the economic impact from reversing the economy of scale. However, it was learned that economy-of-scale effects could be offset by several beneficial factors that apply to smaller nuclear plants. This includes the shift of major portions of the work from the site to the factory; the learning effects appreciated by replication of a larger number of smaller units in a factory environment and the elimination or simplification of many components/systems no longer required for smaller plants.

These considerations led to the reconfiguration of the HTGR plant into a system of one or more downsized 350 MWt modular reactors. The physical arrangement of a single reactor module, designed for installation in a below-grade silo, is shown in Fig. 20. The primary components are contained within two vertically oriented metal pressure vessels connected by coaxial cross-duct. Thus, the field-erected PCRV, which was used on previous large HTGRs, was eliminated in favor of shop-fabricated metal pressure vessels. The use of metallic pressure vessels also facilitates installation in underground silos, which enhances the safety of the plant.

The reactor vessel, which is approximately 72 feet (22 m) high by 22.5 feet (6.9 m) in diameter, contains the graphite core, reflector, and shutdown heat removal system (non-safety). The other vessel contains a single helical coiled steam generator and motor-driven circulator with magnetic bearing instead of water-lubricated bearings as in previous concepts. The size of both vessels is within allowable limits for barge, rail, and overland transportation.

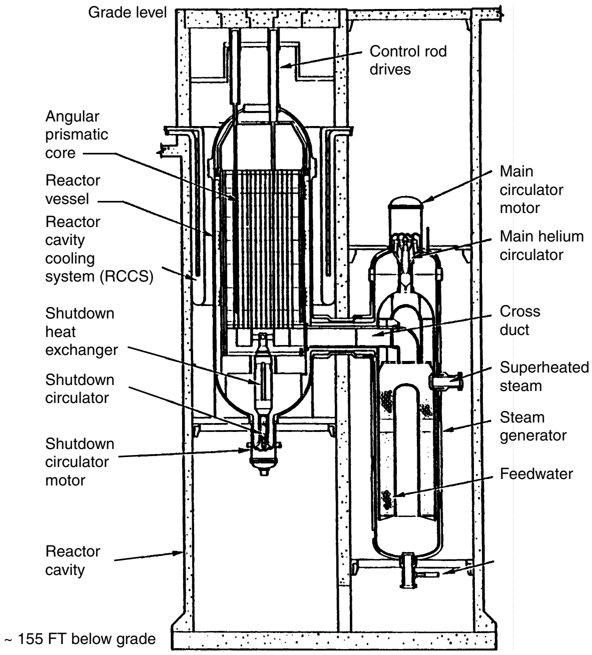

Fig. 20. Elevation of 350 MW modular HTGR. (*GA Technologies*)

During normal operation, the main circulator transports hot helium at 1266°F (686°C) from the bottom of the core to the steam generator which, in turn, produces superheated steam at 1005°F (541°C) and 2500 psia. The cold helium at 496°F (258°C) is returned to the top of the reactor core. During normal shutdown and refueling, the non-safety auxiliary shutdown heat removal system removes core afterheat if the main heat transport system is not operational.

A principal feature of the modular HTGR is its capacity for safely rejecting core afterheat in a completely passive manner (i.e., without the need for any active core cooling systems) such that any release of fission products from the fuel is prevented during severe accident conditions. This feature is a result of both the reactor system configuration and the high temperature capability of the fuel. In the event of a loss of forced circulation cooling of the core via either the main circulator/steam generator or auxiliary shutdown circulator/heat exchanger, core afterheat will continue to be safely removed by direct conduction through the core and reflector to the reactor vessel wall. The heat is then dissipated from the reactor vessel surface by radiation and natural convection to cooling panels surrounding the interior surface of the reactor cavity. See Fig. 20, previously mentioned. These panels are part of the Reactor Cavity Cooling System (RCCS) which consists of natural convection air ducts that ultimately transport the core afterheat directly to the atmosphere.

In order to achieve this passive core cooling capability in a reactor with a power level and power density that are economically attractive, the annular core arrangement shown in Fig. 21 was adopted. The active core consists of an annular region of hexagonal graphite fuel blocks containing standard HTGR fuel. Unfueled graphite reflector blocks make up the region inside the active core annulus and the region surrounding the outside of the annulus. This arrangement results in a higher radial heat conductance for fuel at the innermost radius than for a solid cylindrical active core. Thus, the annular core arrangement permits operation at a higher power for a given volume than a solid active core.

The modular HTGR uses the same form of fuel as the large HTGR and Fort St. Vrain installation except for the important difference that the ^{235}U enrichment was reduced to about 20% from the previous value of 93%. The fuel is in the form of coated fuel and fertile particles which are bonded into graphite rods and inserted into the hexagonal graphite fuel blocks. See Fig. 22. The fuel and fertile particles consist of uranium oxycarbide and thorium oxide kernels (about 350 micrometers in diameter), respectively, first coated with a porous graphite buffer, followed by three successive layers of pyrolytic carbon, silicon carbide, and pyrolytic carbon. The outer diameter of the coated particles is about 800 micrometers for the uranium particles and slightly larger for the thorium particles. The coatings essentially form a high-temperature refractory-based pressure vessel around each fuel/fertile kernel for the purpose of retaining fission products. Extensive operation and test data on these particles confirm that essentially no failure of the refractory coating occurs if the fuel is maintained below 3272°F (1800°C). As previously mentioned, the reactor design parameters were selected such that passive core afterheat removal will prevent this temperature from being reached during any credible accident condition. Thus, the modular HTGR is inherently, passively safe.

The reference plant arrangement features four 350 MWt HTGR modules supplying steam to two turbine generators that produce a net electrical output of 558 MWe at a new plant efficiency of 39.9%. Each reactor module is housed in an independent, vertical, cylindrical, concrete confinement, which is fully embedded in the earth. The four reactor modules share common systems for fuel handling, helium processing, and other essential services. A common control room is used to operate all four reactors and the turbine plant. Operation of the entire complex is completely automated. Human operator actions are not required for control during power production or to assure safe shutdown during hazardous conditions.

Potential for HTGRs

The HTGR's use of ceramic-coated fuel and graphite moderator enables operation of the reactor core at much higher temperatures than are required for electric power production via a steam Rankine cycle. Core outlet helium temperatures in excess of 1800°F (982°C) are achievable without impacting the integrity of the HTGR fuel or core structures. This very high temperature capability opens up the possibility for more efficient methods of power production or direct use of high-temperature thermal energy for process heat applications. See also **Cogeneration (Electricity and Thermal Energy)**.

An attractive electric power producing concept for the 21st century is the HTGR gas-turbine (HTGR-GT) which has the potential for thermal efficiencies over 50% by taking advantage of the high HTGR core outlet temperature. Although several variations in system configuration are possible, the most straightforward HTGR-GT concept is the direct Brayton cycle, illustrated in Fig. 23. This cycle is closed and the helium

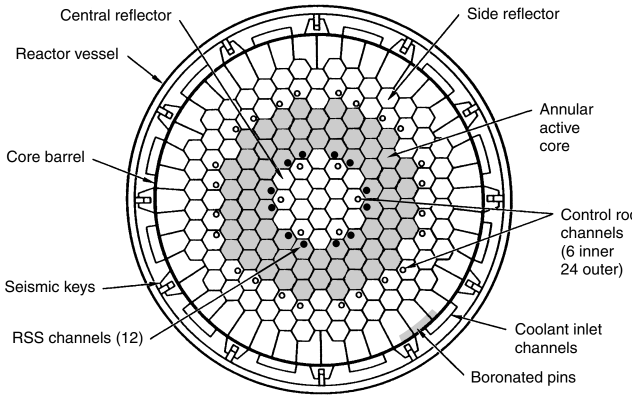

Fig. 21. Reactor core cross section of 350 MW modular HTGR. (*GA Techno logies*)

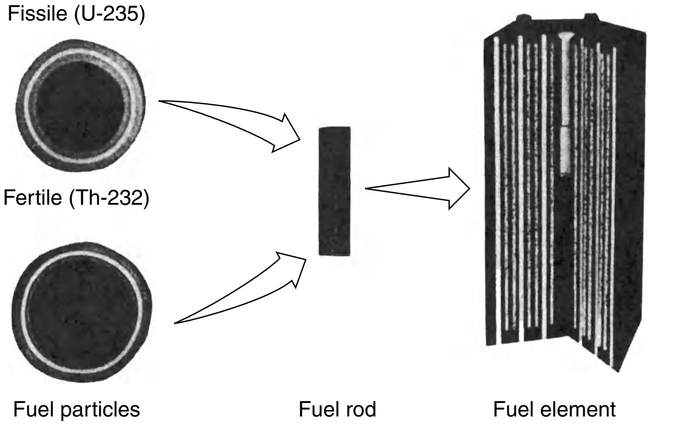

Fig. 22. Fuel components of HTGR. (*GA Technologies*)

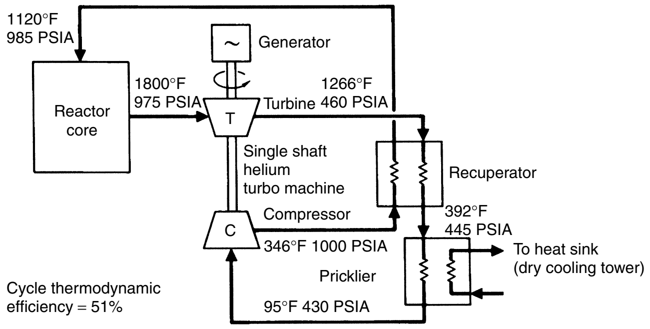

Fig. 23. HTGR gas turbine system with exceptional cycle thermodynamic efficiency. (*GA Technologies*)

primary coolant is also the working fluid for the power conversion system. The entire heat source and power conversion system of an HTGR-GT, which is capable of a net electric output of 170 MWe, can be enclosed within the two pressure vessels and cross-duct arrangement similar to the modular steam cycle HTGR previously shown in Fig. 20. The recuperator and precooler would occupy the same space as the steam generator and the turbo-compressor would replace the circulator.

Perhaps the most significant potential use of the HTGR's high temperature capability is the production of synthetic fuels from coal. The HTGR is an important option for supplanting the current consumption of oil and natural gas with synthetic natural gas (SNG). The HTGR can supply the necessary energy for this endothermic process and, therefore, increase the recoverable energy in the SNG product by at least 60% over traditional coal combustion processes.

The most effective method of SNG production with an HTGR is the steam-carbon reforming process in which superheated steam reacts with pulverized coal to form methane-rich SNG. A system for accomplishing this process is shown in Fig. 24. In this system, an intermediate heat exchanger (IHX) has been used to isolate the nuclear heat source from the process steam, thus allowing the use of conventional equipment for the SNG production portion of the plant. The IHX and reactor can be configured in the same arrangement as previously shown in Fig. 23, except that the IHX would occupy the space allocated to the steam generator.

Both gas turbine and process heat versions of the HTGR are based on the demonstrated high-temperature capability of the fuel and core structure. However, some development in the metallic components, such as the turbine, hot ducts and intermediate heat exchanger is necessary. Present commercial alloys would have limited lifetime under service conditions at 1650°F (899°C) and above. However, currently envisioned advancements in ceramics and carbon-carbon composites indicate that high-temperature nonmetallic substitutes for metallic alloys will soon be available. These materials advances are the key to making future application of the HTGR a reality.

Heavy Water Reactor (HWR)

During the atomic energy developments in the World War II years and for a period thereafter, the United States, the United Kingdom, and Canada cooperated closely and many of the nuclear scientists of these countries appreciated the merits of heavy water as a moderator. Each of these countries pursued some development of HWRs for commercial power generation, but at different paces and dedication. Only Canada took to the HWR for commercial power generation. See Figs. 25 and 26.

One of the first high-priority nuclear applications of the United States was for naval propulsion. Because of a very tight minimal physical size criterion, LWRs offered advantages over the HWR. The United Kingdom placed emphasis on the production of plutonium for weapons programs. Gas graphite reactors were a reasonable early choice. When commercial nuclear power was recognized as a needed source of energy, because of the accumulated operating experience it was reasonable to adapt the reactors which had already been developed in the United States and the United Kingdom for military purposes. Long-term savings at that time was not a major criterion.

In the postwar years, hydroelectric power amply met a large portion of Canada's power needs and its abundance made nuclear power quite noncompetitive. Canadian utility operators were used to capital-intensive plants combined with low operating costs. In analyzing the prospects for nuclear power in Canada, utility planners and engineers placed a

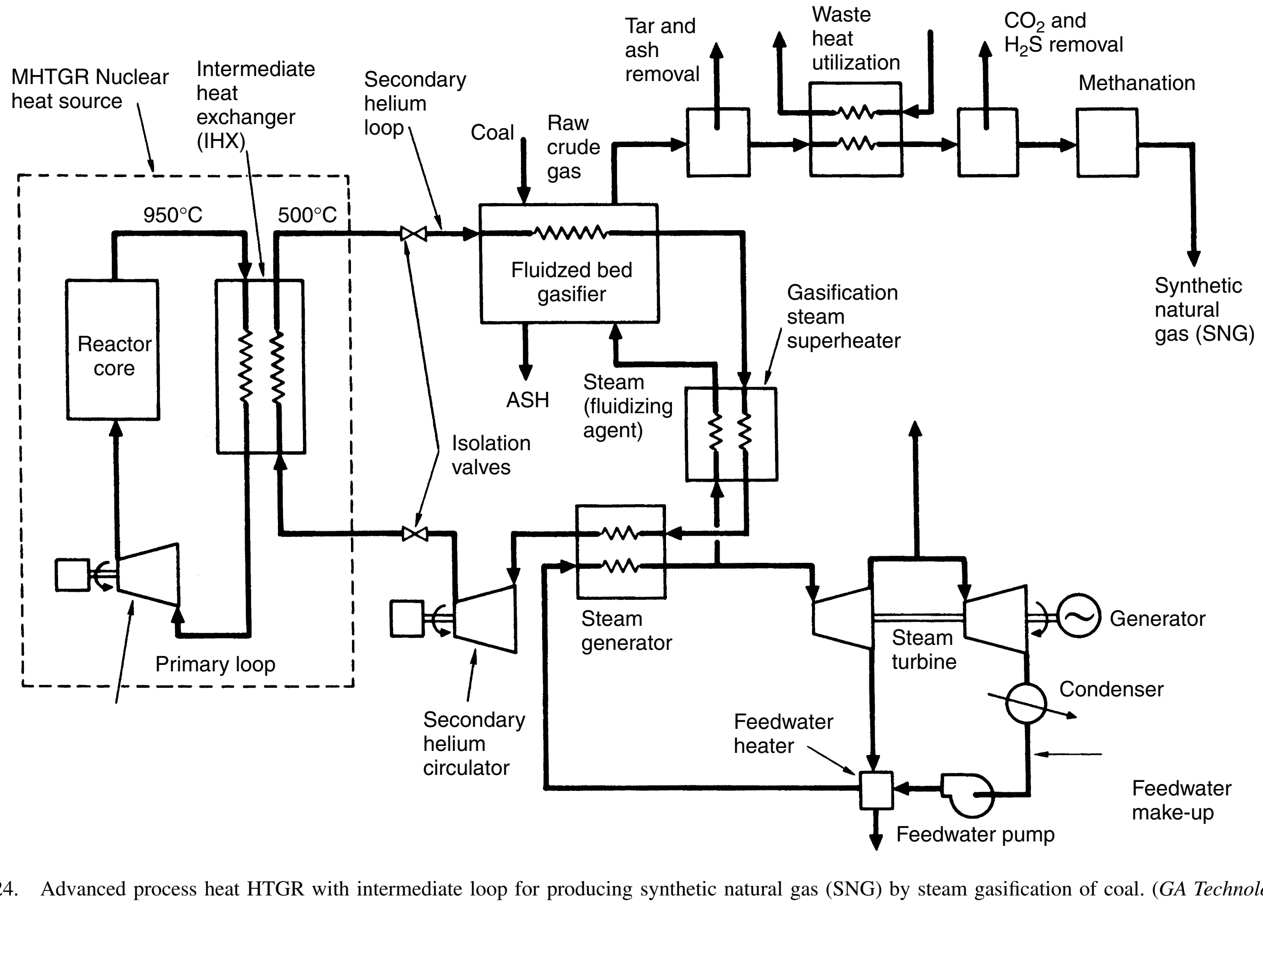

Fig. 24. Advanced process heat HTGR with intermediate loop for producing synthetic natural gas (SNG) by steam gasification of coal. (*GA Technologies*)

Fig. 25. Series of towers comprising part of the heavy water production plant at Ontario Hydro's Bruce nuclear power complex near Tiverton on the shores of Lake Huron. Heavy water is a clear, colorless liquid that looks and tastes like ordinary water. It occurs naturally in ordinary water in the proportion of approximately one part heavy water to 7000 parts of ordinary water. While ordinary water is a combination of hydrogen and oxygen (H_2O), heavy water (D_2O) is made of up of deuterium—a form, or isotope, of hydrogen—and oxygen. Deuterium is heavier than hydrogen in that it has an extra neutron in its atomic nucleus, so heavy water weighs about 10% more than ordinary water. It also has different freezing and boiling points. It is the extra neutron that makes heavy water more suitable than ordinary water for use in CANDU nuclear reactors as both a moderator and a heat transport medium. (*Ontario Hydro, Toronto, Ontario, Canada*)

significant value on low fueling costs, and thus neutron economy was paramount. Therefore, when commercial nuclear power studies commenced in Canada in the mid-1950s, the choice was the HWR. This choice was bolstered by experience with, and knowledge about, heavy water production plants gained when Canadian scientists were trading experience from the heavy water-moderated NRX research reactor when the United States was developing the Savannah River production facility, which was dismantled in the early 1990s.

Principal advantages of heavy-water reactors are: (1) more efficient absorption of the energy released in the reactor, (2) greater fuel "burn-up" and, therefore, fuel economy, and (3) refueling can take place while the reactor is in service.

The first Canadian nuclear power demonstration (NDP) reactor was of 20-MWe capacity and was configured similarly to a light water reactor. Because of limited facilities for making large pressure vessels, a modular pressure-tube design of the configuration shown in Fig. 24 was investigated. Zircaloy-2 had become available at that time for fabrication of the pressure tubes. Hence the NPD was constructed using Zircaloy as cladding material and uranium dioxide as fuel. The NPD reactor has been in operation since 1962. The CANDU (Canada Deuterium Uranium) power reactors, including the NPD, number over twelve facilities. See Figs. 27, 28, and 29.

CANDU power reactors are characterized by the combination of heavy water as moderator and pressure tubes to contain the fuel and coolant. Their excellent neutron economy provides the simplicity and low costs of once-through natural uranium cycling. Future benefits include the prospect of a near-breeder thorium fuel cycle to provide security of fuel supply without the need to develop a new reactor, such as the fast breeder. The CANDU system is appropriate for countries of intermediate economic and industrial capacity, such as Canada. Producing heavy water is fundamentally simpler than enriching uranium and commercial heavy water plants have been built in smaller sizes than would be possible for uranium enrichment plants. Although Canada has rather generous supplies and reserves of uranium, there is increasing pressure on Canada to export uranium, a pressure that will probably intensify further if the introduction of fast breeder reactors in other countries is delayed. The current simplest possible fuel cycle for the CANDUs, which is not dependent upon fuel reprocessing, will probably be retained in Canada so long as uranium remains plentiful and comparatively economical. However, for future planning, research to date has indicated that a "self-sufficient thorium cycle" may be practicable in the CANDUs with minimal modification. It has been observed that, at equilibrium, the thorium cycle would require no further uranium. Only small quantities of thorium, which is more abundant than uranium, would be required. Also of interest for the future is *electronuclear breeding*, i.e., the use of electric power to convert fertile to fissile material for neutron economy.

Fast Breeder Reactors

The fast breeder reactor derives its name from its ability to breed, that is, to create more fissionable material than it consumes. This ability stems from

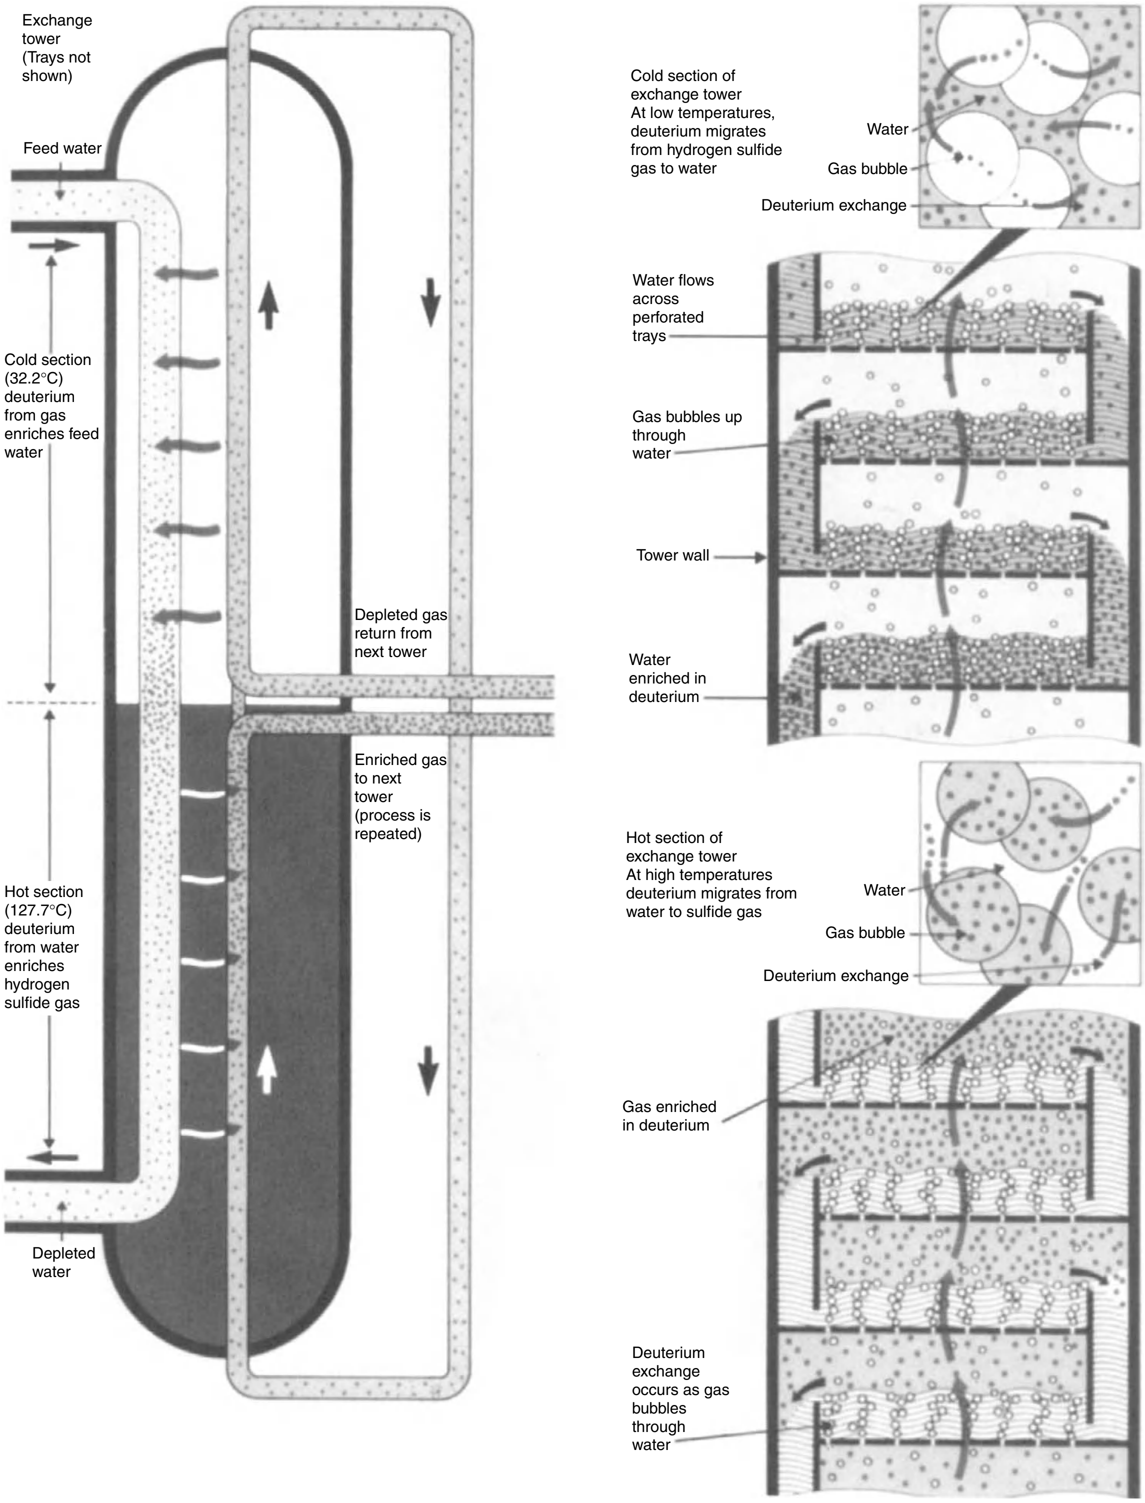

Fig. 26. The production of heavy water is based upon the behavior of deuterium in a mixture of water and hydrogen sulfide. When liquid H_2O and gaseous H_2S are thoroughly mixed, the deuterium atoms exchange freely between the gas and the liquid. At high temperatures, the deuterium atoms tend to migrate toward the gas, while they concentrate in the liquid at lower temperatures. In the first and second stages of production, the towers of a heavy water plant are operated with the top section cold and the lower section hot. Hydrogen sulfide gas is circulated from bottom to top and water is circulated from top to bottom through the tower. In the cold section, the deuterium atoms move toward the water and are carried downward, while in the hot section, they move toward the gas and are carried upward. The result is that both gas and liquid are enriched in deuterium at the middle of the tower. A series of perforated trays are used to promote mixing between the gas and water in the towers. A portion of the H_2S gas, enriched in deuterium, is removed from the tower at the juncture of the hot and cold sections and is fed to a similar tower for the second stage of enrichment

the fact that neutrons travel faster than they do in a thermal reactor. The breeding process depends, in part, upon the neutrons maintaining a high speed, or high energy. If their speed or energy is allowed to degrade as occurs in thermal reactors, the number of neutrons produced per absorption in uranium or plutonium decreases. Furthermore, at lower velocities, neutrons tend to be captured in various structural materials of the reactor, and this further reduces the breeding potential. It is important, therefore, in fast reactors to keep the velocity of the neutrons high. Water, which is used as a coolant in some thermal reactors, tends to slow the neutrons down and thus prevent efficient breeding. Therefore, it is necessary to use

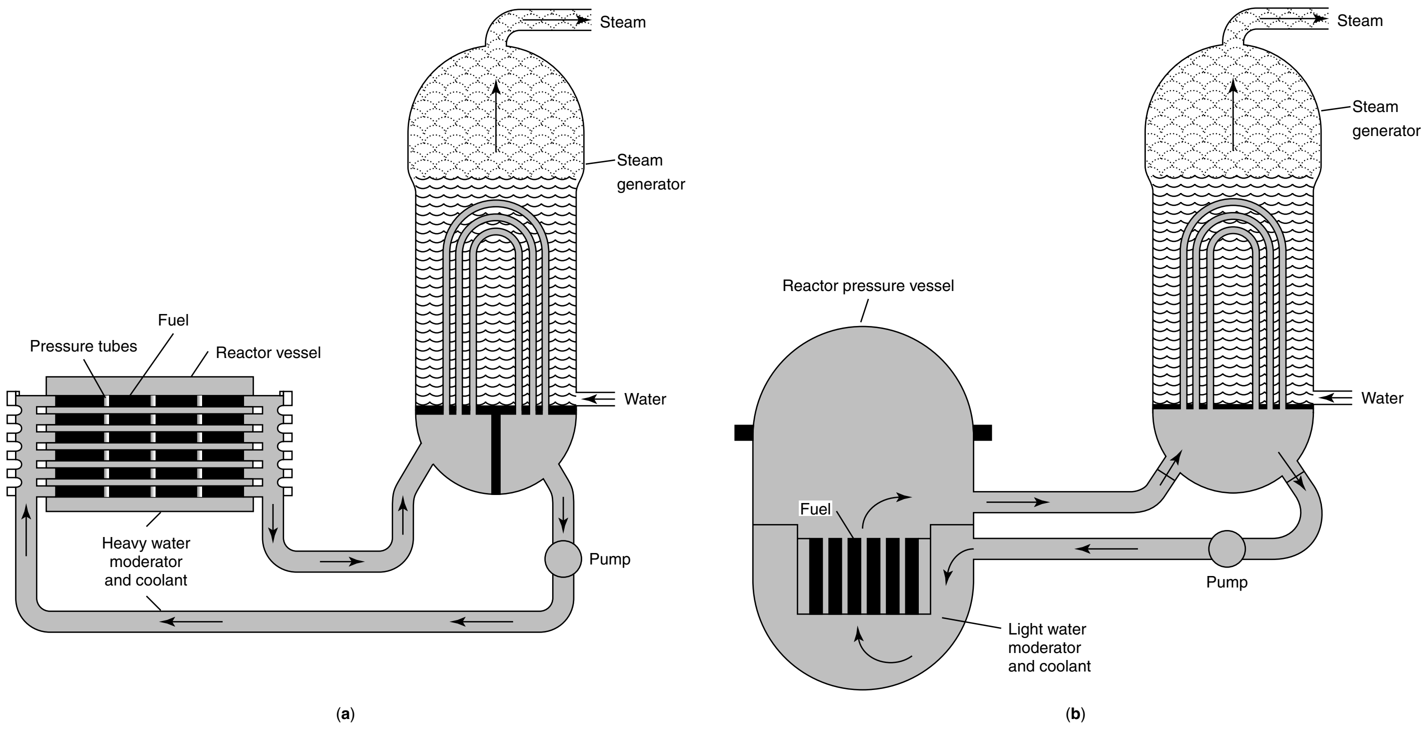

Fig. 27. Comparison of heavy water reactor (**a**) with light water reactor (**b**). (*After Robertson, Atomic Energy of Canada Limited*)

a coolant that does not slow the neutrons or capture them as they travel through the coolant. Liquid sodium and gaseous helium under pressure are the two principal coolants used to date.

The first stage of the process enriches the gas from 0.015% deuterium to 0.07%. A second stage further enriches it to about 0.35%. Again, the enriched gas is fed forward to a third stage. The product from this third stage, now in the range of 10 to 30% heavy water, is sent to a distillation unit for finishing to 99.75% purity "reactor-grade" heavy water. Because the production of heavy water uses a toxic gas, H_2S, safety is a top priority at heavy water plants. H_2S is a colorless gas, slightly heavier than air. To

Fig. 28. Pickering (Ontario) "A" generating station's initial performance was outstanding and the station was hailed as a major Canadian technological achievement at the time of its commissioning in February 1971. It reached full power in 3 months, well ahead of schedule. The final Unit 4 went on line in May 1973. At full output (2,160,000 kW), Pickering "A" generates enough power to supply more than 1.5 million homes. In 1974, construction was begun on a twin station, Pickering "B," also shown in this view. The "B" station has the same capacity as its forerunner and all four units became operational in 1986. (*Ontario Hydro, Toronto, Ontario, Canada*)

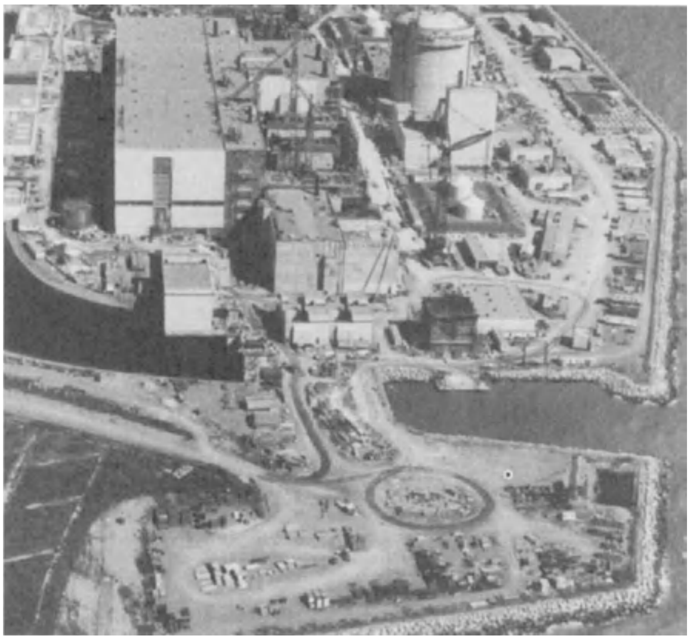

Fig. 29. Darlington, Ontario, nuclear generating station, one of the largest energy projects undertaken in North America. The plant is shown in late stages of construction in 1986. It is located on the shores of Lake Ontario, 5 km southwest of Bowmanville in the Town of Newcastle. Currently nuclear power plants provide one-third of Ontario's electricity needs (the other two-thirds comes from hydro installations). Selected because of its proximity to the residential, industrial, and commercial energy markets of Ontario, the 1200-acre (485-hectare) site has good transportation access, an abundant supply of cooling water from Lake Ontario, relative isolation, and excellent bedrock for station foundations. When the four-unit station is completed it will provide 3,524,000 KW of electricity, enough to serve a city of 3 million people. Electricity from the four units (each 881,000 KW net) will be fed into the Ontario Hydro electricity grid system through 500,000 V transmission lines already crossing the site. The Darlington generating station was approved by the provincial government in July 1977. Site preparation began in 1978 and by 1981, the first concrete was poured for the station's foundations. Construction activity peaked in 1986–1987 with approximately 6800 workers on site. (*Ontario Hydro, Toronto, Ontario, Canada*)

safely expel H_2S from the system, it is directed to a flare tower where it is burned off. Initially, each of Ontario Hydro's reactors requires about 800 megagrams, or one year's production from a heavy water plant. After that, less than 1% of the heavy water is lost and has to be replenished each year. (*Ontario Hydro, Toronto, Ontario, Canada.*)

Fuel Cycle Considerations. Approximately 99.3% of uranium as it is found in nature is the isotope ^{238}U and 0.7% is ^{235}U. Uranium-235 is a fissile isotope, that is, if it is struck by a neutron it will split; this fission yields on the average approximately two neutrons and 200 MeV of energy. This amount of energy corresponds to approximately 78 million Btu for every gram of uranium which fissions (3.5×10^{10} Btu/pound) (1.95 Calories/kilogram). Most reactors today are largely dependent upon ^{235}U for their energy. However, some of the neutrons released in fission of ^{235}U also are absorbed in nonfissionable ^{238}U. As the ^{238}U absorbs a neutron, it is transformed into fissionable ^{239}Pu (plutonium). Thus, while the reactor is sustaining the fission process and thereby creating energy, it is also generating fresh fuel, which can later be used to create more energy. Unfortunately, this is an inefficient process in present thermal reactors where the neutron velocity is established by the temperature, or thermal energy, so only limited amounts of additional energy are made available by transformation of ^{238}U into ^{239}Pu.

The fast breeder reactor makes possible the recovery of most of the available energy in uranium. This occurs because during fission in the fast breeder nearly three neutrons are released for every neutron absorbed as compared with only approximately two neutrons in a thermal reactor. On the average, between one and two neutrons are necessary for sustaining the fission process, and the extra neutron in a fast reactor can be absorbed in nonfissionable ^{238}U and thereby transformed into fissionable ^{239}Pu. Reactors which have a breeding ratio greater than one create more fuel than they need for their own purposes, and the extra plutonium can be used to fuel new breeder reactors. By this means, 80% or more of the available energy in uranium can be recovered and used in reactors.

In a typical fast breeder, most of the fuel is ^{238}U (90 to 93%). The remainder of the fuel is in the form of fissile isotopes, which sustain the fission process. The majority of these fissile isotopes are in the form of ^{239}Pu and ^{241}Pu, although a small portion of ^{235}U can also be present. Normally, the fissile isotopes are located in a central "core" region that is surrounded by the fertile isotopes in the "blanket" region. This is illustrated in Fig. 30.

When the fuel is initially loaded into the reactor, the core region will typically contain from 10 to 15% fissile isotopes with the remainder being ^{238}U. Essentially all of the blanket will be ^{238}U. As energy is extracted from the fissile isotopes, they become depleted (the initial plutonium is gradually used up). However, in a breeder reactor, new plutonium will be formed in the core and blanket regions faster than it is consumed. Additionally, undesirable fission products are formed which must ultimately be removed. This process is schematically illustrated in Fig. 31. The "before" chart

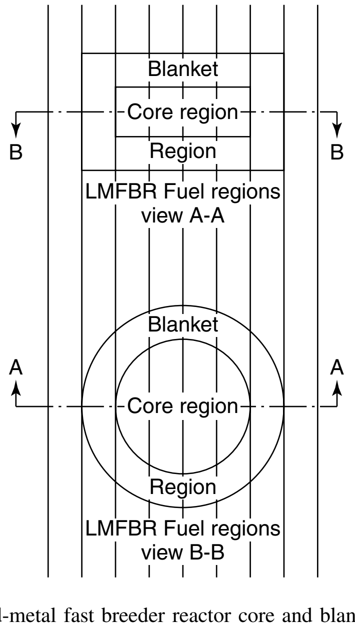

Fig. 30. Liquid-metal fast breeder reactor core and blanket arrangement

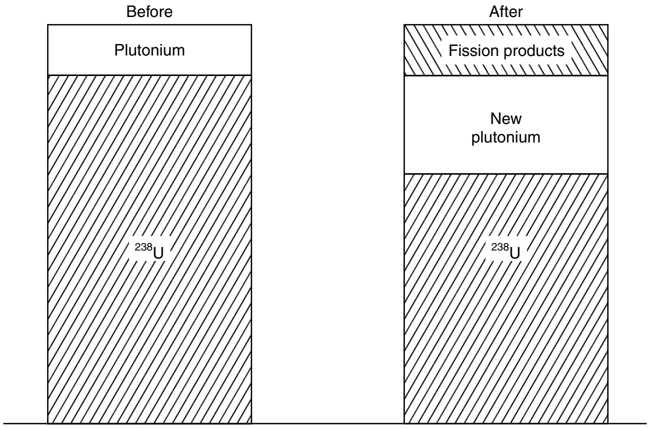

Fig. 31. Basic operation of the breeder reactor. The illustration does not include geometrical disposition of fuel in the core and blanket system. (*General Electric*)

represents the new fuel condition and the "after" chart corresponds to the situation when the fuel is removed for reprocessing. Typically, the fuel removed for reprocessing will contain from 1 to 3% new plutonium. It is in this manner that the fast breeder can recover from 80 to 90% of the available energy in uranium resources. Most present reactors require some enrichment of the ^{235}U isotope used to fuel them. This enrichment process requires a plant, which, in turn, uses large amounts of electrical energy. Because the fast breeder converts the fertile isotope ^{238}U into the fissile isotope ^{239}Pu, no enrichment plant is necessary. The fast breeder serves as its own enrichment plant. The need for electricity for supplemental uses in the fuel cycle process is thus reduced.

Fast Breeder Reactors in Perspective

Of the several fundamental ways to use nuclear fission reactions to generate electric power, the fast breeder reactor (notably the liquid-metal-cooled fast breeder reactor, LMFBR) probably has the most checkered history. The fast breeder reactor received its early impetus when there was serious concern over what appeared to be a limited supply of uranium and consequent increasing prices of uranium fuels. With the fast breeder concept offering up to a 100-fold increase in the utilization efficiency of uranium, it appeared to be the logical replacement (second generation) for light-water reactors. It would present a technical solution in time for the expected tight supplies of uranium. The United States funded LMFBR research quite generously until a serious reduction in 1982. Then, it was determined that the shortage of uranium fuels no longer posed a serious threat in the short-term, thus establishing the general consensus in the U.S. that the breeder, if needed at all, could be delayed until well into the next century. The interest of the French and Japanese in breeders also stemmed from early concerns with uranium shortages and prices, but was much more serious because these countries are extremely uranium poor and, further, these countries have fewer energy options. For example, the cost of coal ranges from 1.6 to 2.5 times the cost of coal in the United States. Continued progress in fast breeder development, particularly in France, also has been accelerated by a very heavy past investment in the technology coupled with a desire to be fully self-contained as regards the generation of electric power.

Particularly, in the United States, because of its several energy fuel options and its current "rethinking of nuclear power," the principal nuclear power research targets no longer include uranium supplies. Rather, the targets are the lowering of capital costs for existing light-water reactor technology, shortening the plant construction and licensing lead times, achieving higher plant availability (essentially eliminating long power outages), and increasing plant safety. From this "rethinking" process, the U.S. Congress suspended funding for the Clinch River Breeder Reactor.

It is interesting to note that, as of the early 1990s, most authorities were not quite willing to "forget" the fast breeder altogether. The differences in views essentially reside in timing. The fast breeder, even though costly to build today, does offer several temptations. For example, experience gained from the Experimental Breeder Reactor (Idaho Falls, ID) which commenced operation in 1964 is reported to operate better now than when it was first built, showing no evidence of corrosion. It is suggested that if such experience were extrapolated the useful life of an LMFBR could be between 100 and 150 years! Weinberg (1986 reference listed) recalls,

"that one of Newcomen's original steam engines, built in the mid-18th century, continued to operate until 1918." It does appear that the economy of the LMFBR is somewhat analogous to large hydroelectric projects that require very large investments of capital, but coupled with low operating costs, provide really cheap electric power once they are fully amortized. However, one usually must wait a generation before this situation occurs. Weinberg also observes, "Because the breeder requires little, if any, mining of uranium, its environmental impact is much smaller, at least at the front end of the fuel cycle, than is the impact of the LWR. The roughly 300,000 tons of depleted uranium stored outside the diffusion plants, if used in breeders, could fuel our (U.S.) entire electric system for centuries!"

Davis (1984 reference listed) observes that there is sufficient know-how today to build and operate fast breeder reactors with confidence of their safety and reliability, as exemplified with large units in France. Davis further suggests that the principal problems remaining in fast breeder technology include: (1) a reduction in overall costs to make the fast breeder competitive with coal and the light-water reactors—an estimated reduction factor of 1.5 to 2; (2) assurance of adequate safeguard on the plutonium fuel cycle; (3) more demonstrations of commercial-scale operations, such as the engineering scale-up of important system components—pumps and steam generators; (4) implementing a large, overall system which must include parallel facilities for fuel processing and refabrication; and (5) setting in place the reprocessing of light-water reactor fuel to provide the "start up" plutonium for the fast breeders.

Some technical successes with the fast breeder have occurred in France: (1) demonstrations of a positive breeding gain of 0.15 ± 0.04 in a complete breeder fuel cycle, and (2) demonstration at several laboratories of uranium and plutonium oxide fuel elements that can sustain more than 10% burnup of the original mixture of $^{238}U/^{239}Pu$ before the fuel has to be reconstituted, representing a tenfold improvement (Weinberg, 1986). It has also been observed that, compared with a number of so-called alternative fuels, the new Super-Phoenix (France) plant can produce electricity at costs that are markedly less than electrical energy from solar-powered photovoltaics, for which funding remains significant. Another proposed inexhaustible power source, nuclear fusion, still remains in an early stage of development. See **Fusion Energy**.

LMFBR Design Principles. There are many design differences among the reactor designs, including: (1) primary coolant system arrangement; (2) refueling mechanism design and arrangement; (3) steam generator type and arrangement; (4) core support method; (5) structural material choices; and (6) safety features. Perhaps the most noticeable difference is that of the primary system arrangement. This difference is schematically illustrated in Figs. 32 and 33. The system of Fig. 32 corresponds to a "loop" or "piped" arrangement where the reactor, pumps, and intermediate heat exchangers are located separate from each other and piping carries the sodium from one point to the other. The "pool" or "tank" arrangement of Fig. 33 includes the reactor, intermediate heat exchangers and pumps in one large pool of sodium which is contained in a separate tank. Each concept has advantages and disadvantages. The pool concept is somewhat easier to design for certain hypothetical accident situations. The loop concept is easier to construct and to maintain.

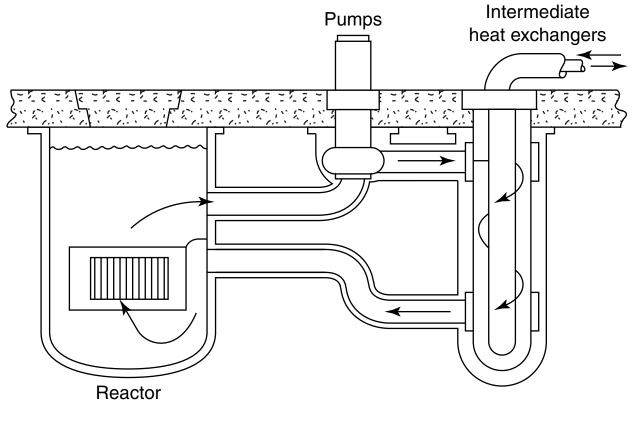

Fig. 32. Loop arrangement in the liquid-metal fast breeder reactor. (*General Electric*)

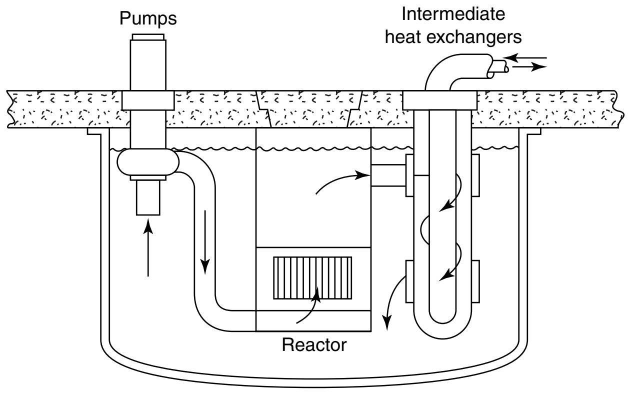

Fig. 33. Pool arrangement in the liquid-metal fast breeder reactor. (*General Electric*)

The flow circuit for an LMFBR where two sodium circuits are included is shown schematically in Fig. 34. The reactor is cooled by the primary sodium, which becomes radioactive as it picks up heat in passing through the core or fueled region. In this particular arrangement, the sodium is heated to 560°C and flows through pipes (schematically shown as a single line in the figure) to the intermediate heat exchangers. In the heat exchangers, the primary sodium transfers heat to the nonradioactive sodium. After being cooled to 393°C in the heat exchangers, the primary sodium is pumped back into the reactor where it again repeats the circuit. The nonradioactive secondary sodium is circulated from the intermediate heat exchangers through steam generators where the heat from the sodium is transferred to water, which becomes superheated steam for use in the turbine. The cooled secondary sodium is pumped back through the intermediate heat exchangers where the process is repeated. Steam from the steam generators is used to turn the rotor of the turbine generator to generate electricity. In the arrangement shown, 1,200 MW of electricity are generated at a net overall efficiency of 39%. This relatively high efficiency is possible because of the excellent thermal characteristics of sodium.

Nuclear Power Innovations for 1995 and Beyond

Increasing concerns over the impact of fossil fuel-burning electric power generating plants on the environment, the accelerating demands for electric power, and a growing dependence on foreign oil supplies brought about a resurgence of interest in nuclear power reactor research during the mid-1980s. Advanced programs were established to create new plant designs that would reflect past experience to achieve an extremely high degree of operating safety, competitive construction, and operating costs, including the streamlining of the licensing process and consumer confidence in nuclear power technology. Thus, during the past decade, much private and government-sponsored research has been directed toward nuclear reactor research in three areas, namely, light water reactors (LWRs), high-temperature gas-cooled reactors (HTGRs), and liquid metal-cooled reactors (LMRs).

The innovative program commenced with an impressive nuclear power base—some 107 nuclear plants with full-power licenses operating in the United States and producing 18% of the nation's electricity—worldwide, 414 plants in 26 countries generate 298,000 megawatts of electricity (MWe), accounting for 16% of the world's generating capacity.

A survey of reactor developments of the three aforementioned types reveals a number of common generic technical features. These include passive stability, simplification, ruggedness, ease of operation, and modularity.

Overall goals for the innovative program can be summarized as follows:

1. Assured safety with features that minimize the negative consequences of human error, especially a reduction in the chance of occurrence of severe core damage by at least a factor of 10 less than former, contemporary designs.
2. Significantly simpler designs, with increased safety and performance margins in key operational parameters.
3. High reliability throughout a lifetime on the order of 60 years and an increase in plant availability to 85% or greater than the contemporary average of less than 70%.

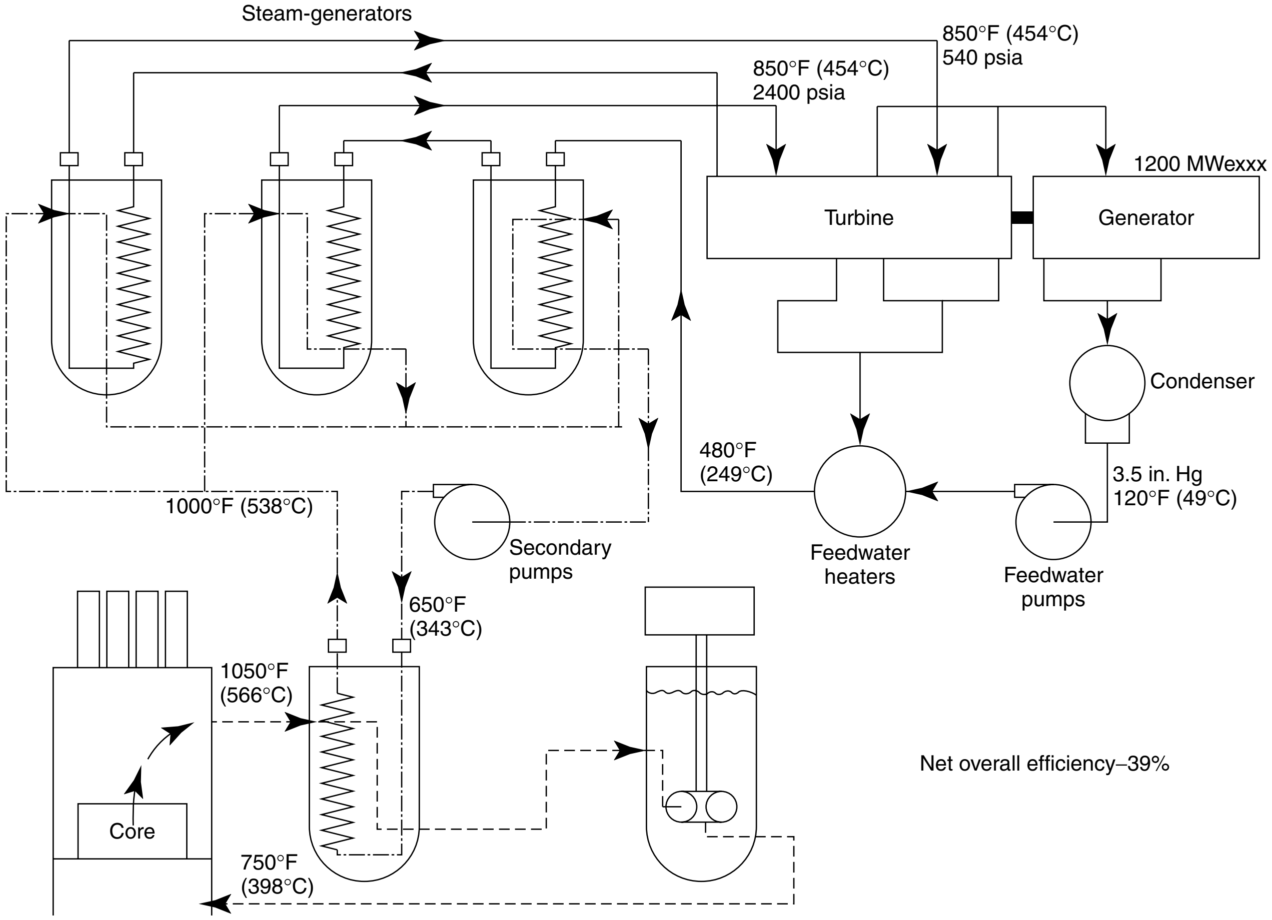

Fig. 34. Liquid-metal fast breeder reactor flow circuit. (*General Electric*)

4. Reduction in capital, operating, maintenance, and fuel costs to meet the economic competition with coal-burning generators. A reduction in construction time to the range of 3 to 5 years as compared with more than 10 years, which has been the experience with some of the later contemporary reactors.
5. A modular design that is standardized at a highquality level and thus predictably licensable.

Passive Stability. Passive design characteristics ensure core stability by eliminating the potential for a runaway chain reaction. In the innovative program, this has been a hallmark from the outset of the program. Passive characteristics are internal governors—that is, physical laws ensure that the reaction rate decreases instantaneously as the temperature of the coolant or fuel or the power of the reactor increases, without the need for external control devices.

Ruggedness. In some past designs, long-term reliability has been impaired by attempts to achieve the highest in efficiency and economic performance. In response to this negative experience, the margin in certain key performance parameters is being increased in order to lessen the burden on the equipment. By reducing power densities and coolant temperatures, higher reliability will be achieved over a longer lifetime. Past field experience has identified more effective methods of coolant chemistry control and materials selection, factors that will contribute to the long-lived reliability of the components of future systems. Greater emphasis is being given to the selection of proven, high-quality materials and components and on improved methods and quality control over assembly and construction.

Ease of Operation. Thorough investigation of the Three Mile Island incident some years ago showed that a lack of attention had been given to the human factor. The innovation program is addressing this problem in several ways. The computer and telecommunication revolution has made it more practical to use improved technology and human engineering methodologies to revamp the control room and the reactor instrumentation system. These improvements will make the plant easier to operate and provide the operator with a greatly increased amount and quality of information on plant conditions. Graphic displays, diagnostic aids, and expert systems are being developed for such advanced control rooms.

The other design goals complement the new technology to make the operator's task even easier. The passive safety features substantially extend the response time required of the operators in an emergency condition. The margin being built into the systems provides broader normal operating regimes and longer response times for operator action. Greater emphasis is being placed on simplification of operating procedures.

Modularity. Economic competitiveness requires that the construction time be shortened dramatically. Modular construction techniques are a key contributor to achieving this goal and are a proven approach to cost control in major construction projects. Modularization provides for a larger percentage of factory construction, rather than field construction. New innovative concepts will rely heavily on modularization and will be centered around lower unit power outputs, factory assembly, and transportation of modules to the plant site. The overall plant size target is 600 MWe net electrical output.

The AP600 Advanced Plant

As of 1994, the AP600 (Westinghouse) plant was in the most advanced stage of the innovative program. The first unit may be put on line just prior to the expiration of the last century. This design satisfies all of the previously mentioned goals of the innovative program. A sectional view of the AP600 is shown in Fig. 35. The site plan is shown in Fig. 36.

AP600 Passive Safety System Details. These features reduce operator responsibilities and add an extra margin of safety over contemporary PWR designs. See Fig. 37 on p. 1121. Large volumes of water stored in the containment eliminate the need for operator action to assure make-up water, either for small leaks that may occur during normal operation or for a major loss of coolant accident (LOCA). A passive plant is a system that assures public safety even if the operators fail to act.

The passive residual heat removal heat exchangers remove core decay heat if steam generator heat removal is not available. Passive residual heat removal heat exchangers in the in-containment refueling water storage

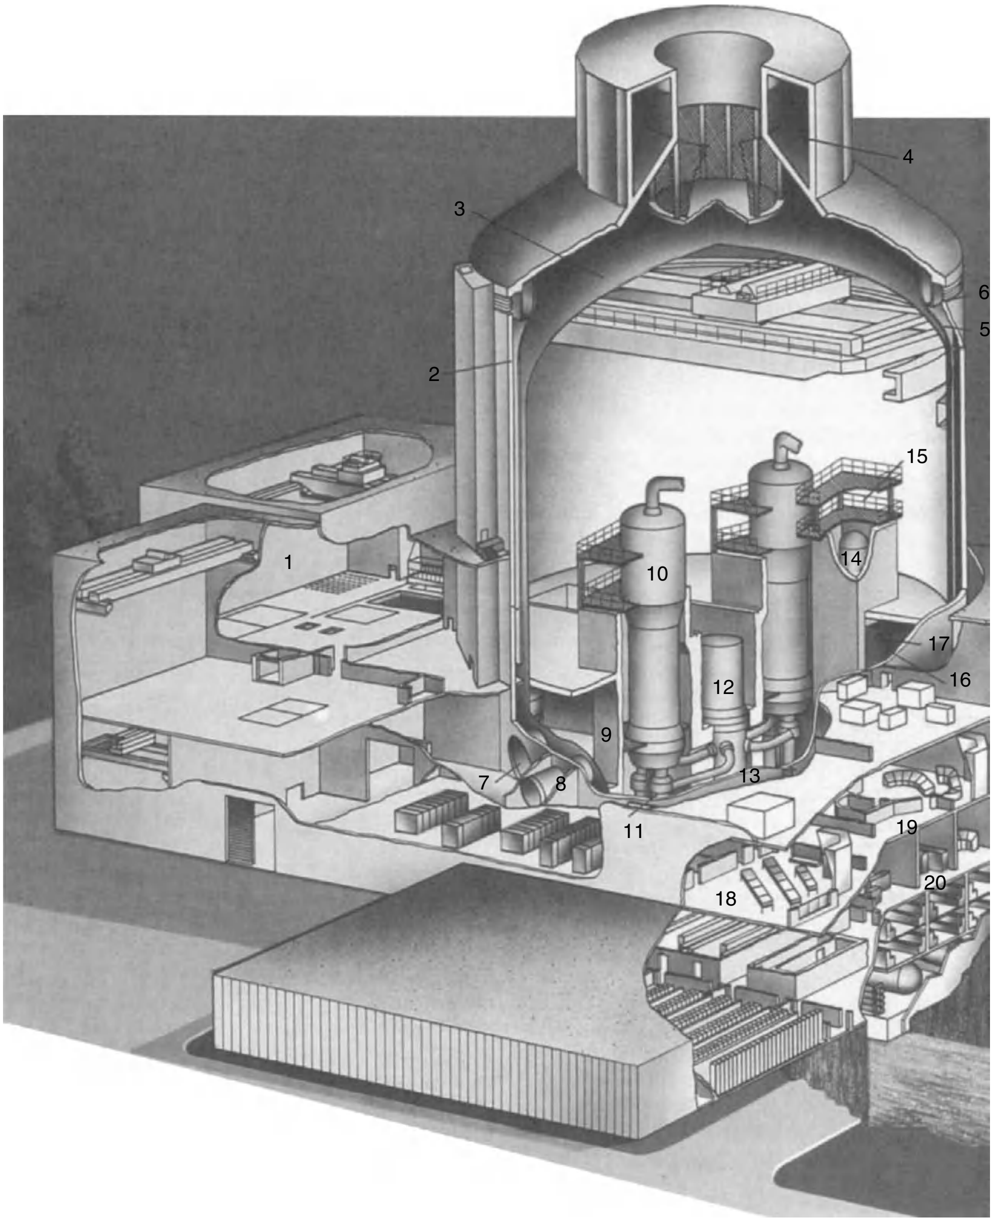

Fig. 35. Sectional view of the 600 MWe pressurized water reactor (PWR) expected to be operational by 1995. Considered the PWR of the future, the plant is designed for a minimum useful life span of 60 years and features numerous economic and safety features, including passive systems for ultimate protection. tanks are connected to the reactor coolant system (RCS) piping, forming a full-pressure, closed, natural circulation cooling loop.

Two core make-up tanks provide borated make-up water whenever the normal make-up system is unavailable. The tanks are located above the reactor coolant system loop piping and kept at system pressure by steam lines from the pressurizer. These tanks function at any system pressure, using only gravity as a motive force. If the reactor protection system detects a need for make-up water, core make-up tanks discharge and isolation valves open automatically, allowing the tanks to drain into the reactor vessel.

Two accumulators provide the high make-up flows initially required by a large LOCA. These tanks contain 1700 cubic feet (about 48 cubic meters) of borated water pressurized with 300 cubic feet (about 8.5 cubic meters) of nitrogen at 700 psi (4.8×10^6 Pa). The accumulators are isolated from the RCS by check valves. Each accumulator is paired with a core make-up tank, the pair sharing an injection line to the reactor vessel downcomer.

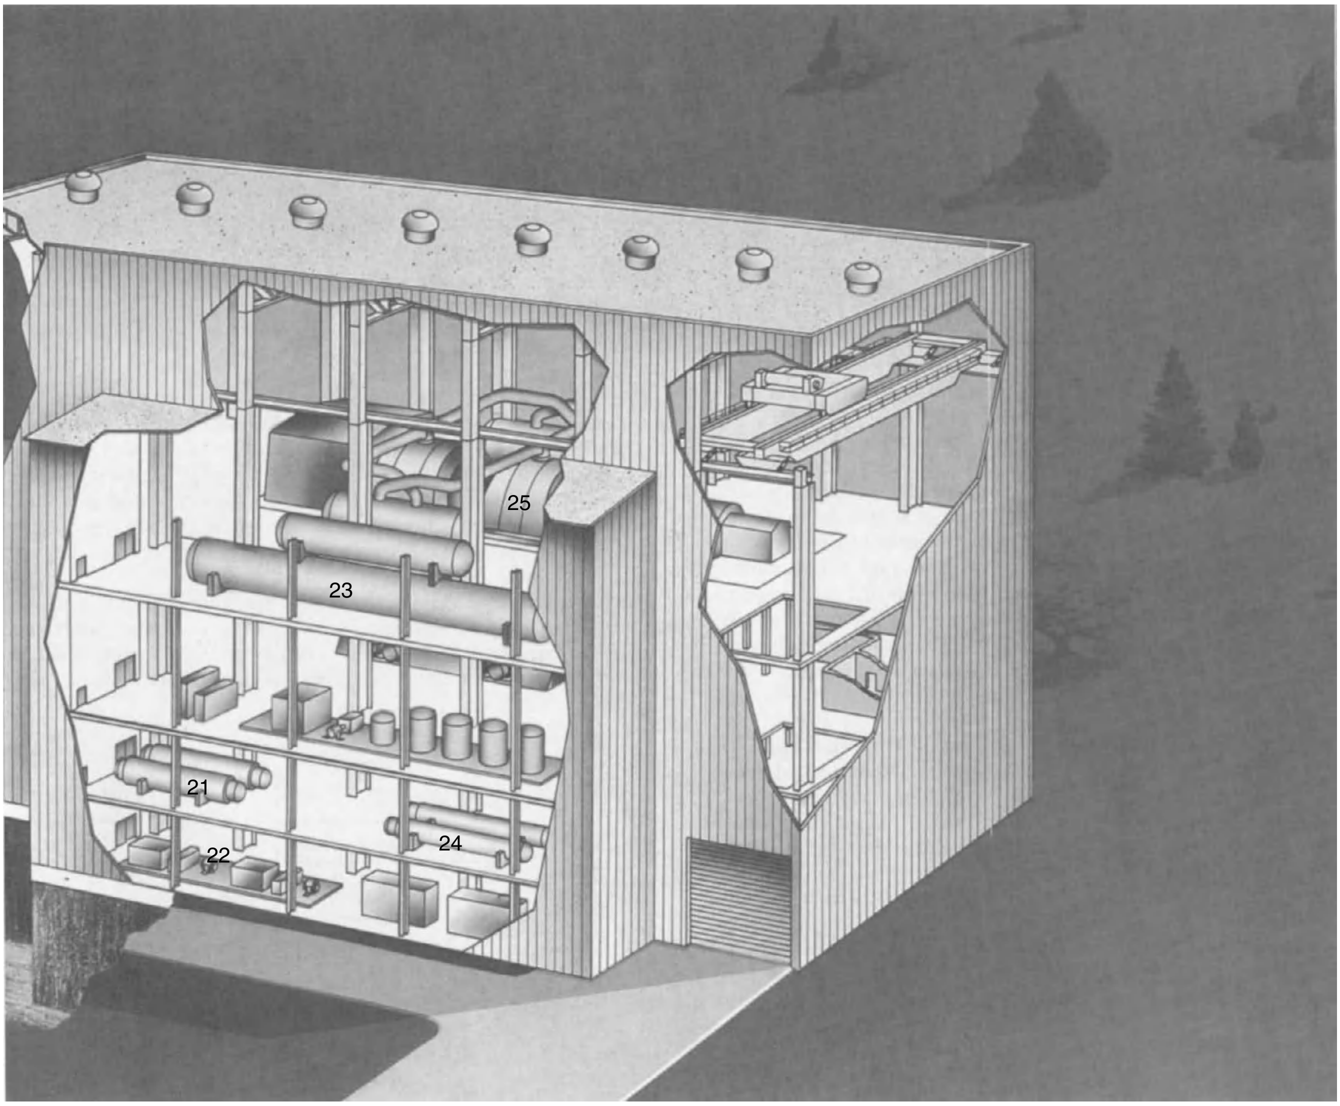

Fig. 35. (*continued*)

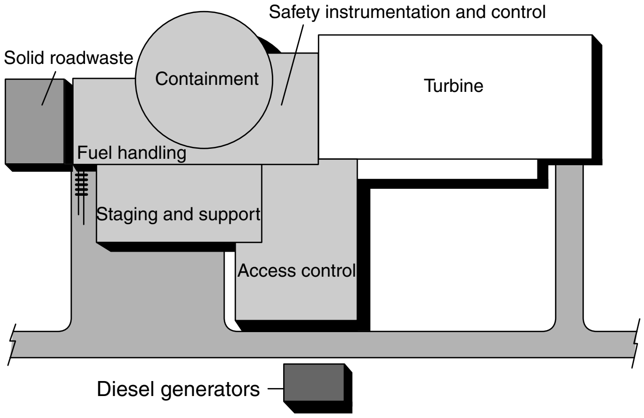

Fig. 36. Site plan for the advanced pressurized water reactor (PWR). (*Westinghouse Electric Corporation, Energy Systems*)

This ensures that at least one accumulator/core make-up tank pair would be available following an injection line LOCA.

The in-containment refueling water storage tank provides 500,000 gallons (about 1900 cubic meters) of water with a gravity head above the core. This water inventory is sufficient to flood the containment above the level of the reactor core and provide decay heat removal by natural circulation.

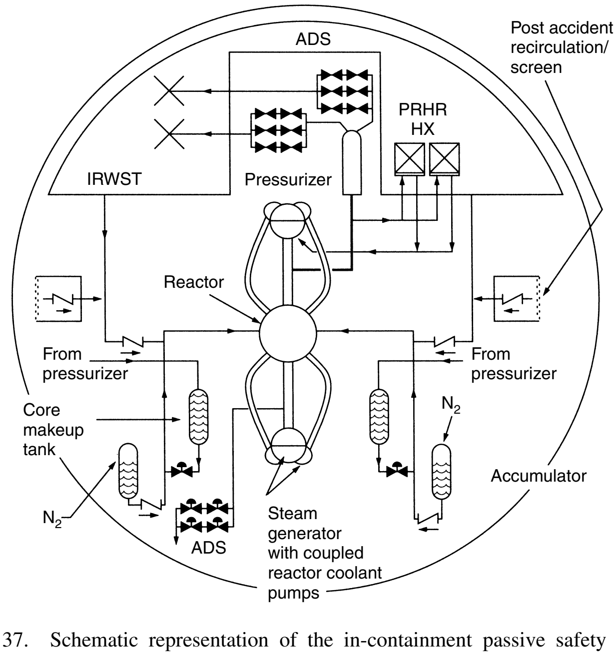

Fig. 37. Schematic representation of the in-containment passive safety injection system (PSIS). IRWST = in-containment refueling water storage tank. PRHR-HX = passive residual heat removal heat exchanger. ADS = automatic depressurization system (four stages). (*Westinghouse*)

The automatic depressurization system depressurizes the RCS if core make-up tank level is low. Depressurization allows gravity injection from the in-containment refueling water storage tank, which is at atmospheric pressure. To ensure that the automatic depressurization system works when needed, while minimizing the consequences of spurious valve operation, the system provides phased depressurization with two redundant sets of valves connected to the pressurizer. The discharge is sparged into the in-containment refueling water storage tank. The automatic depressurization system valves are arranged in three stages to reduce peak flow rates. A fourth depressurization stage is provided directly on the RCS hot leg.

The passive containment cooling system provides the safety grade ultimate heat sink that prevents the containment shell from exceeding its design pressure of 45 psig [3.1×10^5 Pa (g)]. The system uses natural air circulation between the steel containment shell and the concrete shield building. During postulated accidents, air cooling is enhanced by draining water onto the steel containment shell. The water is provided by gravity from a 350,000-gallon (about 1300 cubic meters) annular tank in the roof of the shield building. This tank has sufficient water to provide three days of cooling.

RADIOACTIVE WASTES

Decisions pertaining to the location of radioactive waste sites mainly derive from political and sociological sources. A condensed overview of the technical aspects is given here.

The radioactive wastes associated with nuclear reactors fall into two categories: (1) *commercial wastes*—the result of operating nuclear-powered electric generating facilities; and (2) *military wastes*—the result of reactor operations associated with weapons manufacture. Because the fuel in plutonium production reactors, as required by weapons, is irradiated less than the fuel in commercial power reactors, the military wastes contain fewer fission products and thus are not as active radiologically or thermally. They are nevertheless hazardous and require careful disposal.

Nuclear power plants use fuel rods with a life span of about three years. Each year, roughly one-third of spent fuel rods are removed and stored in cooling basins, either at the reactor site or elsewhere. Typical modern nuclear power plants discharge about 30 tons of the spent fuel per reactor per year. Comparatively little of the radioactive wastes, as is currently reliably known worldwide, has been processed for return to the fuel cycle. Actually, fuel reprocessing causes a net increase in the volume of radioactive wastes, but, as in the case of military wastes, they are less hazardous in the long term. Nevertheless, the wastes from reprocessing also must be disposed of with great care.

Spent fuel from a reactor contains unused uranium as well as plutonium-239 which has been created by bombardment of neutrons during the fission process. Mixed with these useful materials are other highly radioactive and hazardous fission products, such as cesium-137 and strontium-90. Since reprocessed fuels contain plutonium, well suited for making nuclear weapons, concern has been expressed over the possible capture of some of this material by agents or terrorists operating on behalf of unfriendly governments that do not have a nuclear weapons capability.

Categories of Wastes by Content

In addition to the two source categories previously mentioned, radioactive wastes are classified in accordance with their content:

High-level wastes contain 99.9% of the nonvolatile fission products, 0.5% of the uranium and plutonium, and all the actinides formed by transmutation of the uranium and plutonium in the reactors. Among the actinides are neptunium and americium. High-level wastes are either the aqueous wastes resulting from reprocessing; or the spent-fuel rods to be disposed of in the absence of reprocessing.

Cladding wastes are comprised of solid fragments of Zircaloy and stainless steel cladding (tube in which the fuel is placed) and other structural elements of the fuel assemblies remaining after the final cores have been dissolved.

Low-level transuranic wastes are solid or solidified materials which contain plutonium or other long-lived alpha-particle emitters in known or suspected concentrations higher than 10 nanoCuries per gram and external radiation levels after packaging sufficiently low to allow direct handling.

Intermediate level transuranic wastes are solids or solidified materials that contain long-lived alpha-particle emitters at concentrations greater than 10 nanoCuries per gram and which have, after packaging, typical surface dose rates between 10 and 1000 mrems/hour due to fission product contamination.

Nontransuranic low-level wastes are diverse materials which are contaminated with low levels of beta- and gamma-emitting isotopes, but which contain less than 10 nanoCuries of long-lived alpha activity per gram.

Permanent Disposal Methodologies

Because of many doubts among various authorities pertaining to the permanent geologic depositories, as previously mentioned, considerable effort continues as regards semipermanent and permanent types of depositories. Many methodologies involve the so-called "sequence of barriers" approach. The first barrier is the form in which radioactive materials are embedded—vitrification, calcination, etc. The requirements for the first barrier are that it not be corrosive and possess excellent thermal stability and mechanical integrity. Wastes generate much heat during their initial decade of confinement. This affects decisions as regards the wasteform and the second barrier, the frequently mentioned canister which encapsulates the wasteform. The principal function served by the canister is protection of the material during the collection and transportation (to geologic site) phases. The canisters also should provide excellent protection of their contents for a minimum of 50 years, just in case it is desired to retrieve the wastes at some future date. Canisters must resist corrosive chemicals, they must withstand extremely high radiation fluxes caused by fission-product decay and the heat generated by the decaying wastes. It is interesting to note that an unprotected stainless steel canister will not resist structural deterioration arising from salt brines for that long a period. Provision must be made for cooling the canisters, either by air or water. The canisters should be designed to permit maximum heat transfer and, currently, the cylinder and annulus configurations are preferred. A third barrier would be the geologic site itself, obviously impervious to water penetration and in a seismically stable location. To fulfill all the foregoing requirements (and more), consideration is being given to phasing the waste storage procedure, possibly storing the canisters for water cooling during the first few years, after which air cooling would suffice.

The predominant preference appears to be the underground depository option. Along these lines, it is interesting to review the rock formations in the United States, as shown in Fig. 38.

Commenting briefly on other proposed methodologies, as shown in Fig. 39: (a) In *solution-mined cavities*, it is proposed that chemical solutions would be used to mine cavities in appropriate media, such as rock salt; (b) in the *drilled-hole matrix*. A series of large-diameter holes would be drilled into the geologic media to depths up to 2 kilometers to form a grid of holes. The solid wastes would be packed into these holes, then sealed. (c) In the *rock-melting concept*, liquid wastes (no solidification) are poured into a subterranean cavity, which would be created by an underground explosion. (d) In the *hydrofracture concept*, liquid radioactive wastes are converted into a type of grout (cement or cementlike materials used). This grout is pumped under high pressure into shale as deep as 1 kilometer. The pressure of the operation causes the underlying shale to fracture and the wastes fill up the cracks so formed. This procedure has been used for years in the petroleum field. See also **Petroleum**. (e) In the *polar ice concept*, the wastes would melt through the ice (although this approach would require considerable new technology); or the wastes would be placed on the surface of the ice or anchored within the ice. Advantages include long distances from populations and excellent thermal cooling. Disadvantages include extensive transport and poor retrievability. This method is not high on the list of choices mainly because of too many unknown factors that will require considerable research and experimentation. (f) *Oceanic disposition*, in addition to the polar ice cap concept, are subduction zones and other deep sea trenches and rapid sedimentation areas. A "Seabed Disposal Program Annual Report" states, "Placing high-level wastes on the seafloor, i.e., in the water column, effectively puts the waste contained directly into the biosphere. Since it is difficult to conceive of a practical man-made wasteform/container system that would survive without releasing radionuclides for hundreds of thousands of years in a marine environment, one must assume the radioactive material would eventually enter the ecosystem." The sub-seabed sediments in the central North Pacific are loosely packed, fine-grained, deepsea "red clays" and have not been fully dismissed from continuing investigation.

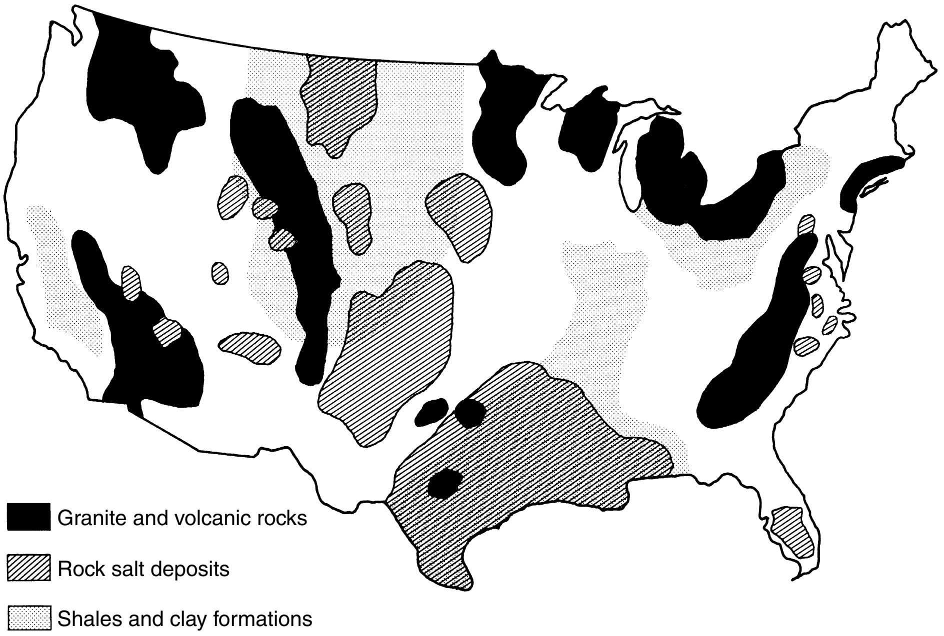

Fig. 38. Some authorities prefer rock salt deposits for the permanent disposal of nuclear wastes on the assumption that the heat generated by radioactive decay would fuse salt and wastes into an impermeable mass. Other experts question the integrity of salt formations. Increasing attention has turned to hard media, such as the granitic and basaltic rocks, and to shale and clay formation, with the hope that the extensive occurrence of such formations would minimize the need to transport wastes over long distances

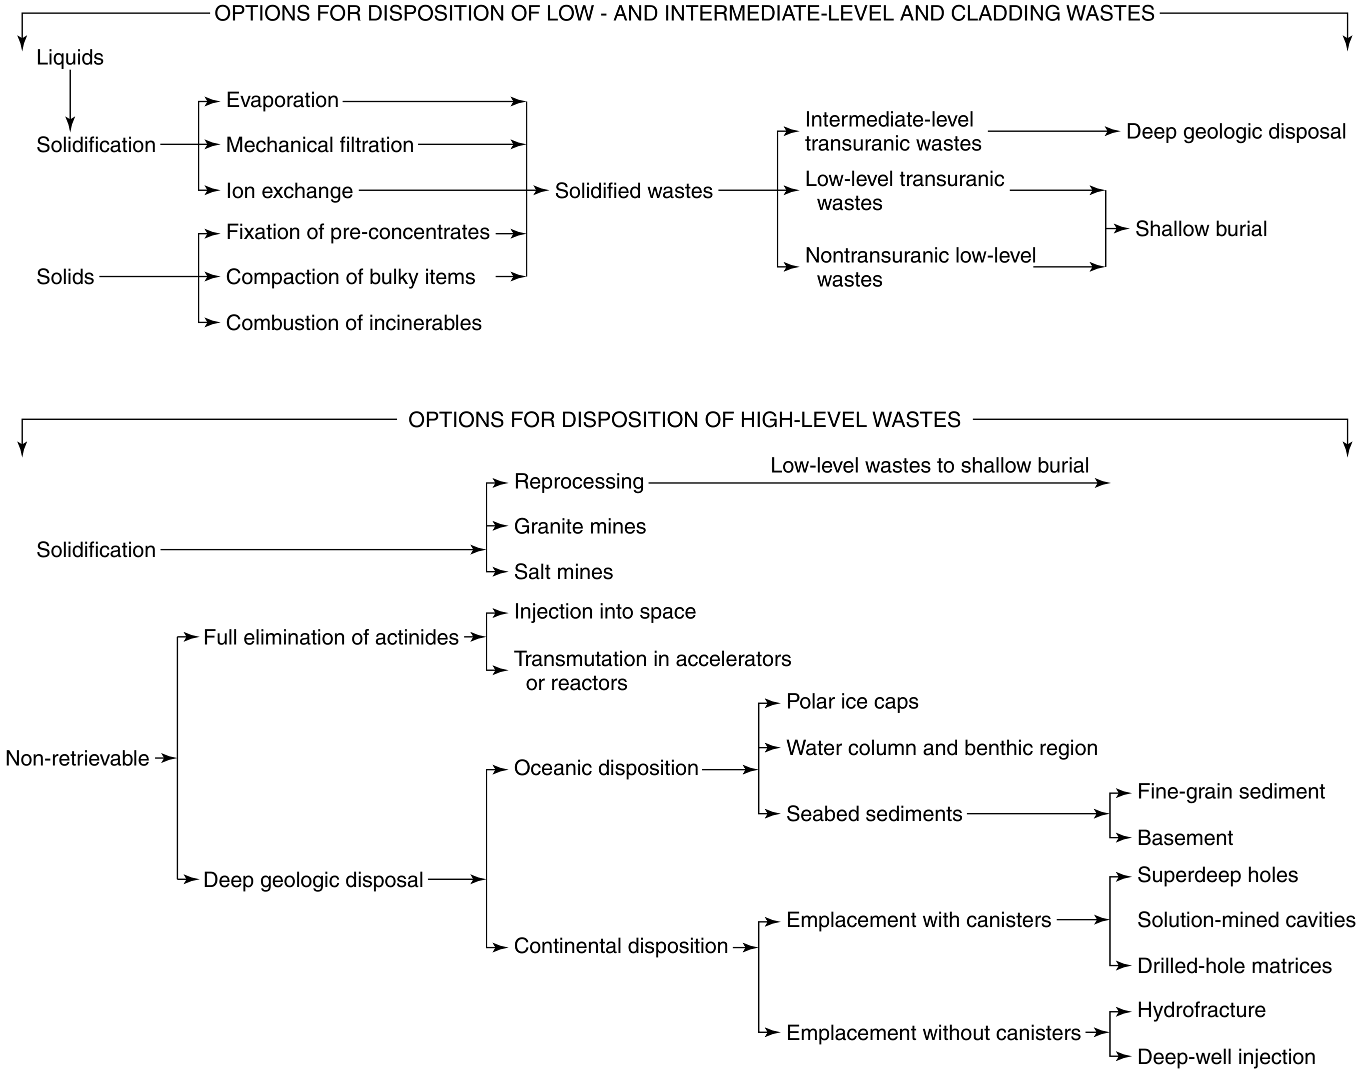

Fig. 39. Panorama of options for consideration in the disposition of radioactive wastes. (*Top portion of chart*: Options for disposition of low- and intermediate-level and cladding wastes. *Bottom portion of chart*: Options for disposition of high-level wastes)

NUCLEAR REACTOR. See **Nuclear Power Technology**.

NUCLEAR SPIN. The intrinsic angular momentum of the atomic nucleus due to rotation about its own axis. It is usually designated I and has the magnitude, $\sqrt{I(I+1)}h/2\pi \approx I(h/2\pi)$, where I is the nuclear spin quantum number which has different (integral or half-integral) values (including zero) for different nuclei. In spectroscopy, the nuclear spin is of importance for the explanation of the hyperfine structure, and of the intensity alternation in band spectra.

NUCLEAR STRUCTURE. The nucleus of an atom of atomic number Z and mass number A contains Z protons and $A-Z$ neutrons, bound together under the influence of shortrange nuclear forces much as molecules are bound together in a drop of liquid. The strength of binding may be determined by subtracting the actual mass of the atom from the mass of its constituent particles considered as free particles. The binding energy E_B is then related to this mass defect ΔM by Einstein's relation, $E_B = \Delta Mc^2$, where c is the velocity of light. The precise value of E_B depends upon the nucleus concerned, and upon how many neutrons and protons it contains but it is of the order of 8 MeV per nucleon in most nuclei.

The binding energy determines whether the nucleus is stable or unstable. Among the lighter nuclei, the ones which are stable are those in which the number of protons is approximately equal to the number of neutrons, so that $A \approx 2Z$. In heavier stable nuclei, there is an excess of neutrons over protons owing to the repulsive electrostatic forces between the protons. Thus, the most stable oxygen nucleus is ^{16}O, containing 8 protons and 8 neutrons, while the most nearly stable uranium nucleus is ^{238}U, containing 92 protons and 146 neutrons. Nuclei containing a disproportionate number of neutrons tend to be unstable and decay radioactively by emission of electrons whereby neutrons are converted into protons; those containing an excess of protons similarly tend to decay by emission of positrons or by capture of orbital electrons.

It has been shown that the nucleus is approximately spherical in shape and of volume proportional approximately to its mass. It is, however, capable of executing oscillations about the spherical form, and in certain circumstances may even acquire a permanent deformation. The heaviest nuclei are unstable under deformation, as a result of which they undergo spontaneous fission. These properties may be described qualitatively by regarding the nucleus as an electrically charged drop of liquid possessing volume energy and surface tension.

Although the nucleus is normally found in its lowest energy state, it may be produced as the result of a nuclear reaction, or through radioactivity in a number of excited states whose detailed properties may differ quite markedly from the lowest state. If formed in an excited state, it will decay, normally by the emission of electromagnetic radiation (gamma rays) to the lowest state, or by the emission of particles to another nucleus.

NUCLEAR TRANSMUTATION. The transformation of one nuclide into another, which differs from it in nuclear charge, mass, or stability, i.e., in a nuclear reaction or a process of radioactivity. Such changes occur in natural radioactive processes, but the general need for a systematic notation for expressing them came only with the great number of transmutations discovered after particle accelerators provided high-energy ion beams capable of penetrating the Coulomb barrier of all stable atomic nuclei.

Two representative transmutation equations are

$$^{27}\text{Al} + n \longrightarrow {}^{27}\text{Mg} + {}^{1}\text{H}$$

which shows the transmutation of aluminum atoms of mass number 27, by bombardment with neutrons, to magnesium atoms of mass number 27, with the emission of a proton, and

$$^{9}\text{Be} + \gamma \longrightarrow {}^{8}\text{Be} + n$$

which shows the transmutation of beryllium atoms of mass number 9, under gamma-ray bombardment, to beryllium atoms of mass number 8, with the emission of a neutron.

The two reactions above may also be expressed in condensed from as

$$^{27}\text{Al}(n,\ p)^{27}\text{Mg}$$

and

$$^{9}\text{Be}(\gamma, n)^{8}\text{Be}.$$

NUCLEIC ACIDS. Nucleic acids are polymeric materials formed from nucleotides and essential to all organisms. Deoxyribonucleic acid (DNA), most often a double-helical biopolymer, encodes the genetic information contained in each cell. Ribonucleic acid (RNA) constitutes a more diverse class of biopolymers that are able to adopt both helical and other more complex tertiary structures. The structural diversity of RNAs enables these molecules to carry out a variety of intracellular functions, including transmitting the genetic message to the site of protein synthesis. See also **Proteins**. Both DNA and RNA interact with a host of other molecules, e.g., proteins, drugs, as well as other RNAs and DNAs. The specificity of these interactions is thought to be related to local sequence-dependent structural variation.

Development of techniques to synthesize oligonucleotides, i.e., short, well-defined sequences of DNA or RNA, has provided the opportunity to study nucleic acid structure in detail. In addition, oligonucleotides have proved invaluable in analytical procedures used in genetic engineering (qv), protein engineering (qv), affinity chromatography, and forensics, as well as in medicine. See also **Chromatography**; and **Forensic Chemistry**. The unique ability of nucleic acids to bind to self-complementary sequences has been exploited in the design of oligonucleotide probes and in antisense drug strategies.

DNA Structure

The structure of DNA is characterized by its primary sequence, secondary helical structure, and higher order structure or topology. The primary sequence of DNA refers to the atomic connectivities required to construct the polynucleotide chain. The helical conformation of these polynucleotide chains constitutes the secondary structure of DNA. Sequence-dependent structural diversity and flexibility are important DNA characteristics and play a crucial role in biological processes. The organization of helical DNA in topologically distinct three-dimensional conformations represents the higher order structure. Higher order structural features, in particular the supercoiling of DNA, are thought to have a profound influence on the dynamic processes and biology of nucleic acids within living cells.

The DNA double helix was first identified by Watson and Crick in 1953. Not only was the Watson-Crick model consistent with the known physical and chemical properties of DNA, but it also suggested how genetic information could be organized and replicated, thus providing a foundation for modern molecular biology.

The primary structure of DNA is based on repeating nucleotide units, where each nucleotide is made up of the sugar, i.e., 2′-deoxyribose, a phosphate, and a heterocyclic base, N. The most common DNA bases are the purines, adenine (A) and guanine (G), and the pyrimidines, thymine (T) and cytosine (C) (see Fig. 1). The base, N, is bound at the 1′-position of the ribose unit through a heterocyclic nitrogen.

The nucleotides are linked together via the phosphate groups, which connect the 5′-hydroxyl group of one nucleotide and the 3′-hydroxyl group of the next to form a polynucleotide chain (Fig. 1**a**). DNA is not a rigid or static molecule; rather, it can adopt a variety of helical motifs.

In A- or B-form DNA, two self-complementary polynucleotide strands associate with one another to form a right-handed double helix. The two polynucleotide chains are antiparallel.

In addition to A- and B-form DNA, several other helical conformations have been identified. Among these, the most well-studied is Z-DNA, a left-handed helix first characterized by x-ray crystallographic analysis of the oligonucleotides d(CGCGCG) and d(CGCG). Other alternating purine—pyrimidine sequences, in particular alternating CG sequences, have been shown to adopt the Z-conformation at high ionic strength.

RNA Structure

RNA has a variety of functions within a cell; for each function, a specific type of RNA is required. Messenger RNA (mRNA) serves as intermediaries for carrying genetic messages from the DNA to the ribosomes where protein synthesis takes place. Ribosomal RNA (rRNA) serves both structural and functional roles in the ribosome; it is diverse, both in terms of its size and structure. Transfer RNAs (tRNAs) are small molecules that have a central role in protein synthesis. Other RNA molecules, called ribozymes, function as enzymes to catalyze chemical transformations. Although ribozymes most often catalyze cleavage of the

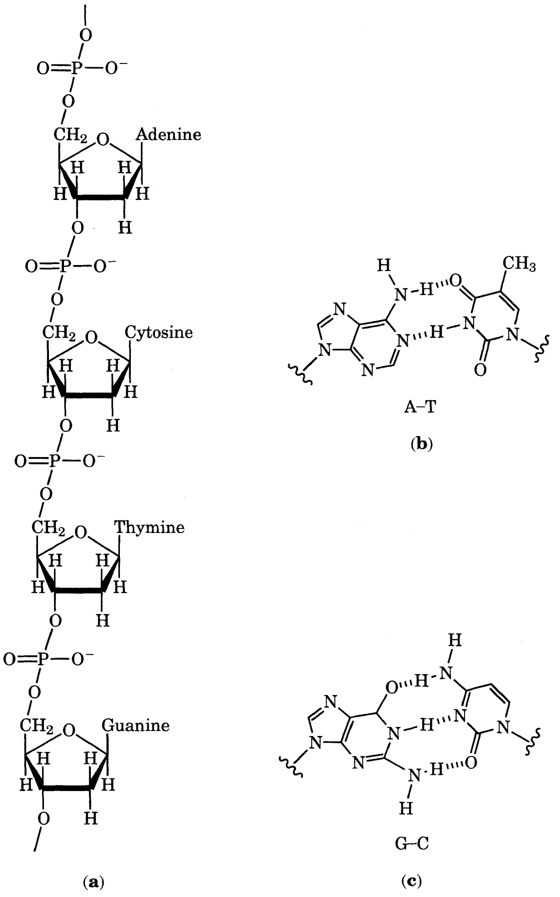

Fig. 1. Elements of DNA structure: (**a**) a deoxypolynucleotide chain, which reads d(ACTG) from 3′ → 5′ or d(GTCA) from 3′ → 5′; and (**b**) and (**c**) the Watson-Crick purine–pyrimidine base pairs, A–T and G–C, respectively, where —∼ represents attachment to the deoxyribose

RNA phosphodiester backbone, they have also been shown to participate in cleavage of DNA, replication of RNA, and reactions with phosphate monoesters. Other RNAs are associated with enzymes to form riboprotein complexes involved in many biological processes. The multifunctional character of RNA, particularly the involvement of RNA in enzymatic processes, has led to the hypothesis that life on earth evolved from RNA, and that RNA had both the genetic and catalytic functions commonly associated with DNA and proteins, respectively.

The primary structure of RNA is similar to that of DNA, but with a few notable exceptions. First, in RNA, instead of thymine, the pyrimidine base uracil (U) occurs, forming a complementary base pair with adenine in regions of double-stranded RNA. Also, a wide variety of ribonucleotides having modified or minor bases are found in naturally occurring RNA, one of the most common of which is pseudouridine. In human tRNAs, as many as 25% of the bases are nonstandard. Over 80 modified bases have been characterized in naturally occurring tRNA; although the role of base modification is not clear, it may be important for biological recognition.

The other important feature of the primary structure of RNA is the presence of the 2′-hydroxyl group in ribose. Although this hydroxyl group is never involved in phosphodiester linkages, it does impose restrictions on the helical conformations accessible to double-stranded RNA.

RNAs are single-stranded molecules that fold, allowing different regions of the ribonucleotide to form distinct secondary structural elements. When self-complementary regions of the RNA strand are aligned, duplex regions, which may have Watson-Crick base pairs, are formed. In contrast to DNA, double-stranded regions in RNA are much more likely to have unusual base-pairing between noncomplementary bases and to incorporate non-Watson-Crick base-pairing. Owing to the steric requirements of the 2′-hydroxyl group on the ribose sugar, these duplex regions are constrained to an A-form helix, i.e., a 3′-endo sugar conformation. Although double-stranded RNA has the general features of an A-form helix,

actual duplex characteristics, such as rise per base pair, groove dimensions, and base pair displacement from the helical axis, may vary.

The functional diversity of RNA is directly related to its structural diversity. In contrast to DNA, RNA molecules are synthesized as single-stranded polynucleotides that fold to give complex tertiary structures. These structures, which incorporate hairpins, loops, bulges, and junctions between single-stranded and double-stranded regions, exhibit long-range interactions within the folded tertiary structure. Long-range intramolecular interactions serve to stabilize the three well-characterized RNA structures.

Oligonucleotide Synthesis

Synthetic oligonucleotides are widely used in scientific investigations. Most synthetic oligonucleotides are produced for use as primers in the polymerase chain reaction (PCR), a widely used analytical technique having commercial applications in diagnostic medicine, genetic engineering (qv), and forensics. See also **Forensic Chemistry**. A large volume of oligonucleotides are also synthesized for use as primers in DNA-sequencing. Demands for sequencing primers have increased rapidly to support large-scale DNA mapping and sequencing efforts such as the human genome project. Although the quantities of oligonucleotides used are relatively small, these materials are essential in many areas of basic research.

In molecular biology, synthetic oligonucleotides are used as linkers in gene-cloning and to introduce site-directed mutations in genes. Synthetic oligonucleotides are required for structural, biochemical, and biophysical studies of DNA and RNA. Oligonucleotides also are important for examining the association of proteins and small molecules, e.g., for intercalating drugs with nucleic acids on a molecular level.

The first procedures for oligonucleotide synthesis, typically carried out in solution, made use of *H*-phosphonate and phosphotriester chemistry. These approaches are useful in some large-scale syntheses and in syntheses of various oligonucleotide analogues. Most modern procedures, however, are based on solid-phase phosphoramidite chemistry. Automated oligonucleotide synthesizers are commercially available, as are the required reagents and phosphoramidites. Together these permit the rapid production of custom oligonucleotides and oligonucleotide analogues.

Modified Oligonucleotides. Much of the interest in modified oligonucleotides is related to use as antisense agents. Antisense agents are typically short (15–30 base pairs in length) oligonucleotides having sequences that are complementary to coding or regulatory regions within mRNA, although some antisense oligonucleotides have also been designed to target DNA. The antisense sequence recognizes and binds to a complementary sequence via the formation of a double-stranded duplex that have normal Watson-Crick base-pairing. Antisense oligonucleotides can inhibit gene expression at the translational level. The potential to design oligonucleotides having the ability to recognize and inhibit specific genes makes the antisense approach promising in the development of new therapeutic agents. In addition, antisense oligonucleotides can be used in research to elucidate gene function by providing a mechanism for regulating a gene artificially.

Although all natural antisense oligonucleotides are short RNA sequences, most of the synthetic antisense oligonucleotides are deoxyoligonucleotides. In the design of an effective antisense oligonucleotide, several factors must be considered. First, the oligonucleotide must be specific, binding with high affinity to a single sequence within the target RNA. A second consideration is stability within the cellular environment. Thus all unmodified oligonucleotides are degraded too rapidly to be used effectively as therapeutic agents. A significant research effort has been directed toward discovering chemical modifications that can increase the nuclease resistance of the oligonucleotide backbone.

An effective therapeutic agent must also have the ability to reach its target sequence *in vivo*. In order to enhance membrane transport, antisense oligonucleotides are frequently modified by covalent attachment of carrier molecules or lipophilic groups.

Antisense oligonucleotides are usually designed to inhibit gene expression by interfering with the translation of mRNA. One mechanism for this type of inhibition involves binding the oligonucleotide to the translation-initiation sequences of the mRNA, which prevents ribosome association and protein synthesis. Another potential mechanism involves hybrid formation at some other sequence within the mRNA, thus impeding translocation of the ribosome along the mRNA strand by steric blocking. These two mechanisms are based on blocking a sequence of RNA or DNA by double-stranded duplex formation using a specific antisense oligonucleotide.

A less specific mechanism based on the action of Rnase H, an enzyme catalyzing single-strand cleavage of RNA, may be predominate for unmodified, thioate and dithioate oligonucleotides. In the Rnase H mechanism, the duplex formed by the antisense oligonucleotide and the target RNA is a substrate for Rnase H. The enzyme cleaves the RNA at the complexes site rendering the RNA vulnerable to further degradation and inactivation by cellular exonucleases. The oligonucleotide, which is probably not a substrate for Rnase H, can target multiple copies of complementary RNA. Where applicable, antisense oligonucleotide action mediated by the Rnase H mechanism has been shown to be a potent inhibitor of gene expression.

Modified oligonucleotides can also be designed for binding to double-stranded DNA by forming a triple helix.

Oligonucleotides can also inhibit gene expression at the transcriptional level by binding to a single-stranded or open sequence of DNA. In this mechanism, the antigene oligonucleotide is designed to be complementary to a regulatory sequence preceding a gene. For example, an oligonucleotide complementary to the *lac* operator sequence (repressor protein binding site) has been found to inhibit specifically β-galactosidase synthesis in *E. coli*. Normally, expression of the lactose-metabolizing enzyme, β-galactosidase, is blocked at the transcriptional level by the repressor binding to the operator sequence. In the presence of a lactase metabolite, the repressor is converted to a nonbinding form and dissociates from the operator, which results in the transcription of the gene and β-galactosidase production. However, in the presence of the antisense oligonucleotide, the synthesis of β-galactosidase is inhibited. The antisense oligonucleotide can then act as a repressor by binding to an open or single-stranded region within the operator.

Although development of modified oligonucleotides as antisense and antigene agents is a principal focus of research in the 1990s, there are many other interesting applications that have greater immediate commercial significance. Included among these are applications using nucleic acid probes, which are oligonucleotides that have been modified by the attachment of a detectable chemical group. Probes can be designed to recognize RNA or DNA sequences characteristic of specific eukaryotic genes, viruses, or bacteria. Several analytical and diagnostic procedures have been developed based on the hybridization of the probe with its target sequence and the subsequent detection of the hybrid by the group attached to the oligonucleotide. Probes, particularly useful in automated sequencing protocols, may contain fluorescent groups, phosphors, radioactive tracers (qv), etc. In addition, probes can be designed to help elucidate the structure of biological molecules. DNA-binding molecules, including intercalators, alkylating agents, and photosensitive molecules, have also been linked to oligonucleotides as a way of directing a drug to a specific DNA sequence. These modifications often enhance binding as well.

Oligonucleotide Bioconjugates

Although many molecules, including proteins and small intercalating and groove-binding ligands, bind to RNA and DNA, only nucleic acids are able to bind with the high specificity required to recognize a single sequence within the 3×10^9 base-pairs of the human genome. The unique specificity of oligonucleotides can be exploited to direct a multitude of other chemical agents to a sequence of interest by attaching these agents to oligonucleotides through molecular linkers. Oligonucleotides labeled with fluorescent or other detectable groups provide nucleic acid probes that can be used to screen a large pool of DNA for a specific sequence. Cationic or lipophilic groups can be attached to improve the binding and bioavailability of antisense oligonucleotides. Bioconjugates have also been widely used in research because they enable scientists to learn more about the structure and function of nucleic acids and ligands that bind to them.

Several strategies have been devised to attach various chemical groups to oligonucleotides. Groups can be attached to the 3′- or 5′-terminus of the oligonucleotide, along the backbone through the phosphate or the 2′-hydroxy group of ribose, or to modified purines or pyrimidines.

NUCLEONICS. The applications of nuclear science in physics, chemistry, biology, and other sciences, including military science, and in industry, and the techniques associated with these applications.

NUCLEONS. Two nuclear particles, the proton and the neutron, and their antiparticles are known as *nucleons*. The rest mass of the proton is 1.0076 amu; that of the neutron, 1.0089 amu. The antiproton bears the same relation to the proton that the electron does to the positron, i.e., its charge is equal and opposite and its mass is the same, the charge being equal in magnitude to the electronic charge. Protons and antiprotons also annihilate each other when they collide, the reaction of a single pair producing positive and negative pions or kaons. If the proton and antiproton do not collide, but experience a "near miss," then an exchange of charge can occur, resulting in the formation of a neutron-anti-neutron pair. The four nucleon particles are fermions and have a spin angular momentum quantum number of $\frac{1}{2}$. See also **Neutron**; **Particles (Subatomic)**; and **Proton**.

NUCLEOPHILE. An ion or molecule that donates a pair of electrons to an atomic nucleus to form a covalent bond. The nucleus that accepts the electrons is called an *electrophile*. This occurs, for example, in the formation of acids and bases according to the Lewis concept, as well as in covalent bonding in organic compounds.

NUCLEOPHILIC REACTION. A reaction in which a nucleophilic reagent attacks an electrophilic compound. The reagent is taken to be the inorganic substance (in the case of reactions of inorganic and organic substances) or the simpler of two reacting organic compounds. The electron pair for the bond formed is furnished by the nucleophilic reagent.

NUCLEOPROTEINS AND NUCLEIC ACIDS. Nucleic acids are compounds in which phosphoric acid is combined with carbohydrates and with bases derived from purine and pyrimidine. Nucleoproteins are conjugated proteins consisting of a protein moiety and a nucleic acid. Originally, nucleoproteins were thought to occur only in the nuclei of cells, but it was later established that they are far more widely distributed, being found in cells of all types, animal and plant. They are found in the chromosomes, in the genes, in viruses, and bacteriophages.

The protein portion of the nucleoproteins is basic in nature and being complex in structure may form several types of linkage, depending upon the type of nucleic acid. In gastric digestion or hydrolysis with weak acid, nucleoproteins yield protein and nuclein. The latter in pancreatic digestion or hydrolysis with weak alkali yields additional protein and nucleic acid. See also **Nucleic Acids**.

NUCLEOSIDE. A compound of importance in physiological and medical research, obtained during partial decomposition (hydrolysis) of nucleic acids and containing a purine or pyrimidine base linked to either *d*-ribose, forming ribosides, or *d*-deoxyribose, forming deoxyribosides. They are nucleotides minus the phosphorus group. See also **Adenosine**; and **Nucleic Acids**.

NUCLEUS. 1. The nucleus of an atom is the positively charged core, with which is associated practically the entire mass of the atom, but only a minute part of its volume.

2. The nucleus of a molecule is a group of atoms connected by valence bonds so that the atoms and their bonds form a ring or closed structure, which persists as a unit through a series of chemical changes.

3. A group of cell bodies in the central nervous system of vertebrates. Examples of such groups are the red nucleus in the midbrain, through which impulses are routed for the control of subconscious muscular movements, and Deiter's nucleus, lying at the junction of the medulla with the hindbrain. Through this center impulses pass for muscular action involved in the maintenance of equilibrium.

4. A somewhat spherical or oblong body in most living cells. This nucleus contains the chromosomes, which, in turn, bear the genes of heredity. The nucleus also contains a nucleolus, or sometimes two or more nucleoli and a basic ground substance, the nucleoplasm. A nuclear membrane surrounds it on the outside, but this membrane is very porous, allowing materials to pass through rather freely.

5. Condensation nuclei take part in phase changes, as in the formation of clouds; in seeding concentrated solutions to bring about crystallization, precipitation, etc.

NUCLIDES. See **Chemical Elements**.

NUTRIENTS (Soil). See **Fertilizer**.

NYLON. [CAS: 63428-83-1]. $(C_6H_{11}NO)_n$. Generic name for a family of polyamide polymers characterized by the presence of the amide group −CONH. By far the most important are nylon 66 (75% of U.S. consumption) and nylon 6 (25% of U.S. consumption). Except for slight difference in melting points, the properties of the two forms are almost identical, though their chemical derivations are quite different. Other types are nylons 4, 9, 11, and 12.

The first nylon developed (type 6/6) was discovered in 1938 by W. H. Carothers. Since that time, nylons have filled an important role for industry and the consumer in various formulations, shapes, and forms, e.g., oriented fibers, which are subsequently processed into fabrics, fishing line, and other monofilament uses; injection-molded nylons, used as bearings, gears, and other parts subjected to wear and impact; extruded nylon tubing and hose, used in large quantity because of its chemical inertness, high strength, and flexibility; oriented nylon strip used as strapping for packaging, displacing traditional steel strapping; and heavy cast-nylon parts, frequently used in the textile, paper-making, and bottle-handling fields.

Most nylons exhibit a combination of high melting point, high strength, impact resistance, wear resistance, chemical inertness, and a low coefficient of friction.

Types of Nylon. Type 6/6 and type 6 nylons are widely used, dominating the field of textile fibers. Nylon 6/10, a lower-strength material produced in less volume, is used for industrial applications requiring improved moisture stability and high dielectric strength. It also has a lower melting point, lower specific gravity, and higher cost than types 6/6 and 6. Nylons 11 and 12 appeared considerably later than the other formulations. Generally, these nylons have a lower order of moisture absorption and are thus preferred where consistent properties are required in the presence of moisture. They are also more chemically inert, flexible, and in certain cases, are transparent.

Formulations. Types 6/6 and 6/10 are formed by the condensation of diamines with dibasic organic acids into linear chains containing amide groups. Types 6, 11, and 12 are self-condensed amino acids.

Type 6/6:

$$\underset{\text{Hexamethylenediamine}}{NH_2(CH_2)_6\,NH_2} + \underset{\text{Adipic acid}}{HOOC(CH_2)_4COOH} \longrightarrow$$

$$\underset{\text{Polyhexamethyleneadipamide}}{[NH(CH_2)_6NHCO(CH_2)_2CO]_n} + H_2O$$

Type 6/10:

$$\underset{\text{Hexamethylenediamine}}{NH_2(CH_2)_6\,NH_2} + \underset{\text{Sebacic acid}}{HOOC(CH_2)_8COOH} \longrightarrow$$

$$\underset{\text{Polyhexamethylenesebacamide}}{[NH(CH_2)_6NHCO(CH_2)_8CO]_n} + H_2O$$

Type 6:

$$\underset{\varepsilon\text{−Caprolactam}}{NH(CH_2)_5CO} \longrightarrow \underset{\text{Polycaprolactam}}{[NH(CH_2)_5CO]_n}$$

Type 11:

$$\underset{\text{Aminoundecanoic acid}}{NH_2(CH_2)_{10}COOH} \longrightarrow \underset{\text{Polyaminoundecanamide}}{[NH(CH_2)_{10}CO]_n} + H_2O$$

Type 12:

$$\underset{\text{Laurolactam}}{NH(CH_2)_{11}CO} \longrightarrow \underset{\text{Polydodecanolactam}}{[NH(CH_2)_{11}CO]_n}$$

In addition to the basic nylons, a variety of copolymers can be manufactured, some of which are commercially available. Nylons and nylon copolymers can be blended to form alloys with specific customized properties.

Nylons can be modified by the addition of certain plasticizers, fillers, reinforcements, and stabilizers. Ordinarily, nylons used for injection molding, such as type 6/6, have relatively low molecular weights (on the order of 15,000 to 20,000). High molecular weights are available to provide higher melt viscosity for nylon resins which are to be extruded into tubing or shapes. The molecular weight of nylon generally is determined by the ASTM relative-viscosity test.

Nylon resins usually are supplied in the form of cylindrical or rectangular diced pellets. Most commercial nylon molding. resins are nontoxic. If a large amount of residual monomer is retained in the resin, as can occur with certain unextracted formulas, the material should not be in prolonged contact with food because of the possibility of monomer leaching.

Nylons require modification or stabilization to improve their resistance to certain environmental effects. Unstabilized nylon is degraded by ultraviolet light. The most widely used stabilizer has been approximately 2% well-dispersed carbon black, which has proved effective in the absorption of ultraviolet light. The nylons are considered adequate for outdoor applications if they are not exposed to direct sunlight.

OCEAN RESOURCES (Mineral). Since antiquity, the oceans and seas have been a major source of salt (sodium chloride) and continue to be so. Today, solar sea salt is produced in about 60 countries. The People's Republic of China, Australia, Mexico, India, Brazil, the Bahamas, Spain, and France are among the leading producers. At present, about 38% of the sodium chloride produced is evaporated from seawater. The value is estimated at over $400 million per year. Solar salt is very important to many countries, such as Japan, where there are few or no salt deposits. For several decades, seawater has been a significant source for bromine (production commenced by DuPont in 1931); iodine (from kelp, once very important, but no longer an economic source); magnesium (production started by Dow in 1941); potassium; sulfur; and several other elements and their compounds. Today, over 13% of the requirements for bromine come from seawater, as do over 70% of magnesium metal and 33% of magnesium compounds required by industry. Sulfur, associated with the cap rock of salt domes, has been produced from two salt domes just off the coast of Louisiana for many years. For a few decades, the continental shelves under the oceans have been producing large volumes of natural gas and petroleum. And also, for a few decades, the oceans have provided fresh water for many regions through various desalination processes. There are over 500 desalination plants in operation or under construction, with plants in arid and semiarid locations, such as the Middle East, but also in some highly urbanized regions and cities where fresh water is in short supply, such as in Italy and the Netherlands.

Many of the ore deposits found on the continents are the result of ancient oceans. Tin is found in offshore deposits, such as in Indonesia, in Cornwall (Saint Ives Bay), and Phuket Island off the west coast of the Malay Peninsula.

Within the past 20–30 years, much interest has been shown in manganese nodules on the seafloor in various locations. More recently, the discovery of hot brines in the Red Sea, "black smokers" on the East Pacific Rise and suspected in many other locations, and ophiolites has excited the scientific community and attracted industrialists because these phenomena are associated with metals, such as cadmium, copper, nickel, and zinc. These findings have largely resulted from the funding provided for geological and oceanographic research as part of the Deep Sea Drilling Project (DSDP) and the International Decade of Ocean Exploration (IDOE), projects which have been in place since the late 1960s.

More details pertaining to most of these ocean raw materials will be found in a number of specific entries in this encyclopedia. See also **Bromine**; **Chemical Elements**; **Desalination**; **Magnesium**; **Manganese**; **Natural Gas**; **Petroleum**; **Sodium Chloride**; and **Sulfur**.

The resource potential of the oceans awaits further technological development. It is interesting to note that the famous German chemist, Fritz Haber, spent more than eight years after World War I in attempts to recover gold from seawater in order to pay the German war debt. The results were disappointing, but large quantities of gold are in very large quantities of seawater. Currently, there is considerable interest in attempts to recover uranium from seawater, particularly by nations with no assured supply. Should fusion power come to fruition, after a few years, the ocean may be looked to as a source of lithium. Beach sands also have received considerable attention in recent years as sources of metals and other materials. Marine beaches may contain gold, silver, platinum, and diamonds in addition to magnetite, cassiterite, chromite, columbite, ilmenite, rutile, scheelite, zircon, monazite, and wolframite. Heavy-mineral beach sands are usually commercially worked for the titanium content of the rutile and the ilmenite. The same sands may also be processed to recover thorium from monazite and zircon for use in foundry sands. Currently, marine beaches are mined for heavy mineral production in Australia, Brazil, India, Madagascar, Mozambique, Sierra Leone, South Africa, and Sri Lanka, among other countries.

Diamonds are found in the seafloor sediments on the coast of the Kalahari Desert in southwest Africa.* The origin of the diamonds is obscure, but it is generally believed that basaltic and kimberlite pipes exist on the ocean floor as on the nearby land. There is a relative abundance of gemstones in the marine deposits and a few large stones have been recovered. Dredging began in 1961, using suction dredges capable of operating in waters to depths of 50 meters. Because of rough seas on this exposed coast, a number of barges were lost and the operation was concluded. However, in recent years a subsidiary of DeBeers is using a dredge protected by a seawall, thus permitting mining offshore about 120 meters at depths of 90 meters.

Calcium carbonate often precipitates from tropical or subtropical waters when the water becomes supersaturated due to enrichment of the carbonate content by intense biological photosynthesis and by solar heating of carbon dioxide-rich cooler waters. The aragonite precipitates as single needles in the shallow waters at a rate of about one millimeter of wet sediment per year. Continuing deposition leads to cementation and the formation of successive concentric sheaths known as oöids. The most extensively studied oölithic aragonite deposit is that distributed over the 250,000-square-kilometer (96,525-square-mile) Great Bahama Bank on the continental shelf near islands of the Bahamas. Most of the areas are less than 5 meters deep and are composed of quite pure calcium carbonate containing higher levels of strontium and uranium than are found in limestones of biological origin. Similar deposits occur in the Gulf of BatabanÓ (Cuba) and in the Mediterranean Sea off Egypt and Tunisia, as well as on the Trucial coast of the Persian Gulf.

Iron is a common constituent of marine sediments. Magnetite is found in beach sands and iron is common in glauconitic marine silicates. Iron oxides and sulfides occur where anaerobic conditions and elevated temperatures are found, as in the hot, salty brines found near rifts. Iron is a major constituent of the ferromanganese nodules.

Magnetite-rich iron sands have been dredged from the ocean floor just off Kagoshima Bay (Japan) in water averaging from 15 to 40 meters in depth. Iron sand concentrates were produced in Japan as recently as 1976, although a major marine iron sand operation in Kyushu ceased operation in 1966.

Marine sand and gravel for fill and for aggregate have been produced on all coasts of the United States, particularly from San Francisco and San Pedro Bays in California and from Long Island Sound. Marine sand and gravel are found in significant quantities in the United Kingdom.

Phosphorites (marine apatites) are dense, light-brown-to-black concretions, ranging in size from sands to nodules and irregular masses. Phosphorites have been found off Argentina, Chile, Japan, Mexico, Peru, South Africa, and Spain, and several islands in the Indian Ocean. Some also have been found off the west coast of North America and on the eastern North American continental shelf. These deposits occur where water upwelling transports phosphorus and where the rate of sedimentation is slow. The

* Acknowledgement of assistance obtained from W.F. McIlhenny, The Dow Chemical Company, Freeport, Texas in preparation of several of the following paragraphs is hereby made.

nodules are usually found as a monolayer on the surface. The mineralogy of the marine phosphorites is similar to western U.S. land deposits, which were almost certainly marine in origin. Phosphorites are quite constant in composition, containing 45–47% calcium oxide and 29–30% phosphorus trioxide. Seawater is generally saturated with tricalcium phosphate so that, under the oxidative conditions normally present, the phosphates precipitate in colloidal form and accrete to existing surfaces, rather than forming a phosphorite suspension. Although most of the phosphorite is believed to have formed during the Miocene epoch, it is believed that precipitation is currently taking place. The largest known seafloor phosphorite deposit is off the coast of California from Point Reyes to the Gulf of California along the inner edge of the continental shelf. Additional deposits have been found on the edges of the Blake Plateau east of Florida. A recovery project was commenced in 1962–1963, but failed to materialize.

Glauconite or green sands (a hydrated silicate with potassium, iron, and aluminum as cations) is widely distributed on the ocean floor in both ancient and more recent marine sediments. Glauconite is often found with phosphorite and occurs on the tops of banks, submerged hillcrests, and on slopes in water from 50 to 2000 meters in depth. Glauconites are known off the coasts of Africa, Australia, China, Japan, Portugal, South America, the United Kingdom (Scotland), the United States (California and the Atlantic shelf), and New Zealand. A 130-square-kilometer (50-square-mile) deposit has been identified on the Santa Monica shelf off California.

Submarine Hydrothermal Deposits

Discovery of the East Pacific Rise hot springs has created extensive interest and plans are underway to commence a four-year, multi-institutional project to explore the East Pacific Rise for additional areas of hot spring activity and ore deposition. The major objective of the program will be to examine the nature of hydrothermal processes along the mid-ocean ridge system from the slow-spreading to the very fast-spreading segments, such as at 10–30° South. The project will involve the use of surface ships, deeply towed instrument packages, new high-precision multibeam echo sounding for making highly accurate topographic maps of the seafloor, and ultimately manned submersibles, such as *Alvin.*

The knowledge of submarine hydrothermal deposits was advanced by a large measure in 1979 when the hot springs on the East Pacific Rise at 21° north were discovered. Unlike the warm springs discovered on the Galápagos Spreading Center a few years ago, the springs on the East Pacific Rise are hot, with water venting at temperatures as high as 350°C and at velocities of several meters per second. These formations are precipitating large quantities of sulfide ore and minerals rich in copper, zinc, and iron. The precipitates form chimneys around the individual vents that spout black or white smoke composed of precipitated crystals of sulfides and other minerals. The discovery is the most exciting and significant in this field since the discovery of the Red Sea hot brines and metal deposits (Mottl, 1980).

By *hydrothermal* is meant hot water. When deposits are formed by chemical precipitation from hot solutions, they are termed hydrothermal. Hydrothermal deposits on land represent a very important class of economically retrievable ore deposits and provide a significant percentage of various metals, such as copper, zinc, lead, silver, gold, tin, molybdenum, among others. Mottl (1980) suggests that five factors are involved in forming hydrothermal ore deposits: (1) a source of the ore metals; (2) a source of water that dissolves and later precipitates the metals, concentrating them during the total cycle; (3) a source of heat; (4) a pathway between the site where metals are dissolved and precipitated and the site where they are finally deposited which is permeable and permits solution flow; and (5) the ultimate collection or deposition site. For preservation, it is also important that ores be deposited in places where they will not be eroded away, as by weathering. Because so many factors are involved, there is a wide variety of hydrothermal ore deposits.

In terms of submarine hydrothermal ore deposits, the source of heat is the thermal energy associated with the formation of new oceanic lithosphere along the mid-ocean ridge system, where the seafloor is spreading apart and basaltic magma wells up. Because of tensional forces present, the newly formed crust becomes fractured, allowing seawater to percolate down through the fractures. During this percolation, the seawater is heated by contact with hot rock and commences to react with the rock, leaching metals that may be present. Because of the lesser density of the seawater (due to temperature), it rises and ascends to the seafloor and exists at submarine hot springs. Because there are several factors involved, there is, as on land, a wide variety of submarine hydrothermal ore deposits. Much remains to be understood and to confirm some of the early postulates, as given above, pertaining to the actual formation of submarine deposits.

For example, the concentrations of ore metals in most natural waters are quite low, particularly so in "normal" seawater. Measuring these low concentrations has been a problem of marine chemistry for many years. It is interesting to note that when artificial seawater, made up from pure reagent chemicals, is exposed to metallic elements, the ultimate solutions produced will contain from 100 to 1000 times the concentrations of these metals as compared with natural seawater.

The first submarine hot springs discovered along a mid-ocean ridge, those at the Galápagos Spreading Center, were emitting water at only 20°C, but the chemistry of this water indicated that it had reacted with basalt at 350–400°C. Then came the discovery of the 350° springs on the East Pacific Rise. Currently, the chemistry of this water is being studied at the Massachusetts Institute of Technology. To date, no submarine hydrothermal deposit has been sufficiently studied that all components contributing to its formation are known. Nevertheless, data at hand as of the early 1980s suggest some intriguing relationships among known deposits along mid-ocean ridges and point out the importance of special situations in producing and preserving large deposits.

Offshore Oil and Gas Resources

Although oil and gas exploration and production activities which occur offshore involve an extension of continents (the continental margins), they are nevertheless considered more in the general terms of oceanological rather than continental resources (the latter generally considered land or above-sea-level resources). Various aspects of offshore oil and gas production are described briefly in the entries on **Natural Gas**; and **Petroleum**.

As we go into the next century, because of an apparent glut of petroleum on world markets and because of much greater optimism pertaining to the ultimate natural gas reserves in the world, the emphasis on the exploration for petroleum and natural gas in underwater locations has markedly diminished.

Manganese Nodules

Deep-sea nodules, comprised mainly of manganese and iron oxides, have been found in abundance over large areas of the deep ocean floor that have been examined to date. In some locations, the nodules have been found to contain generous proportions of nickel, copper, cobalt, molybdenum, and vanadium, as well as manganese and iron. From the standpoint of potential commercial exploitation, a deposit is not considered promising unless the nickel-copper content is about 1.8% (weight) or greater. On this basis, one of the most promising areas is the Clarion and Clipperton fracture zone, an immense area some 4400 kilometers (2730 miles) long and 900 kilometers (560 miles) wide at its widest point. This zone is located southeast of Hawaii and southwest of Baja California. See Fig. 1.

An investigation of the origin and distribution of manganese nodules and the processes by which they selectively concentrate copper, nickel, and other metals was one of the first major projects under the sea beds Assessment project of the IDOE program. At a workshop attended by over a hundred scientists from various countries, the most likely locations

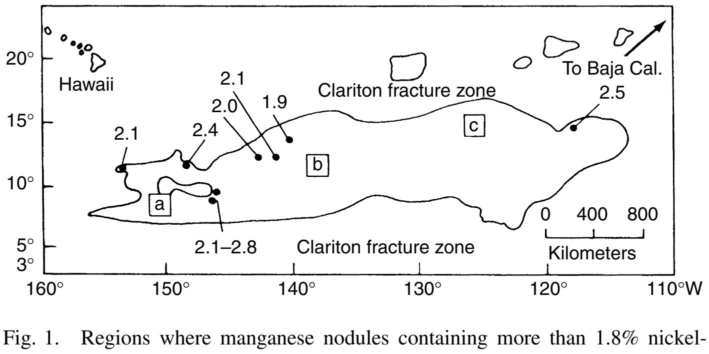

Fig. 1. Regions where manganese nodules containing more than 1.8% nickel-copper occur in the northeastern equatorial Pacific Ocean. Numbers indicate average percent of nickel-copper in one-degree squares. Areas a, b, and c indicate locations of activity carried out as part of Deep Ocean Mining Environmental Studies Program. (*After McKelvey, U.S. Geological Survey*)

for the exploration and study of manganese nodules were selected. The north central Pacific was identified as the zone where the nodules have the highest metal content. A team of American scientific investigators proposed that a comprehensive field and laboratory program be initiated to relate the high metal content to the local geological conditions. Data gathering was concerned along a transect that both academic and industrial scientists agreed could serve as a potential mining site. In addition to dredge sampling and piston cores, bathymetric measurements, sidescan sonar, and high-resolution television pictures were obtained. See Fig. 2. The results provided a broad-scale picture of the conditions under which nodules form, but the mechanisms for concentrating specific metals are still not well defined.

Although the nodules vary widely in their composition over the world oceans, metals are concentrated in three distinct types. One type comprises the nickel-copper-rich nodules of the Clarion-Clipperton variety, which is mainly formed in the equatorial regions. Another type, high in cobalt (1% or more) and low in nickel and copper, appears to be most commonly formed on sea mounts. The third type is high in manganese (35% or more), but low in other metals; it is known mainly on the eastern side of the Pacific Basin. As of the early 1980s, the most economically attractive were the cobalt-rich nodules.

The nodules form in a layered structure around a nucleus, which may be almost any material on the ocean floor. Most deep-sea nodules tend to be spherical or oblate in form. Nodules may occur up to 25 centimeters in diameter, but they average about 5 centimeters. The deposits may occur as slabs or agglomerates, or as incrustations on rocks or as pavement in some areas. The nodules are disorderly crystalline materials with layers of MnO_2 (mixed Mn^{2+}-Mn^{4+} oxides) alternating with $Mn(OH)_2$ and $Fe(OH)_3$. Excess iron appears as a mixture of goethite ($Fe_2O_3 \cdot H_2O$) and lepidocrocite.

The nodules are formed by the oxidation and precipitation of iron and manganese. The oxidation of Mn^{2+} is catalyzed by a reaction surface to a tetravalent state that absorbs additional Fe^{2+} or Mn^{2+} which, in turn, becomes oxidized. A surface is required and the initial deposition may be of iron oxide, possibly from volcanic or geothermal sources. Proper conditions of pH, redox potential, and metal ion concentration are found in deep ocean waters. The rate of accumulation appears to be very slow. The growth also may be discontinuous, and is estimated at a faster rater rate near the continental margins.

Precious Coral

Only a few species of coral have a combination of beauty, hardness, and luster, such the black coral species of Hawaii (*Antipathes dichotoma* and *Antipathes grandis*). These are highly valued by the jewelry trade. There are also a few red, pink, gold, and bamboo varieties that are in demand. Black coral also occurs in the Gulf of California and in the Pacific Ocean off Baja California, plus a few scattered locations in the Pacific Ocean east of Australia and north of New Zealand. Traditional sources of red and pink corals have been the Mediterranean Sea, various locations in the western Pacific Ocean, ranging from the Philippines, the Ryuku and Bonin islands and south of Japan. There is also a string of precious red and pink coral beds northwest of Hawaii and off the Cape Verde islands in the Atlantic Ocean off west Africa. A submersible vessel, the *Star II*, operated by Maui Divers of Hawaii, Ltd., is used to harvest pink coral (*Corallium secundum*) from the Makapuu bed. State regulations permit the collection of only 4400 pounds (1996 kilograms) within a 2-year period.

OCEAN THERMAL ENERGY CONVERSION (OTEC). Utilization of ocean temperature differentials between solar-heated surface water and cold deep water as a source of electric power. In tropical areas such differences amount to 35–40°F. A pilot installation now operating near Hawaii utilizes a closed ammonia cycle as a working fluid, highly efficient titanium heat exchangers, and a polyethylene pipe 2000 feet long and 22 inches inside diameter to handle the huge volume of cold water required. Alternate uses for such a system, such as electrolysis of water,

ammonia production, and desalination, are envisaged. There has been active interest in the possibilities of this energy source in France from the time of d'Arsonval (1881) that continues, especially in Japan and Hawaii. Ongoing research indicates that OTEC may be harder to commercialize than once projected.

OCEAN WATER. An electrolyte solution containing minor amounts of nonelectrolytes and composed predominantly of dissolved chemical species of fourteen elements O, H, Cl, Na, Mg, S, Ca, K, Br, C, Sr, B, Si, and F (Table 1). The minor elements, those that occur in concentrations of less than 1 ppm by weight, although unimportant quantitatively in determining the physical properties of sea water, are reactive and are important in organic and biochemical reactions in the oceans.

Dissolved Species

The form in which chemical analyses of sea water are given records the history of our thought concerning the nature of salt solutions. Early analytical data were reported in terms of individual salts NaCl, $CaSO_4$, and so forth. After development of the concept of complete dissociation of strong electrolytes, chemical analyses of sea water were given in terms of individual ions Na^+, Ca^{++}, Cl^-, and so forth, or in terms of *known* undissociated and partly dissociated species, e.g., HCO_3^-. In recent years there has been an attempt to determine the thermodynamically stable dissolved species in sea water and to evaluate the relative distribution of these species at specified conditions. Table 1 lists the principal dissolved species in sea water deduced from a model of sea water that assumes the dissolved constituents are in homogeneous equilibrium, and (or) in equilibrium, or nearly so, with solid phases.

Both associated and nonassociated electrolytes exist in sea water, the latter (typified by the alkali metal ions Li^+, Na^+, K^+, Rb^+, and Cs^+) predominantly as solvated free cations. The major anions, Cl^- and Br^-, exist as free anions, whereas as much as 20% of the F in sea water may be associated as the ion-pair MgF^+, and IO_3^- may be a more important species of I than I^-. Based on dissociation constants and individual ion activity coefficients the distribution of the major cations in sea water as sulfate, bicarbonate, or carbonate ion-pairs has been evaluated at specified conditions by Garrels and Thompson (1962).

About 10% each of Mg and Ca is tied up as the sulfate ion-pair. It is likely that the other alkaline earth metals, Sr, Ba, and Ra, also exist in sea water partly as undissociated sulfates; about 60% and 21%, respectively, of the total $SO_4^=$ and HCO_3^- are complexed with cations, and two-thirds of the $CO_3^=$ is present as the ion-pair $MgCO_3^0$.

The activities of Mg^{++} and Ca^{++} obtained from the model of sea water proposed by Garrels and Thompson have recently been confirmed by use of specific Ca^{++} and Mg^{++} ion electrodes, and for Mg^{++} by solubility techniques and ultrasonic absorption studies of synthetic and natural sea water. The importance of ion activities to the chemistry of sea water is amply demonstrated by consideration of $CaCO_3$ (calcite) in sea water. The total molality of Ca^{++} in surface sea water is about 10^{-2} and that of $CO_3^=$ is 3.7×10^{-4}; therefore the ion product is 3.7×10^{-6}. This value is nearly 600 times greater than the equilibrium ion activity product of $CaCO_3$ of 4.6×10^{-9} at 25°C and one atmosphere total pressure. However, the activities of the free ions Ca^{++} and $CO_3^=$ in surface sea water are about 2.3×10^{-3} and 7.4×10^{-6}, respectively; thus the ion activity product is 17×10^{-9} which is only 3.7 times greater than the equilibrium ion activity product of calcite. Thus, by considering activities of sea water constituents rather than concentrations, we are better able to evaluate chemical equilibria in sea water; an obvious restatement of simple chemical theory but an often neglected concept in sea water chemistry.

Constancy and Equilibrium

The concept of constancy of the chemical composition of sea water, i.e., that the ratios of the major dissolved constituents of sea water do not vary geographically or vertically in the oceans except in regions of runoff from the land or in semienclosed basins, was first proposed indirectly in 1819 by Marcet and expanded later by Forchammer and Dittmar. The concept

TABLE 1. ABUNDANCES OF THE ELEMENTS AND PRINCIPAL DISSOLVED CHEMICAL SPECIES OF SEAWATER, RESIDENCE TIMES OF THE ELEMENTS

Element	Abundance (mg/l)	Principal species	Residence time (years)
O	857,000	H_2O; $O_2(g)$; SO_4^{2-} and other anions

was established on a purely empirical basis whereas in actual fact there is a theoretical basis for the concept.

Barth (1952) proposed the concept of residence (passage) time of an element in the oceanic environment and formalized this concept by the equation

$$\lambda = \frac{A}{dA/dt},$$

where λ is the residence time of the element, A is the total amount of the element in the oceans, and dA/dt is the amount of the element introduced or removed per unit time. Sea water is assumed to be a steady-state solution in which the number of moles of each element in any volume of sea water does not change; the net flow into the volume exactly balances the processes that remove the element from it. Complete mixing of the element in the ocean is assumed to take place in a time interval that is short compared to its residence time. Table 1 shows the residence times of the elements, and Table 2 compares the residence times of some elements on the basis of river input and removal by sedimentation. For the major elements the results are strikingly similar and suggest that at least as a first approximation sea water is a steady-state solution with a composition fixed by reaction rates involving the removal of elements from the ocean approximately equalling rates of element inflow into the ocean. Thus, as a first approximation the steady-state oceanic model implies a fixed and constant sea water composition and provides a theoretical basis for the concept of the constancy of the chemical composition of sea water. However, it is possible that at any time, t_0, for example, the present, the ratios of the major dissolved constituents in the open ocean may be nearly invariant simply because the amounts of new materials introduced by streams and other agents to the ocean are small compared to the amounts in the ocean, and these new materials are mixed into the oceanic system relatively rapidly. But over time periods of 1000 to 2000 years or more the major ionic ratios can only remain constant if the ocean is a steady-state solution whose composition is controlled by mechanism(s) other than simple mixing.

Further insight into the constancy concept can be gained by exploring possible mechanisms governing the steady-state composition of sea water. The steady-state solution could be simply a result of the rates of major element inflow into the oceans being equal to rates of outflow by biologic removal, flux through the atmosphere, absorption on sediment particles, and removal in the interstitial waters of marine sediments. For example, Ca^{++} carried to the oceans by streams is certainly removed, in part, in sea aerosol generated at the atmosphere-ocean interface and transported into the atmosphere, later to fall as rain or dry fallout on the continents. However, recent theoretical and experimental work suggests that sea water may be modeled as a steady-state solution in equilibrium with the solids

TABLE 2. THE RESIDENCE TIMES OF ELEMENTS IN SEA WATER CALCULATED BY RIVER INPUT AND SEDIMENTATION

Element	Amount in ocean (in units of 10^{20} g)	Residence time in millions of years	
		River input	Sedimentation
Na	147.8	210	260

After Goldberg, E. D., "Minor elements in sea water," in "Chemical Oceanography," v. 1, p. 173, J. P. Riley and G. Skirrow, Eds., Academic Press, New York, 1965.

that are in contact with it. Sillén has modeled the oceanic system as a near-equilibrium of many solid phases and sea water. Experimental work has shown that aluminosilicate minerals typical of those in the suspended load of streams and in marine sediments react rapidly with sea water containing an excess or deficiency of dissolved silica. Reactions involving these aluminosilicates may control on a long-term basis the activities of H_4SiO_4 and other constituents in sea water. Thus it has begun to emerge that the composition of the oceans represents an approximation of dynamic equilibrium between the water and the solids that are carried into it in suspension or are precipitated from it by the continuous evaporation and renewal by streams. Therefore, if sea water is a solution in equilibrium with solid phases, or even closely approaches such a system, then the *ion activity ratios* of the major dissolved species would be fixed and the chemical composition of the ocean would be "constant." Consequently, the activity of Ca^{++} in the ocean is not simply a result of removal processes involving sea aerosol, adsorption and so forth but is controlled by solid-solution equilibria. A model leading to nearly invariant ion activity ratios geographically and vertically at any time, t_0, in the oceans based on mixing rates alone may be sufficient to explain the constancy of sea water composition but is somewhat misleading and uninformative when

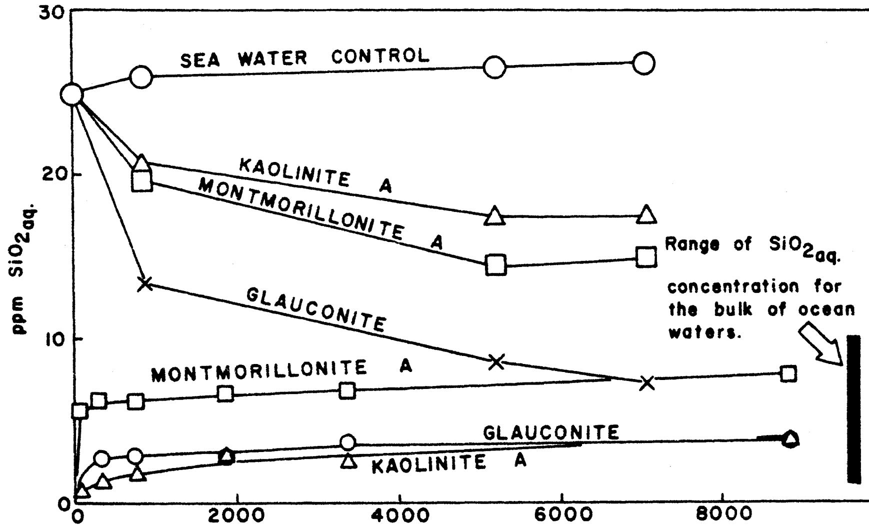

Fig. 1. Concentration of dissolved silica as a function of time for suspensions of silicate minerals in sea water. Curves are for 1-g (<62 μ) mineral samples in silica-deficient (SiO_2 in water was initially 0.03 ppm) and silica-enriched (SiO_2 was initially 25 ppm) sea water at room temperature. Notice that the minerals react rapidly and that the dissolved silica concentration for individual minerals becomes nearly constant at values within or close to the range of silica concentration in the oceans (from Mackenzie, F. T., Garrels, R. M., Bricker, O. P., and Bickley, F., "Silica in sea water: Control by silica minerals" *Science*, **155**, 1404 (1967)).

considered in light of the recent advances in treating the oceans as an equilibrium system.

Some limitations of the equilibrium model of sea water do exist. Sillén has pointed out that based on equilibrium calculations all the nitrogen in the ocean-atmosphere system should be present as NO_3^- in sea water; however, most of the nitrogen is present as N_2 gas in the atmosphere. Also, the concentrations of the major alkaline earth elements, Mg, Ca, and Sr, in sea water may vary slightly with depth or geographic location.

Buffering and Buffer Intensity of Sea Water

The view has long been held that hydrogen-ion buffering in the oceans is due to the $CO_2-HCO_3^--CO_3^=$ equilibrium. Within recent years this view has been challenged, and the importance of aluminosilicate equilibria in maintaining the pH of sea water emphasized. The buffer intensity of a system is of thermodynamic nature and is defined as

$$\beta_{c_j}^{c_i} = \frac{dC_i}{dpH},$$

where $\beta_{c_j}^{c_i}$ is the pH buffer intensity for incremental addition of C_i to a closed system of constant C_j at equilibrium. Homogeneous buffer intensities are defined for systems without solid phases, e.g., the addition of a strong acid to a carbonate solution, whereas heterogeneous buffer intensities are defined for systems with solid phases, e.g., the addition of a strong acid to a solution in equilibrium with calcite, $CaCO_3$, or with kaolinite and muscovite. The homogeneous buffer intensities for the range of sea water and interstitial marine water pH values (7.0 to 8.3) are about 10- to 100-fold less than the heterogeneous intensities involving equilibrium between calcite and sea water or kaolinite, muscovite, and sea water. Both of these heterogeneous equilibria represent large capacities for resistance to sea water pH changes. Unfortunately, the kinetic aspects of these buffer systems have not been investigated quantitatively. However, it is apparent that aluminosilicate equilibria have buffer intensities equal to and perhaps greater than (the buffer intensities of most aluminosilicate equilibria in natural waters have only been qualitatively evaluated) the $CO_2-CaCO_{3(s)}$ equilibria in sea water. Small additions of acid or base to the oceans could be buffered by the homogeneous equilibrium $CO_2-HCO_3^--CO_3^=$. However, large incremental additions of acid or base or additions over a duration of time would involve the heterogeneous carbonate and aluminosilicate equilibria; the relative importance of each would depend on the buffer intensities of the various equilibria and the relative rates of aluminosilicate and carbonate reactions.

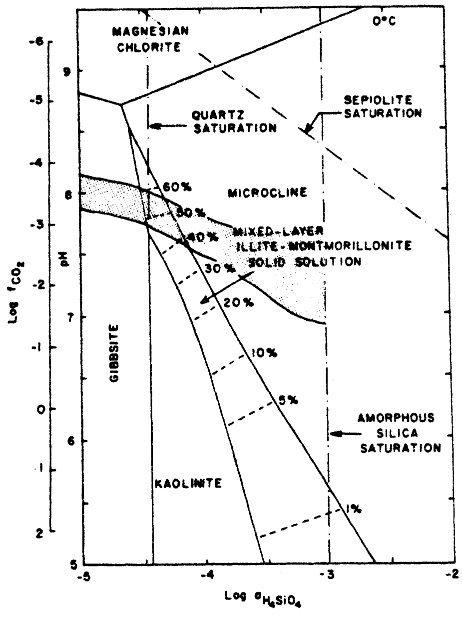

Fig. 2. Logarithmic activity diagram depicting equilibrium phase relations among aluminosilicates and sea water in an idealized nine-component model of the ocean system at the noted temperatures, one atmosphere total pressure, and unit activity of H_2O. The shaded area represents the composition range of sea water at the specified temperature, and the dot-dash lines indicate the composition of sea water saturated with quartz, amorphous silica, and sepiolite, respectively. The scale to the left of the diagram refers to calcite saturation for different fugacities of CO_2. The dashed contours designate the composition (in % illite) of a mixed-layer illitemontmorillonite solid solution phase in equilibrium with sea water (from Helgeson, H. C. and Mackenzie, F. T., 1970, Silicate-sea water equilibria in the ocean system: Deep Sea Res.).

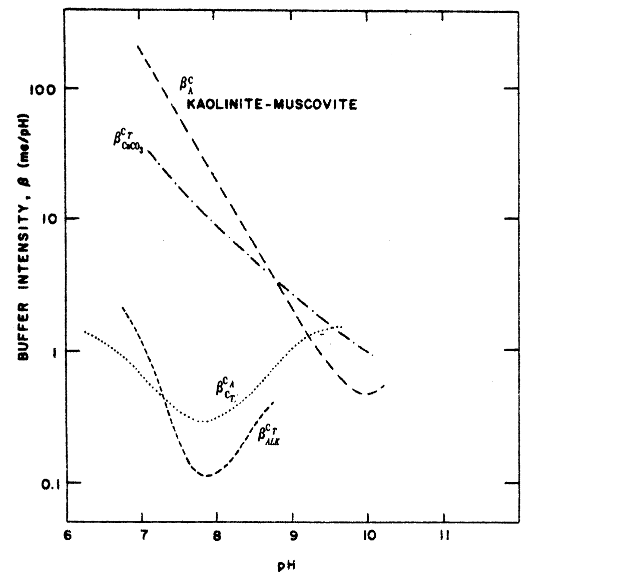

Fig. 3. Buffer intensity as a function of pH for some homogeneous and heterogeneous chemical systems. The buffer intensities are defined for $\beta^{C_A}_{\text{Kaolinite-muscovite}}$, addition of a strong acid (or base) to sea water in equilibrium with kaolinite and muscovite; $\beta^{C_T}_{CaCO}3$, addition of CO_2 in a sea water system of zero noncarbonate alkalinity in equilibrium with $CaCO_3$; $\beta^{C_A}_{C_T}$, addition of a strong acid (or base) to a sea water solution of constant total dissolved carbonate; and $\beta^{C_T}_{Alk}$, addition of total CO_2 to a sea water solution of constant alkalinity (data from Morgan, J. J., preprint, "Applications and limitations of chemical thermodynamics in natural water systems").

For geologically short-term processes on the order of a few thousands of years, it is likely that the carbon dioxide-carbonate system regulates oceanic pH. The long-term pH is controlled by an interplay of various near-equilibria involving carbonates and silicates.

Fred T. Mackenzie
Northwestern University
Evanston, Illinois

OCHER. Any of various colored earthy powders consisting essentially of hydrated ferric oxides mixed with clay, sand, etc. Some grades are calcined (burnt ocher). The colors are yellow, brown, or red.

OCTANE NUMBER. A number indicating the antiknock properties of an automotive fuel mixture under standard test conditions. Pure normal heptane (a very high-knocking fuel) is arbitrarily assigned an octane number of zero, while 2,2,4-trimethylpentane, or isooctane (a branched-chain paraffin), is assigned 100. Thus, a rating of 80 for a given fuel indicates that its degree of knocking in a standard test engine is that of a mixture of 80 parts isooctane and 20 parts *n*-heptane.

Octane ratings as high as 115 have been obtained by addition of tetraethyllead to isooctane. Premium leaded gasolines have a research octane rating of about 100, but this value drops to 85–90 for unleaded gasolines, though it may be improved by addition of methyl-*tert*-butyl ether. The octane rating scale ends at 125, and any higher figure is meaningless.

Research octane numbers are those obtained under test or laboratory conditions; they generally run about ten points higher than the so-called motor octane numbers, which represent actual road operating conditions.

ODOR. An important property of many substances, manifested by a physiological sensation caused by contact of their molecules with the olfactory nervous system. Odor and flavor are closely related, and both are profoundly affected by submicrogram amounts of volatile compounds. Attempts to correlate odor with chemical structure have produced no definitive results. Objective measurement techniques involving chromatography are under development. Even potent odors must be present in a concentration of 1.7×10^7 molecules/cc to be detected. It has been authentically stated that the nose is 100 times as sensitive in detection of threshold odor values as the best analytical apparatus.

Many compounds have a characteristic odor that is an effective means of identification. Toxic and noxious gases have distinctive odors often utilized for warning purposes. An important exception is carbon monoxide, which is almost odorless. The penetrating, banana-like odor of amyl acetate has been used in mine rescue work. Among the most powerful unpleasant odors are those of organic sulfur compounds, especially ethyl mercaptan (skunk). Organic substances having a pleasant odor are broadly designated as aromatic, regardless of chemical nature. The cyclic aromatic (benzene) series of essential oils have a pleasant odor and are the basis of perfumes and fragrances. Odor research, including evaluation by test panels, is conducted at the Olfactronics and Odor Sciences Center at Illinois Institute of Technology, Chicago, IL.

ODORANT. A substance having a distinctive, sometimes unpleasant odor that is deliberately added to essentially odorless materials to provide warning of their presence. For example, mercaptan derivatives may be added to natural gas for this purpose. In a broad sense, perfumes are odorants that are added to cosmetics, toilet goods, etc, largely for consumer appeal.

See also **Odor**; and **Odor Modification**.

ODOR MASKING. Addition of a substance with strong odor to obtain a less-offensive effect without changing the composition of the original odorous substance.

See also **Odor Modification**.

ODOR MODIFICATION

Olfaction

Olfaction begins when an odorant stimulates the olfactory receptor cells, triggering the opening or closing of the ion channels, which in turn convert this stimulus to an electrical response to the olfactory bulb and ultimately to other parts of the brain. The olfactory neurons send messages to the olfactory bulbs, structures about the size and shape of peach pits, located on the underside of the large overhanging frontal lobes of the cerebrum. The fact that there is a gene responsible for odor receptor proteins was discovered in 1991.

Perception of odor is therefore a physical mechanism by which information is processed in the brain. Day by day new odors are appearing, all of which are immediately accepted and sorted within the seemingly unlimited categories of the olfactory brain. The brain not only recognizes this information, but evaluates it, sorts it, and associates it with experiences, events, likes, and dislikes.

Some substances are odorous, others are not. Humans can smell at a distance; if one smells the roses in a garden, it is not ordinarily considered that part of the rose is in contact with the nose. Substances of different chemical constitution may have similar odors.

The sense of smell is rapidly fatigued. Fatigue for one odor does not affect the perception of other dissimilar odors, but will interfere with the perception of similar odors. Two or more odorous substances may cancel each other out; this compensation means that two odorous substances smelled together may be inodorous.

Odor travels downwind. Many animals have a keener sense of olfaction than humans. Insects have such extraordinary keenness of smell that it may be a different modality of the chemical sense from that known to humans.

Odors

Odors have been classified according to Carolus Linnaeus, the eighteenth century Swedish botanist who proposed seven odoriferous qualities: aromatic, fragrant, musky, garlicky, goaty, repulsive, and nauseous. Later in the twentieth century, ethereal (fruity) and empyreumatic (burnt organic matter), together with subdivisions of Linnaeus' classification, were added. In the 1990s, researchers concentrate less on categorizing odors, and more on how people detect and interpret them. Although the average person can name only a handful of common odors, this limitation results from memory retrieval failure, rather than a failure to detect the differences.

Odors are measured by their intensity. The threshold value of one odor to another, however, can vary greatly. Detection threshold is the minimum physical intensity necessary for detection by a subject where the person is not required to identify the stimulus, but just detect the existence of the stimulus. Accordingly, threshold determinations are used to evaluate the effectiveness of different treatments and to establish the level of odor control necessary to make a product acceptable. Concentration can also produce different odors for the same material.

Evaluation Methodologies

Industry has standardized procedures for the quantitative sensory assessment of the perceived olfactory intensity of indoor malodors and their relationship to the deodorant efficacy of air freshener products. Synthetic malodors are used for these evaluation purposes. These malodors should be hedonically associated to the "real" malodor, and must be readily available and of consistent odor quality. These malodors should be tested in various concentrations and be representative of intensities experienced under normal domestic conditions. Panelists are trained to evaluate malodor intensity and the degree of modification.

Modification

Masking. Masking can be defined as the reduction of olfactory perception of a defined odor stimulus by means of presentation of another odorous substance without the physical removal or chemical alteration of the defined stimulus from the environment. Masking is therefore hyperadditive; it raises the total odor level, possibly creating an overpowering sensation, and may be defined as a reodorant, rather than a deodorant. Its end result can be explained by the simple equation of $1 + 1 => 2$.

Odor masking does little or nothing to control malodors; it merely covers them up. Many materials used in masking odors are aldehydes, which are very chemically reactive and usually comprise the top note of a fragrance. Odor masking is used in many areas of household, industrial, and institutional use via products that mask such malodors as pet smells, smoke, cooking, and numerous other odors. The forms by which masking is executed vary, and can be solid, liquid, and aerosol.

Counteraction. Counteraction, sometimes referred to as neutralization, occurs when two odorous substances are mixed in a given ratio and the resulting odor of the mixture is less intense than that of the separate components. The acceptable term to describe this occurrence is compensation. Materials that can accomplish this are basically organic odors which are highly polarized, have a strong affinity for each other, and may also have a low vapor pressure. Some of these molecules have the ability to compensate physiologically for certain malodor materials; others to react chemically with them. Counteraction occurs when the compensating substrate is able to form a coordinate bond with osmophoric sites unique to malodor molecules, such as amino- and thio- moieties. The result is overall reduction in odor; the malodor is transformed into an acceptable state, often with some residual freshening odor. This result lowers the total odor perception and can be exemplified by $1 + 1 =< 2$.

Commercial Aspects

Translating odor modifiers into consumer products results in forms, such as solids, liquids, and aerosols, for a market defined as products "for the nose." This includes products that cover up or eliminate odors, perfume the home, or cleanse the air. The categories of this market can be broken out as traditional air fresheners, cat litter products, aroma care, air purification, and disinfectant in both consumer and industrial applications.

Behavior Modification by Odor

Although odorous materials no doubt impact each other, much discussion centers around the ability of odorous materials to influence human behavior. In articles ranging from scientific journals to trade magazines, there is discussion on the potential of fragrances, i.e., essential oils, to affect

people's moods, their ability to focus and maintain attention, to relax and sleep, and even their sexual capability.

The words aromatherapy, aromachology, and aromakinetics are coinages of the 1990s. Aromatherapy, once based on a tradition of folklore and herbal medicine, is being investigated scientifically.

A technique known as contingent negative variation (CNV) measures brain-wave reaction to olfaction. These types of studies have shown the effect of materials such as lavender and nutmeg in reducing stress or anxiety, and the ability of oils such as peppermint to stimulate brainwave activity. CNV research was incorporated into the development of the fragrance for a consumer personal care product launched in the late 1980s.

The interrelationship between fragrance and psychology has been the subject of systematic investigation only recently. Consumer moods can be calculated in both positive and negative directions, and changes can be measured subjectively after exposure to fragrance.

Odors play a much greater role in human behavior than previously thought. The sense of smell provides a direct link with the function of the brain; therefore, the further study of olfaction can only advance the learning of causes and effects of stimuli to the brain.

The future in research will certainly lead to a better understanding of how odors are recognized, sorted, and classified. Studies promise, among other things, to determine whether perceptually similar, but structurally different, odors share the same class of receptor proteins, whether responses to odors can be modified, and possibly why olfactory neurons regenerate but other neurons do not.

OIL BLACK. A carbon black made from oil, usually and aromatic-type petroleum oil. See also **Petroleum**.

OIL BLUE. Violet-blue copper sulfide pigment use in varnishes.

OIL CAKE. The residue obtained after the expression of vegetable oils from oil-bearing seeds, used as cattle feed and fertilizer.

OIL GAS. A gas made by the reaction of steam at high temperature on gas oil or similar fractions of petroleum, or by high-temperature cracking of gas oil. One typical analysis is heating value 554 Btu/ft^3, illuminants 4.2%, carbon monoxide 10.4%, hydrogen 47.6%, methane 27.0%, carbon dioxide 4.6%, oxygen 0.4%, nitrogen 5.8%, autoign temp 637°F (336°C).

OILINESS. That property of a lubricant that causes a difference in coefficient of friction when all the known factors except the lubricant itself are the same. This concept is also expressed by the term *lubricity*.

OIL (Petroleum). See **Petroleum**.

OIL SANDS. See **Tar Sands**.

OILS, ESSENTIAL. The volatile etherial fraction obtained from a plant or plant part by a physical separation method is called an essential oil. The physical method involves either distillation (including water, steam, water and steam, or dry) or expression (pressing). For the most part, essential oils represent the odorous part of the plant material, and therefore these oils have traditionally been associated with the fragrance and flavor industry (See **Perfume**). Since essential oils frequently occur as a very small percentage by weight of the original plant material, the processing of large quantities is often required to obtain usable amounts of oil. As a result, expression of an essential oil is only employed in those cases where both the form of the natural plant material, such as a citrus peel, and the quantity of oil present make the process feasible.

It has frequently been observed that the aroma of an essential oil is substantially different from that of the plant before processing. Because this phenomenon is largely the result of the treatment of the plant material with heat or hot water, various other methods have evolved over the years in an attempt to obtain a concentrate of the volatiles which more truly represents the aroma of the original. With the exception of the method of expression, almost all of these involve treatment of the plant material with one or more organic solvents (or mixtures thereof) followed by concentration of the extracted solute. Solvent extraction frequently yields, in addition to the volatile oil, various quantities of semi- or nonvolatile organic material such as waxes, fats, fixed oils, high molecular weight acids, pigments, and even alkaloidal material. However, because solvent extraction often results in a product with superior and more representative odor properties to that of a distilled oil, many natural products critically important to the flavor and fragrance industry are available as various extracts in addition to an essential oil.

Some of the commonly used botanical extracts include the following.

Absolute. This is concentrated extract obtained by treatment of a concrete or other hydrocarbon-type extract of a plant or plant part with ethanol.

Absolute Oil. This is the steam distillable portion of an absolute.

Aroma Distillate. Used by the flavor industry, aroma distillates are the product of continuous extraction of the plant material with alcohol at temperatures between ambient and 50°C followed by steam distillation, and, lastly, concentration of the combined hydro-alcoholic mixture.

Concrete. Hydrocarbon extracts of plant tissue, concretes are usually solid to semisolid waxy masses often containing higher fatty acids such as lauric, myristic, palmitic, and stearic as well as many of the nonvolatiles present in absolutes.

Infusion. Infusion botanical extracts are tinctures that have been concentrated by either total or partial removal of the alcohol by distillation.

Oleoresin. Natural oleoresins are exudates from plants, whereas prepared oleoresins are solvent extracts of botanicals, which contain oil (both volatile and, sometimes, fixed), and the resinous matter of the plant. Natural oleoresins are usually clear, viscous, and light-colored liquids, whereas prepared oleoresins are heterogeneous masses of dark color.

Pommade. These are botanical extracts prepared by the enfleurage method wherein flower petals are placed on a layer of fat which extracts the essential oil.

Resin and Resinoid. Natural resins are plant exudates formed by the oxidation of terpenes. Many are acids or acid anhydrides. Prepared resins are made from oleoresins from which the essential oil has been removed. A resinoid is prepared by hydrocarbon extraction of a natural resin.

Tincture. This is prepared by aqueous alcoholic extraction of the raw plant material. Since the extract is not further concentrated, the plant extract is not exposed to heat.

Essential oils are isolated from various plant parts, such as leaves (patchouli), fruit (mandarin), bark (cinnamon), root (ginger), grass (citronella), wood (amyris), heartwood (cedar), gum (myrrh oil), balsam (tolu balsam oil), berries (pimento), seeds (dill), flowers (rose), twigs and leaves (thuja oil), and buds (cloves).

Exceptions to the simple definition of an essential oil are, for example, garlic oil, onion oil, mustard oil, or sweet birch oils, each of which requires enzymatic release of the volatile components before steam distillation. In addition, the physical process of expression, applied mostly to citrus fruits such as orange, lemon, and lime, yields oils that contain from 2–15% nonvolatile material.

Economic Aspects

Essential oils are used as flavoring and fragrance agents in every possible application. Combinations have raised greatly the total sales volume; e.g., mint and cinnamon are used in toothpaste, mouthwash, or lozenges. Combinations can be found in every fragranced product, such as fine fragrances, soaps, detergents, room fresheners, paper, printing ink, paint, candles, condiments, floor polishes, etc. Convenience foods and frozen foods are flavored best by essential oils or oleoresins. Although citronella oil was used as such as an insect repellant, synthetic repellants have, for the most part, taken their place. Flavor essential oils are encountered in baked goods, snack foods, soft drinks, liqueurs, tobacco, sauces, gravies, salad dressings, and other food products.

Composition

The volatile components of essential oils, for the most part, are made up of relatively low molecular weight ($\leq \sim 300-350$) organic molecules of

carbon, hydrogen, and oxygen, and occasionally nitrogen and sulfur. By far the largest class of natural volatiles of plants is the terpenes, which consist of head-to-tail condensation products of unsaturated five-carbon isoprene units.

Other commonly occurring chemical groups in essential oils include aromatics such as β-phenethyl alcohol, eugenol, vanillin, benzaldehyde, cinnamaldehyde, etc; heterocyclics such as indole, pyrazines, thiazoles, etc; hydrocarbons (linear, branched, saturated, or unsaturated); oxygenated compounds such as alcohols, acids, aldehydes, ketones, ethers; and macrocyclic compounds such as the macrocyclic musks, which can be both saturated and unsaturated.

An essential oil may contain >200 components, and often the trace substances (≤ppm) are essential to the odor and flavor of the oil. The absence or decreased presence of even one component may be cause for odor or flavor rejection of the oil. The same species of plant grown in different parts of the world usually contains the same chemical components, but the relative percentages may be different. Climatic and topographical conditions affect plant chemistry and can alter the essential oil content both qualitatively and quantitatively.

Commercial Essential Oils

Commercial essential oils include rose, jasmin, orange flower (neroli) oil, lavender and lavandin, geranium oil, citronella oil, bergamot oil, lime oil, orange oil, grapefruit oil, sandalwood oil (East Indian), patchouli oil, vetiver oil, galbanum oil, myrrh, oakmoss, tonquin musk, ambergris, tobacco, osmanthus, olibanium, amyris oil, anise oil, anise oil (star), sweet basil oil, bay oil, bitter orange oil, black pepper, bois de rose oil, cannaga oil, caraway oil, cardamom oil, cassia oil, cedarleaf oil, cedarwood oil, Roman chamomile oil, cinnamon bark oil, citronella oil, clove bud oil, coriander oil, cornmint oil, eucalyptus oil, ginger oil, juniper oil, labdanum oil, lemon oil, nutmeg oil, oregano oil (Spanish), orris, palmarosa oil, peppermint oil, petitgrain bigarade oil, pimento berry oil, pine oil, rosemary oil, sage oil (Dalmatian), sage (clary) oil, spearmint oil (native), tagetes oil, thyme oil, turpentine oil, wintergreen oil, and ylang ylang.

Safety and Regulatory Aspects

Essential oils possess a variety of biological properties which may result in varying responses by humans on exposure. An important factor in these effects is the dose to which one is exposed. Thus, essential oils may have both beneficial and toxic effects, depending on their dose. The potential for biological effects from essential oils is not surprising; many botanical species are known to contain substances that possess biological properties, and their identification has contributed significantly to knowledge of biochemistry and physiology as well as the development of therapeutic agents, e.g., quinine and digitalis.

The toxicities of many essential oils have been reported in monographs. Most essential oils used by the flavor and fragrance industries are relatively nontoxic or slightly toxic on acute oral or dermal exposure, and are considered safe when used at levels present in consumer products. In general, the levels of fragrances and flavors in consumer products, and thus the levels of any essential oil ingredients, are relatively low. For example, a fragrance oil may typically be used in a soap at 0.5%. The oil may contain 5% of orange oil distilled. The final concentration of orange oil distilled in the soap therefore is 0.025%.

Because essential oils are used predominantly by the flavor and fragrance industries, these commercial oils must undergo the same scientific scrutiny as all other flavor and fragrance substances and must be in compliance with all applicable health, safety, and environmental regulations. Guidelines and regulations on the use of essential oils in fragrances differ from those applying to essential oils used in flavors.

Many essential oils have been designated by the FDA or by the expert panel of FEMA as Generally Recognized As Safe (GRAS) for their intended use in foods and flavors. The use and safety of these GRAS substances are continuously being reviewed and the list of GRAS substances updated. New essential oils intended to be used as a flavor ingredient must undergo extensive safety evaluations and scrutiny by one or more of these groups of experts before they may be used in flavors.

Many countries have adopted chemical substance inventories in order to monitor use and evaluate exposure potential and consequences. In the case of essential oils used in many fragrance applications, these oils must be on many of these lists. New essential oils used in fragrances are subject to premanufacturing or premarketing notification (PMN). PMN requirements vary by country and predicted volume of production. They require assessment of environmental and human health-related properties, and reporting results to designated governmental authorities.

Essential oils are also influenced by legislation that regulates specific products that may contain these oils, e.g., the U.S. Food, Drug, and Cosmetic Act and the European Community Cosmetic Directive. Essential oils would not be anticipated to be of environmental concern, considering that they originate from botanical sources. Thus, natural processes exist to degrade essential oils and recycle their components effectively in the environment.

OIL SHALE. This term refers to a carbonaceous rock that can produce oil when heated to pyrolysis temperatures of 427 to 538°C (800–1,000°F). The oil cannot be extracted with organic solvents at room and moderate temperatures with known technology. The oil precursor in the rock is a high-molecular-weight organic polymer, *kerogen*. An elemental analysis of kerogen derived from the upper zones of Colorado and Utah oil shales is: Carbon, 80.5% (weight); hydrogen, 10.3%; nitrogen, 2.4%; sulfur, 1.0%; and oxygen 5.8%. Usually, the host rock is comprised of dolomite, calcite, quartz, and clays.

Status of Oil Shale Technology

As with most other alternative sources of energy and notably hydrocarbons, the so-called oil glut of the 1980s essentially brought to a halt the further development of oil shale technology. With the fading of federal support in connection with the demise of the Synthetic Fuels Corporation (SFC) in the mid-1980s and the abandonment by most petroleum companies of their earlier interest in alternative energy sources, the shale oil program is essentially a "dead issue" as of the late 1980s. It is estimated that few researchers are now engaged in advancing the technology. One of the last major investments made in oil shale retorting was sponsored by Union Oil Company in connection with its plant located near Parachute Creek, Colorado.

Resources

Within a radius of about 200 kilometers (124 miles) of a center point where the borders of Colorado, Utah, and Wyoming intersect, an area comprised of four great basins—the Green River, Piceance, Uinta, and Washakie Basins as shown on the map in Fig. 1—some authorities estimate there is the equivalent of 2 trillion barrels of oil to be found—more than 50 times the total reserves for petroleum in the United States as presently known. These shales can be expected to yield from 25 to 30 gallons of oil per ton of shale. Of the explored basins, it is estimated that about 83% of these shales are in Colorado; 8.8% in Utah; and 8.2% in Wyoming. These deposits are generally referred to as occurring in the Green River formation. These oil shale resources occur in beds at least 30 meters (98 feet) in thickness. A comparatively small percentage may be mined by surface techniques. For the deeper veins, essentially underground mining technology or in-situ recovery technology will be required. Geologists consider that these deposits date from the Eocene era.

There are also Eastern oil shales, which represent petroleum locked in older shales dating back to the Devonian and Mississippian eras. It is estimated that these shales contain some 2 trillion barrels of oil and underlie an area of over a million square kilometers (400,000 square miles) in Michigan, western Pennsylvania, eastern Ohio, southwestern Indiana,

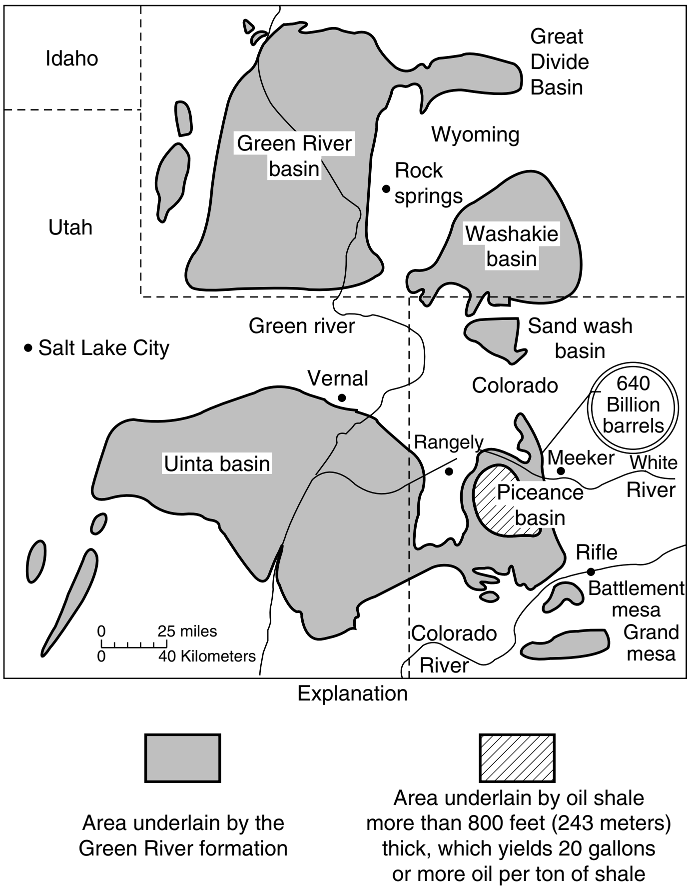

Fig. 1. Distribution of oil shale in the Green River formation. (*U.S. Geological Survey*)

eastern and southern Illinois, most of Kentucky and Tennessee, much of Oklahoma, and northern Alabama. They are sometimes broken down into what are known as the Eastern and Midwestern oil shale deposits. In Michigan, the shale is approximately 60 meters (197 feet) thick and is in a basin at depths ranging from about 0.8 kilometer (0.5 mile) to outcroppings in three of the northern counties. In general, the Eastern oil shales become thicker and deeper toward the east.

Processing Oil Shale

Work on the production of petroleum-like materials from oil shale in the Green River formation dates back many years. One of the first major efforts was that undertaken by the U.S. Bureau of Mines in 1944. This program involved two 40-ton capacity retorts that operated between 1947 and 1951, with a production of some 920 runs and a total consumption of 37,500 tons of raw shale. This was a batch process and much was learned from this experience.

In a status report (1983), one of the largest (12,800 tons/day) and the last of numerous oil shale retorting processes (Union Oil Company) is described in considerable detail by Duir, Griswold, and Christolini in the February 1983 issue of *Chemical Engineering Progress* (pp. 45–50). This paper includes several diagrams and provides an excellent starting point for the reader who may be interested in this topic.

OIL (Vegetable). See **Vegetable Oils (Edible)**.

OLAH, GEORGE A. (1927–). Born in Hungary, now an American citizen, he won the Nobel prize for chemistry in 1994 for his work with carbocations. These are positively charged hydrocarbons with lifetimes on the order of microseconds. Olah developed methods of studying carbocations with different physical techniques, changing the direction of this field. He received a Ph.D. from the Technical University of Budapest in 1949.

OLEATE. Salt made up of a metal or alkaloid with oleic acid. It is used for external medications and in soaps and paints.

See also **Oleic Acid**.

OLEFIN FIBERS. Olefin fibers, also called polyolefin fibers, are defined as manufactured fibers in which the fiber-forming substance is a synthetic polymer of at least 85 wt % ethylene, propylene, or other olefin units. Several olefin polymers are capable of forming fibers, but only polypropylene (PP) and, to a much lesser extent, polyethylene (PE) are of practical importance. Olefin polymers are hydrophobic and resistant to most solvents. These properties impart resistance to staining, but cause the polymers to be essentially undyeable in an unmodified form.

Advances in olefin polymerization provide a wide range of polymer properties to the fiber producer. Inroads into new markets are being made through improvements in stabilization, and new and improved methods of extrusion and production, including multicomponent extrusion and spunbonded and meltblown nonwovens.

Properties

Physical Properties. Table 1 shows that olefin fibers differ from other synthetic fibers in two important respects: (1) olefin fibers have very low moisture absorption and thus excellent stain resistance and almost equal wet and dry properties, and (2) the low density of olefin fibers allows a much lighter weight product at a specified size or coverage. Thus one kilogram of polypropylene fiber can produce a fabric, carpet, etc, with much more fiber per unit area than a kilogram of most other fibers.

Tensile Strength. Tensile properties of all polymers are a function of molecular weight, morphology, and testing conditions. Lower temperature and higher strain rate result in higher breaking stresses at longer elongations, consistent with the general viscoelastic behavior of polymeric materials. Similar effects are observed on other fiber tensile properties, such as tenacity or stress at break, energy to rupture, and extension at break. Under the same spinning, processing, and testing conditions, higher molecular weight results in higher tensile strength.

Creep, Stress Relaxation, Elastic Recovery. Olefin fibers exhibit creep, or time-dependent deformation under load, and undergo stress relaxation, or the spontaneous relief of internal stress. High molecular weight and high orientation reduce creep.

Elastic recovery or resilience is the recovery of length upon release of stress after extension or compression. A fiber, fabric, or carpet must possess this property in order to spring back to its original shape after being crushed or wrinkled, Polyolefin fibers have poorer resilience than nylon; this is thought to be partially related to the creep properties of the polyolefins.

Chemical Properties. The hydrocarbon nature of olefin fibers, lacking any polarity, imparts high hydrophobicity and consequently resistance to soiling or staining by polar materials, a property important in carpet and upholstery applications. Unlike the condensation polymer fibers, such as polyester and nylon, olefin fibers are resistant to acids and bases. At room temperature, polyolefins are resistant to most organic solvents, except for some swelling in chlorinated hydrocarbon solvents. At higher temperatures, polyolefins dissolve in aromatic or chlorinated aromatic solvents, and show some solubility in high boiling hydrocarbon solvents. At high temperatures, polyolefins are degraded by strong oxidizing acids.

Thermal and Oxidative Stability. In general, polyolefins undergo thermal transitions at much lower temperatures than condensation polymers; thus, the thermal and oxidative stability of polyolefin fibers are comparatively poor. Preferred stabilizers are highly substituted phenols such as Cyanox 1790 and Irganox 1010, or phosphites such as Ultranox 626 and Irgafos 168.

Ultraviolet Degradation. Polyolefins are subject to light-induced degradation; polyethylene is more resistant than polypropylene. Because polyolefins readily form hydroperoxides, the more effective light stabilizers are radical scavengers. Hindered amine light stabilizers (HALS) are favored, especially high molecular weight and polymeric amines that have lower mobility and less tendency to migrate to the surface of the fiber. This migration is commonly called bloom.

TABLE 1. PHYSICAL PROPERTIES OF COMMERCIAL FIBERS

Polymer	Standard tenacity, GPa[a]	Breaking elongation, %	Modulus, GPa[a]	Density, kg/m^3	Moisture regain[b]
olefin	0.16–0.44	20–200	0.24–3.22	910	0.01
polyester	0.37–0.73	13–40	2.1–3.7	1,380	0.4
carbon	3.1	1	227	1,730	
nylon	0.23–0.60	25–65	0.5–2.4	1,130	4–5
rayon	0.25–0.42	8–30	0.8–5.3	1,500	11–13
acetate	0.14–0.16	25–45	0.41–0.64	1,320	6

polybenzimidazole	0.33–0.38	25–30	1.14–1.52	1,430	15

[a] To convert GPa to psi, multiply by 145,000.
[b] At 21°C and 65% rh.

Flammability. Most polyolefins can be made fire retardant using a stabilizer, usually a bromine-containing organic compound, and a synergist such as antimony oxide. However, the required loadings are usually too high for fibers to be spun. Fire-retardant polypropylene fibers exhibit reduced light and thermal resistance.

Dyeing Properties. Because of their nonionic chemical nature, olefin fibers are difficult to dye. A broad variety of polymeric dyesites have been blended with polypropylene; nitrogen-containing copolymers are the most favored. In apparel applications where dyeing is important, dyeable blends are expensive and create problems in spinning fine denier fibers. Hence, olefin fibers are usually colored by pigment blending during manufacture, called solution dying in the trade.

Manufacture and Processing

Olefin fibers are manufactured commercially by melt spinning, similar to the methods employed for polyester and polyamide fibers.

Slit-Film Fiber. A substantial volume of olefin fiber is produced by slit-film or film-to-fiber technology. For producing filaments with high linear density, above 0.7 tex (6.6 den), the production economics are more favorable than monofilament spinning. The fibers are used primarily for carpet backing and rope cordage applications.

Bicomponent Fibers. Polypropylene fibers have made substantial inroads into nonwoven markets because they are easily thermal bonded. Further enhancement in thermal bonding is obtained using bicomponent fibers. In these fibers, two incompatible polymers, such as polypropylene and polyethylene, polyester and polyethylene, or polyester and polypropylene, are spun together to give a fiber with a side-by-side or core–sheath arrangement of the two materials. The lower melting polymer can melt and form adhesive bonds to other fibers; the higher melting component causes the fiber to retain some of its textile characteristics. Bicomponent fibers have also provided a route to self-texturing (self-crimping) fibers.

Meltblown, Spunbond, and Spurted Fibers. A variety of directly formed nonwovens exhibiting excellent filtration characteristics are made by meltblown processes, producing very fine, submicrometer filaments. A stream of high velocity hot air is directed on the molten polymer filaments as they are extruded from a spinnerette. This air attenuates, entangles, and transports the fiber to a collection device. Because the fiber cannot be separated and wound for subsequent processing, a nonwoven web is directly formed.

In the spunbond process, the fiber is spun similarly to conventional melt spinning, but the fibers are attenuated by air drag applied at a distance from the spinnerette. This allows a reasonably high level of filament orientation to be developed. The fibers are directly deposited onto a moving conveyor belt as a web of continuous randomly oriented filaments.

Pulp-like olefin fibers are produced by a high pressure spurting process developed by Hercules Inc. and Solvay, Inc. Polypropylene or polyethylene is dissolved in volatile solvents at high temperature and pressure. After the solution is released, the solvent is volatilized, and the polymer expands into a highly fluffed, pulp-like product. Additives are included to modify the surface characteristics of the pulp. Uses include felted fabrics, substitution in whole or in part for wood pulp in papermaking, and replacement of asbestos in reinforcing applications.

High Strength Fibers. The properties of commercial olefin fibers are far inferior to those theoretically attainable. A number of methods, including superdrawing, high pressure extrusion, spinning of liquid crystalline polymers or solutions, gel spinning, and hot drawing produce high strengths, but these methods are tedious and uneconomical for olefin fibers. A high modulus commercial polyethylene fiber with properties approaching those of aramid and graphite fibers is prepared by gel spinning.

Hard-Elastic Fibers. Hard-elastic fibers are prepared by annealing a moderately oriented spun yarn at high temperature under tension. They are prepared from a variety of olefin polymers, acetal copolymers, and polypivalolactone.

Economic Aspects

In the United States, olefin fiber consumption has risen steadily since its introduction in 1961. Olefin fiber is the only synthetic fiber showing market growth in recent years.

Applications

Olefin fibers are used for a variety of purposes from home furnishings to industrial applications. These include carpets, upholstery, drapery, rope, geotextiles, and both disposable and nondisposable nonwovens. Fiber mechanical properties, relative chemical inertness, low moisture absorption, and low density contribute to desirable product properties.

OLEFIN POLYMERS

POLYETHYLENE

Polyethylene (PE) is a generic name for a large family of semicrystalline polymers used mostly as commodity plastics. PE resins are linear polymers with ethylene molecules as the main building block; they are produced either in radical polymerization reactions at high pressures or in catalytic polymerization reactions. Most PE molecules contain branches in their chains. In very general terms, PE structure can be represented by the following formula:

$$(CH_2{-}CH_2)_x{-}\text{branch}_1{-}(CH_2{-}CH_2)_y{-}\text{branch}_2{-}(CH_2{-}CH_2)_z\\ {-}\text{branch}_3\cdots$$

where the $-CH_2-CH_2-$ units come from ethylene, and x, y, and z values can vary from 4 or 5 to over 100. This allows the industry to produce a large variety of PE resins with different molecular weights and branching characteristics.

The total number of monomer units (which approximately equals $x + y + z + \ldots$ in the above formula) in PE chains is called the degree of polymerization. It can vary from small (about 10–20 in PE waxes) to very large (over 100,000 for PE of ultrahigh molecular weight (UHMW)).

TABLE 1. COMMERCIAL CLASSIFICATION OF POLYETHYLENES

Designation	Acronym	Density, d, g/cm^3
high density polyethylene	HDPE	≥0.941
ultrahigh molecular weight polyethylene[a]	UHMWPE	0.935–0.930
medium density polyethylene	MDPE	0.926–0.940
linear low density polyethylene	LLDPE	0.915–0.925
low density polyethylene[b]	LDPE	0.910–0.940
very low density polyethylene	VLDPE	0.915–0.880

[a] Linear polymer with molecular weight of over 3×10^6.
[b] Produced in high pressure processes.

In high pressure ethylene polymerization processes, the branches are formed spontaneously according to peculiarities of radical polymerization reactions. These branches are either linear or branched alkyl groups. Their lengths vary widely, sometimes even within a single polymer molecule, and can be both short (from methyl to isooctyl group, collectively known as short-chain branching) and long, up to several thousands of carbon atoms (long-chain branching). In catalytic polymerization processes, the branches are introduced deliberately by copolymerizing ethylene with α-olefins. The structure of these branches is determined by the type of olefin used in the copolymerization reaction.

Some PE molecules, on the other hand, contain no branches at all. From a chemical standpoint, such resins can be regarded as polymethylene, $H\text{-}(CH_2)_n\text{-}H$.

The distributions of branches among different polymer molecules in PE resins can be quite different, depending on the method of PE production. Some PE resins have uniform branching distributions, which means that any given polymer molecule contains the same relative fraction of branches as all others. PE prepared in high pressure processes and most ethylene copolymers produced with metallocene catalysts belong to this group. In contrast, PE resins produced with heterogeneous titanium- and chromium-based catalysts are mixtures of polymer molecules with very different branching degrees.

Classification of PE resins

The classification of PE resins has developed in conjunction with the discovery of new catalysts for ethylene polymerization as well as new polymerization processes and applications. The classification (given in Table 1) is based on two parameters: the resin density and its melt index. This classification provides a simple means for a basic differentiation of PE resins, even though it cannot easily describe some important distinctions between the structures and properties of various resin brands.

Synthesis Technologies

A variety of technological processes are used for polyethylene manufacture. They include polymerization in supercritical ethylene at a high ethylene pressure and temperature above the PE melting point (110–140°C), polymerization in solution at 120–150°C or in slurry, and polymerization in the gas phase.

Control of PE Properties

The tailoring of PE properties in commercial processes is achieved mostly by controlling the density, molecular weight, and molecular weight distribution, or by cross-linking. Successful control of all reaction parameters enables the manufacture of a large family of PE products with considerable differences in physical properties, such as the softening temperatures, stiffness, hardness, clarity, impact, and tear strength.

The Market

PE resins command a wide range of applications, both as commodity resins and as specialty polymers. Their uses include numerous film grades of LDPE, HDPE, and LLDPE for bags and packaging; coatings for paper, metal, wire, and glass; household and industrial containers such as bottles for various fluids, i.e., water, food products, detergents, liquid fuels, etc; toys; and different types of pipe and tubing. Because of its versatility, PE has become the largest commercially manufactured polymer in the world.

Mobil Chemical Company

LOW DENSITY POLYETHYLENE

The first high molecular weight crystalline polyolefin was produced in 1933 through the high pressure process. Initial production was targeted for use in specialized applications such as insulation for high voltage cable. Since that time, the number of applications of various grades of homopolymers and copolymers have expanded to cover many areas once dominated by paper (qv), glass (qv), steel (qv), and other polymers.

The molecular weight of low density polyethylene (LDPE) ranges from waxy products at about 500 mol wt to very tough products at about 60,000 mol wt. One unique feature of LDPE, as opposed to high density polyethylene (HDPE) or linear low density polyethylene (LLDPE), is the presence of both long- and short-chain branching along the polymer chain. Another important feature of LDPE is its ability to incorporate a wide range of comonomers that can be polar in nature along the polymer chain. Disadvantages of LDPE include the high capital investment for commercial plant construction, engineering problems related to high pressure operation, and high energy costs in production.

LDPE, also known as high pressure polyethylene, is produced at pressures ranging from 82–276 MPa (800–2725 atm). Operating at 132–332°C, it may be produced by either a tubular or a stirred autoclave reactor. Reaction is sustained by continuously injecting free-radical initiators, such as peroxides, oxygen, or a combination of both, to the reactor feed.

Traditionally, LDPE has been defined as homopolymer products having a density between 0.915–0.940 g/cm^3 (products having a density above 0.940 g/cm^3 are considered HDPE). However, with the commercialization of LLDPE via the fluidized-bed or solution processes, this distinction is no longer valid.

Properties

The mechanical properties of LDPE fall somewhere between rigid polymers such as polystyrene and limp or soft polymers such as polyvinyls. LDPE exhibits good toughness and pliability over a moderately wide temperature range. It is a viscoelastic material that displays non-Newtonian flow behavior, and the polymer is ductile at temperatures well below 0°C. Table 2 lists typical properties.

Structure. The physical properties of LDPE depend on the molecular weight, the molecular weight distribution, as well as the frequency and distribution of long- and short-chain branching.

Molecular Weight Distribution. MWD offers a general picture of the range of long, medium, and short molecular chains in the polymer; the broad molecular weight distribution in LDPE, however, is attributed only to the presence of long branches on the polymer molecule. LDPE may have molecules that range in length from a few thousand carbons to a million or more carbons.

With increasing molecular weight, certain properties increase: melt viscosity, abrasion resistance, tensile strength, resistance to creep, flexural stiffness, resistance to brittleness at low temperature, shrinkage, warpage, and film impact strength. On the other hand, increasing mol wt results in reduced film transparence, freedom from haze, and gloss; drawdown rate; neck-in and beading; and adhesion.

Melt Index or Melt Viscosity. Melt index describes the flow behavior of a polymer at a specific temperature under specific pressure. If the melt index is low, its melt viscosity or melt flow resistance is high; the latter is a term that denotes the resistance of molten polymer to flow when making film, pipe, or containers. ASTM D1238 is the designated method for this test.

Film Clarity. Slight haziness is a characteristic of all polyethylene resins. It may be caused either by a surface roughness which diffuses light passing through the film (surface roughness is a function of extrusion conditions and the fundamental structure of the polymer), or it may be caused by the partly crystalline structure of the polymer which has a larger index of refraction than the surrounding amorphous material.

Stress Crack Resistance. Failure caused by environmental stress cracking may be attributed to stored stresses acquired in the molding or extruding operation. These dormant stresses may release themselves by cracking under the combined influence of an adverse environment and polyaxial stretching during use. Polyethylene of narrow molecular weight distribution tends to crack less under environmental stress.

Yield Strength. Yield strength, tensile strength, and elongation are all functions of the basic molecular properties. In other words, a higher

[a] LDPE homopolymers in the 0.2–150 melt index or 100,000–20,000 mPa · s(= cP) viscosity range. Specialty polymers such as greases and waxes or highly cross-linked polymers are not included.
[b] To convert kPa to psi, divide by 6.895.
[c] F_{50} = number of hours at which 50% fail.
[d] Taken at 25°C.

density LDPE homopolymer has higher yield strength, slightly lower tensile strength, and lower elongation; in contrast, a higher average molecular weight polymer has higher tensile strength and slightly higher yield strength.

Low Temperature Brittleness. Brittleness temperature is the temperature at which polyethylene becomes sufficiently brittle to break when subjected to a sudden blow. Because some polyethylene end products are used under particularly cold climates, they must be made of a polymer that has good impact resistance at low temperatures; namely, polymers with high viscosity, lower density, and narrow molecular weight distribution.

Film Appearance. It is important to minimize film imperfections or defects when LDPE is blown into film. The common defects are arrow-heads, pinpoint gels, gels or "fish eyes", and oxidized gels or colored specks.

Film imperfections are one of the more serious quality problems for both the producer and the film converter. Film imperfections can arise from many sources. Most commonly, they are the result of contamination in the reaction system, in post-reactor handling, during shipping and unloading, or in the end users equipment.

Chemical Resistance. LDPE is highly resistant to penetration by most chemically neutral or reactive substances. This is a property of prime importance for all kinds of packaging applications. Because of its high impermeability, polyethylene containers can store and transport many kinds of chemicals without leak hazards. Likewise, easily spoiling foods such as vegetables or meats can be shelved and sold in polyethylene bags without the danger of water infiltration from the outside or irreplaceable moisture being lost from the inside; exchange of gases through the film can also be kept to a minimum. In addition, LDPE is resistant to penetration from most polar liquids, water, aqueous acids, and alkalies, as well as most metal plating solutions. However, it can be easily penetrated by nonpolar liquids such as hydrocarbons, and animal and vegetable oils.

Electrical Properties. LDPE's electrical properties make it extremely well suited for wire and cable insulation for electrical power supplies at high transmission, lower domestic voltage, and high frequency, very high frequency, or ultrahigh frequency applications in electronics. As a dielectric, i.e., electric insulator, LDPE for all practical purposes does not transmit electrical current.

Manufacture

LDPE is produced in either a stirred autoclave or a tubular reactor; total domestic production, divided between the two systems at 45% for tubular and 55% for autoclave, is estimated to be 3.4 million metric tons per year. Neither process has gained a clear advantage over the other, although all new or added capacity production in the 1990s has been through the autoclave.

Recycle and Polymer Collection. Due to the incomplete conversion of monomer to polymer, it is necessary to incorporate a system for the recovery and recycling of the unreacted monomer. Both tubular and autoclave reactors have similar recycle systems.

Additives. Compounds are often added to the polymer at the extruder or melt homogenizer. Common additives are antioxidants, thermal stabilizers, slip agents, antiblock agents, and uv stabilizers.

Blending and Purging. Polymer pellets are air-conveyed to holding silos where they are purged with heated, filtered air and then blended to ensure uniformity. Purging is necessary for removing the entrapped monomer and comonomer.

Environmental Considerations. Good progress has been made in reducing emissions during production. Ethylene is by far the largest fugitive gas; purge from the recycle system is commonly recycled to the ethylene cracking unit for recovery. Owing to improved operation techniques and control equipment, runaway reactions or "decomps" that are vented to the atmosphere have also decreased substantially. In addition, many plants utilize particulate and noise reduction devices on the emergency venting systems.

Many units have waste heat recovery systems that generate low pressure steam from reaction heat. Such steam is often employed to drive adsorption refrigeration units to cool the reactor feed stream and to increase polymer conversion per pass, an energy-saving process that reduces the demand for electrical power.

Pellet degassing, however, still presents a problem. The volume of purge air required to degas the pellets makes recovery of ethylene from the purge stream using conventional methods uneconomical.

Applications

LDPE is used in a wide range of applications, the largest segment of which is taken up by end uses requiring processing into thin film.

Blown Film. Blown film has a number of advantages over flat film. For instance, in blown film extrusion, molecular orientation is achieved in both the machine and transverse direction, the relative degree depending primarily on the drawdown ratio (the die opening to film gauge) and the blow-up ratio. The result is a film with more uniform strength in both directions. Moreover, with proper extrusion conditions, the physical properties of the film are equal in both the machine and transverse direction; such even distribution provides maximum toughness. Another advantage of blown film or tubing is the absence of a lengthwise seam.

In blown film extrusion, the molten polymer enters a ring-shaped die either through the bottom or from the side. It is then forced around a mandrel inside the die, shaped into a sleeve, and extruded through the die opening in the form of a comparatively thick-walled tube.

Flat Film Extrusion. In flat film extrusion, the melt is extruded through a long slot in a "T" or coat hanger-type die, past the die lands. In this setup, the polymer melt is forced into the slot die at its center; it reaches the slot opening by way of a manifold and over the lands. The principal advantages of film casting are substantial improvements in the film's transparency, freedom from haze, improved gloss, and other optical properties.

Extrusion Coating. In extrusion coating, a thin film of molten polymer is pressed onto or into the substrate. Coating thickness may range from 6.5 μm or less to more than 100 μm. In polymer lamination, a related operation, two or more substrates, such as paper or aluminum foil, are combined by using the polymer film as adhesive and moisture barrier. In order to coat a substrate, the polymer must be extruded through a narrow slit in the extrusion coating die by an extruder screw.

Molding Applications. Molding is accomplished by three different methods: blow molding, injection molding, and rotational molding, although the use of LDPE in these applications has been declining since the introduction of LLDPE on the market.

Adhesives and Sealants. Dominated by copolymers, adhesives and sealants remain somewhat of a specialty market. These polymers usually contain high copolymer content and low viscosity, and often require blending with other compounds prior to final application. Their uses are numerous, e.g., as seals for bottled drinks, as tie layers between incompatible polymers, or as automotive adhesives.

Health and Safety Factors

LDPE is nontoxic, and is commonly used in food packaging where Food and Drug Administration requirements must be met. It is also used in

packaging pharmaceuticals and other medical applications such as iv bags and tubes.

Waste management of LDPE can be approached in several different ways, i.e., via recycling, energy recovery, biodegradability, increased packaging efficiency, or uv degradability. Ultraviolet degradable grades for can carriers are available to processors; these products are mandated in several states.

Environmental Degradability. It has become increasingly clear that, for certain end uses at least, plastics with a limited lifetime are preferable because they help to solve problems of litter and waste disposal. These types of plastics are subject to biodegradation, which occurs when microorganisms such as fungi or bacteria secrete enzymes and chemically break down the polymer structure into small fractions that can be digested by other microorganisms.

Biodegradability has been approached in several areas. One attempt is to add fillers such as starches into the product.

Another approach is to replace petrochemical-based polymers with polymers made from carbohydrates. Unfortunately, approaches of this type have yet to produce economically competitive polymers.

LLOYD W. PEBSWORTH
Polyethylene Technology

HIGH DENSITY POLYETHYLENE

High density polyethylene (HDPE) is defined by ASTM D1248-84 as a product of ethylene polymerization with a density of 0.940 g/cm^3 or higher. This range includes both homopolymers of ethylene and its copolymers with small amounts of α-olefins. The first commercial processes for HDPE manufacture were developed in the early 1950s and utilized a variety of transition-metal polymerization catalysts based on molybdenum, chromium, and titanium. Commercial production of HDPE was started in 1956 in the United States by Phillips Petroleum Co. and in Europe by Hoechst. HDPE is one of the largest volume commodity plastics produced in the world. The term HDPE embraces a large variety of products differing predominantly in molecular weight, molecular weight distribution (MWD), and crystallinity.

Molecular Weight. The range of molecular weights of commercially produced HDPE is wide, from several hundreds for polyethylene (PE) waxes to several millions for ultrahigh molecular weight PE resins (UHMWPE). A parameter that is widely accepted, easily measured, and which provides information on molecular weight, is the rheological parameter called the melt index. Different HDPE resins have melt indexes ranging from over 500 (low molecular weight polymers) to less than 0.001.

Molecular Weight Distribution. The width of the molecular weight distribution (MWD) of PE resins is usually represented by the ratio of the weight-average and the number-average molecular weights, $\overline{M}_w/\overline{M}_n$, or by MFR value, which is the ratio of two melt indexes measured at two melt pressures that differ by a factor of 10. The range of MFR values for commercial HDPE resins is wide, from around 25 for injection molding resins with a narrow MWD, to over 150 for some HDPE film resins with a broad MWD.

Crystallinity and Density. Crystallinity and density of HDPE resins depend primarily on the extent of short-chain branching in polymer chains and, to a lesser degree, on molecular weight. The density range for HDPE resins is between 0.960 and 0.941 g/cm^3. UHMWPE is a completely nonbranched ethylene homopolymer, but, due to its very high molecular weight, it crystallizes poorly and has a density of 0.93 g/cm^3.

Molecular Structure and Chemical Properties

HDPE is a linear polymer with the chemical composition of polymethylene, $(CH_2)_n$. Depending on application, HDPE molecules either have no branches at all, as in certain injection molding and blow molding grades, or contain a small number of branches which are introduced by copolymerizing ethylene with α-olefins, e.g., ethyl branches in the case of 1-butene and n-butyl branches in the case of 1-hexene. The number of branches in HDPE resins is low, at most 5 to 10 branches per 1000 carbon atoms in the chain.

HDPE is a saturated linear hydrocarbon and exhibits very low chemical reactivity. The most reactive parts of HDPE molecules are the double bonds at chain ends and tertiary CH bonds at branching points in polymer chains. Because its reactivity to most chemicals is reduced by high crystallinity and low permeability, HDPE does not react with organic acids, most inorganic acids, or with alkaline solutions.

At room temperature, HDPE is not soluble in any known solvent, but at a temperature above 80–100°C, most HDPE resins dissolve in some aromatic, aliphatic, and halogenated hydrocarbons.

HDPE is relatively stable under heat. Chemical reactions at high temperature in the absence of oxygen become noticeable only above 290–300°C. Thermocracking of HDPE is a free-radical C–C bond scission reaction.

At elevated temperatures, oxygen attacks HDPE molecules in a series of radical reactions. These reactions reduce the molecular weight of HDPE and introduce oxygen-containing groups, such as hydroxyl and carboxyl groups, into polymer chains. Other oxidation products are low molecular weight compounds such as water, aldehydes, ketones, and alcohols. Oxidative degradation in HDPE is initiated by impurities, which are mainly catalyst residues containing transition metals, e.g., titanium and chromium. The protection from thermooxidative degradation is provided by antioxidants such as naphthylamines or phenylenediamines, hindered phenols, quinones, and alkyl phosphites, which are used in 0.1–1.0 wt % concentration.

Many commercial processes involving surface dyeing and printing (e.g., on film and containers) employ thermooxidation as a pretreatment step. Dyes adhere poorly to HDPE surfaces but their adhesion can be improved by thermooxidation of the surface layer by treatment with an open flame or in a strong electric field.

Even though degradation of HDPE initiated by oxygen and light resembles thermooxidative degradation, it proceeds at a much lower temperature. Photooxidative degradation of HDPE causes aging, development of surface cracks, brittleness, change in color, and drastic deterioration of mechanical and dielectric properties. The reaction can be slowed down or prevented by utilizing light stabilizers that protect the resin and absorb uv radiation. Photooxidative degradation is the principal process responsible for gradual disintegration of discarded PE litter. The chemical industry manufactures a large number of antioxidants as well as uv stabilizers; their mixtures with other additives are used to facilitate resin processing.

Crystalline Structure and Physical Properties

HDPE is a semicrystalline plastic, whose crystallinity varies from 40 to 80%, depending on the degree of branching and molecular weight. Polymer chains in crystalline HDPE have a flat zigzag configuration. The principal crystalline form of HDPE is orthorhombic, with a density of 1.00 g/cm^3 and the cell parameters $a = 0.740$, $b = 0.493$, and $c = 0.2534$ nm. The polymer chains are aligned in the c-axis direction. HDPE crystallizes from the melt under typical conditions as densely packed morphological structures known as spherulites. Spherulites are small spherical objects (usually from 1 to 10 μm) visible only under high magnification. They are composed of even smaller structural subunits: rod-like fibrils that spread in all directions from the spherulite centers, filling the spherulite volume. These fibrils, in turn, are made up of the smallest morphological structures distinguishable, small planar crystallites called lamellae. Crystalline lamellae offer the spherulites rigidity and account for their high softening temperature, whereas the amorphous regions between lamellae provide flexibility and high impact strength to HDPE articles.

The extrapolated equilibrium melting point of orthorhombic HDPE crystals is 146–147°C. Actual measurements of slowly crystallized samples give the highest melting point, T_m, at 133–138°C.

Owing to the high crystallinity of HDPE, most articles made from HDPE resins are opaque. Thin HDPE film, in contrast, is translucent, but its transparency is significantly lower than that of LDPE or LLDPE film. The ultraviolet transmission limit of HDPE is around 230 nm.

Various properties of HDPE are listed in Table 3.

Catalysts for HDPE Production

HDPE resins are produced in industry with several classes of catalysts, i.e., catalysts based on chromium oxides (Phillips), catalysts utilizing organochromium compounds, catalysts based on titanium or vanadium compounds (Ziegler), and metallocene catalysts.

Polymerization Processes and Processing

All technologies employed for catalytic polymerization processes in general are widely used for the manufacture of HDPE. The three most often

used technologies are slurry polymerization, gas-phase polymerization and solution polymerization. Catalysts are usually fine-tuned for a particular process.

Most high density polyethylene processing technologies require the melting of HDPE. Typical HDPE melt viscosities are between 1,000 and 100,000 Pa · s(10,000 − 10^6 P); the melt viscosity of HDPE strongly depends on temperature and on the resin molecular weight. Some resins can have a viscosity 250 times greater than that of others. The effect of temperature on the HDPE melt viscosity is described by an exponential dependence similar to the Arrhenius equation with an activation energy of 25–29 kJ/mol (6–7 kcal/mol).

Because of its low melting point and high chemical stability, HDPE is easily processed by most conventional techniques (injection molding, blow molding, rotational molding, and extrusion). Blown HDPE film is manufactured on high stalk film lines; specialized techniques have also been described.

Because of high molecular weight and extremely high melt viscosity, UHMWPE cannot be readily processed by any technique involving melt extrusion or thermoforming. Instead, these resins are processed either by compression molding into sheet, block, and precision parts; by ram extrusion into board, rods, pipe, and profiles; or by forging into parts of complex configuration.

Recycling of HDPE. Polyolefins, including HDPE are the second most widely recycled thermoplastic materials after PET. A significant fraction of articles made from HDPE (mostly bottles, containers, and film) are collected from consumers, sorted, cleaned, and reprocessed. Processing of post-consumer HDPE includes the same operations as those used for virgin resins: blow molding, injection molding, and extrusion.

Specifications, Standards, and Quality Control

According to ASTM D1248, HDPE materials are divided into various classifications based on properties. Two of the most easily measured characteristics are density and melt index; the former determines the type of HDPE, the latter its category.

Health and Safety Factors

HDPE by itself is a safe plastic material on account of its chemical inertness and lack of toxicity. Film and containers made from HDPE are used on a large scale in food and drug packaging and HDPE has been used in prosthetic devices including hip and knee joint replacements. All these applications underscore polymer safety. If articles made of HDPE contain fillers, processing aids, and colorants, their toxic effects must be estimated separately.

HDPE can present health hazards when it burns. Heavy smoke, fumes, or potentially toxic decomposition products can result from incomplete combustion. Large-scale fire testing has shown that the products formed from HDPE present no greater hazard than those from cellulosic materials, wood, felt, or rubber.

A significant part of HDPE is collected from consumers for recycling; uncollected HDPE can be disposed of by landfill or incineration. In landfill, HDPE is completely inert, degrades very slowly, does not produce gas, and does not leach any pollutants into groundwater. When incinerated in commercial or municipal facilities, HDPE produces a large amount of heat (the same as heating fuel) and therefore should constitute less than 10% of the total trash.

Uses

Blow-molded products represent the biggest use of HDPE resins, around 40%. Packaging applications account for by far the greatest share of this market. These include such products as bottles (especially for milk, juice, and soap), housewares, toys, pails, drums, and tanks.

Injection-molding products are the second largest application with approximately 20% of the HDPE market. These products includes housewares, toys, food containers, pails, crates, and cases.

Film is the third most important application for HDPE resins accounting for nearly 15% of the total HDPE market. Its share of the market is increasing rapidly as it gradually replaces paper and glass and competes with LLDPE film for many uses.

HDPE pipes are used for transporting water, sewer wastes, and gas; they are also widely used in the chemical industry. Other significant applications include wire and cable coatings, foam, insulation for coaxial and communication cables, as well as those areas where high resistance to oil and chemicals is desirable.

Low molecular weight HDPE with molecular weight of several thousand (waxes) is widely used for paper coatings, spray coatings emulsions, printing inks, crayons, and wax polishes. Waxes are also used as additives to butyl rubber and various higher molecular weight PE grades for improving melt flow characteristics, hardness, and resistance to abrasion and grease.

UHMWPE possesses a unique combination of mechanical and technological properties and enjoys a variety of special applications based on low friction (solid lubricant), wear resistance (protection of metal surfaces), excellent chemical stability, as well as radiation and neutron resistance. UHMWPE is used in chemical processing, food and beverage industries, foundries, the lumber industry; the electrical industry, as medical implants; and in mining and mineral processing sewage treatment, and transportation.

LINEAR LOW DENSITY POLYETHYLENE

The chemical industry manufacturers a large variety of semicrystalline ethylene copolymers containing small amounts of α-olefins. These copolymers are produced in catalytic polymerization reactions and have densities lower than those of ethylene homopolymers known as high density polyethylene (HDPE). Ethylene copolymers produced in catalytic polymerization reactions are usually described as linear ethylene polymers, to distinguish them from ethylene polymers containing long branches which are produced in radical polymerization reactions at high pressures.

TABLE 4. BASIC CLASSIFICATION OF COPOLYMERS

Resin	Designation	α-Olefin, mol %	Crystallinity, %	Density, g/cm^3
PE of medium density	MDPE	1–2	55–45	0.940–0.926
linear PE of low density	LLDPE	2.5–3.5	45–30	0.925–0.915
PE of very low density	VLDPE	>4	<25	<0.915

Densities and crystallinities of ethylene–α-olefin copolymers mostly depend on their composition. The classification in Table 4 is commonly used (ASTM D1248-48).

The large number of commodity and specialty resins collectively known as LLPDE are in fact made up of various resins, each different from the other in the type and content of α-olefin in the copolymer, compositional and branching uniformity, crystallinity and density, and molecular weight and molecular weight distribution (MWD).

Four olefins are used in industry to manufacture ethylene copolymers: 1-butene, 1-hexene, 4-methyl-1-pentene, and 1-octene. Copolymers containing 1-butene account for approximately 40% of all LLDPE resins manufactured worldwide, 1-hexene copolymers for 35%, 1-octene copolymers for about 20%, and 4-methyl-1-pentene copolymers for the rest. The type of α-olefin exerts a significant influence on the copolymer properties.

Two classes of LLDPE resins are on the market. One has a predominantly uniform compositional distribution (uniform branching distribution); that is, all copolymer molecules in these resins have approximately the same composition. Most commercially produced LLDPE resins, in contrast, have pronounced nonuniform branching distributions; there are significant differences in copolymer compositions among different macromolecules in a given resin.

Crystallinity and density of LLDPE, which are closely related, depend mostly on the amount of α-olefin in the copolymer. Both density and crystallinity of ethylene copolymers are also influenced by their compositional uniformity. As a rule, lower α-olefin content is needed in a uniformly branched ethylene copolymer to decrease its crystallinity and density to a given level.

The range of molecular weights of commercial LLDPE resins is relatively narrow, usually from 50,000 to 200,000. One accepted parameter that relates to the resin molecular weight is the melt index, a rheological parameter which, broadly defined, is inversely proportional to molecular weight. A typical melt index range for LLDPE resins is from 0.1 to 5.0, but can reach over 30 for some applications.

Molecular Structure and Properties

LLDPE resins are copolymers of ethylene and α-olefins with low α-olefin contents. Molecular chains of LLDPE contain units derived both from ethylene, $-CH_2-CH_2-$, and from the α-olefin, $-CH_2-CHR-$, where R is C_2H_5 for ethylene–1-butene copolymers, n-C_4H_9 for ethylene–1-hexene copolymers, $-CH_2-CH(CH_3)_2$ for ethylene–4-methyl-1-pentene copolymers, and n-C_6H_{13} for ethylene–1-octene copolymers. In a typical copolymer molecule containing 2–4 mol % of α-olefin, the majority of olefin units stand alone in the chain but most ethylene units form long sequences. As a rule, LLDPE resins do not contain long-chain branches. However, some copolymers produced with metallocene catalysts in solution processes can contain about 0.002 long-chain branches per 100 ethylene units.

LLDPE resins produced with different catalysts vary greatly in their compositional uniformity. The fastest way to evaluate the branching distribution of an LLDPE resin is to measure its melting point. Melting points of copolymers with uniform compositional distributions show a noticeable dependence on their composition and may vary widely: from ~120°C for copolymers containing 1.5–2 mol % of α-olefin to ~110°C for copolymers containing 3.5 mol % of α-olefin. A copolymer with a nonuniform compositional distribution, in contrast, is a mixture that contains copolymer molecules with a broad range of compositions, from almost linear macromolecules (usually of higher molecular weights) to short macromolecules with quite high α-olefin contents. Melting of such mixtures is dominated by their low branched fractions which are highly crystalline. They are not too sensitive to copolymer composition and usually fall in the temperature range of 125–128°C.

LLDPE is a saturated branched hydrocarbon. The most reactive parts of LLDPE molecules are the tertiary CH bonds in branches and the double bonds at chain ends. LLDPE is nonreactive with both inorganic and organic acids and is stable in alkaline and salt solutions. At room temperature, LLDPE resins are not soluble in any known solvent; at temperatures above 80–100°C, however, the resins can be dissolved in various aromatic, aliphatic, and halogenated hydrocarbons.

LLDPE is relatively stable to heat. Thermal degradation starts at temperatures above 250°C and results in a gradual decrease of molecular weight and the formation of double bonds in polymer chains.

Oxidation of LLDPE starts at temperatures above 150°C. To protect molten resins from oxygen attack, antioxidants must be used in concentrations of 0.1–0.5 wt %.

Photooxidative degradation of LLDPE at ambient temperature under sunlight is also a radical oxidation reaction. It causes change in color and drastic deterioration of mechanical and dielectric properties of LLDPE articles. Photooxidation can be prevented by using light stabilizers.

Physical Properties. LLDPE is a semicrystalline plastic whose chains contain long blocks of ethylene units that crystallize in the same fashion as paraffin waxes or HDPE. The degree of LLDPE crystallinity depends primarily on the α-olefin content in the copolymer and is usually below 40–45%. The principal crystalline form of LLDPE is orthorhombic (the same as in HDPE); the cell parameters of nonbranched PE are $a = 0.740$ nm, $b = 0.493$ nm, and c (the direction of polymer chains) = 0.2534 nm.

LLDPE rapidly crystallizes from the melt with the formation of spherulites, small spherical objects 1–5 μm in diameter visible only in a microscope. The elementary structural blocks in spherulites are lamellae, small flat crystallites formed by folded linear segments in LLDPE chains, which are interconnected by polymer chains that pass from one lamella to another (tie molecules). Crystalline lamellae within spherulites give LLDPE articles necessary rigidity, whereas the large amorphous regions between lamellae, constituting over 60% of the spherulite volume, provide flexibility.

The size of the lamellae for a copolymer of a given composition depends on the degree of branching uniformity. If an LLDPE resin is compositionally uniform, all its macromolecules crystallize poorly due to branching, forming very thin lamellae. Such materials have low rigidity (low modulus) and high flexibility. On the other hand, if an LLDPE resin is compositionally nonuniform, its least-branched components are able to form thicker lamellae; consequently, more branched fractions of the resin remain amorphous and fill the voids between the lamellae. Articles made from such resins are more rigid.

Optical properties of LLDPE resins also depend on the degree of branching uniformity. Resins with a uniform branching distribution make highly transparent film with haze as low as 3–4%. In contrast, film manufactured from compositionally nonuniform copolymers is much more opaque, with haze of over 10–15%; this is due to the presence of large crystalline lamellae consisting of nearly nonbranched PE chains.

Because it is a saturated aliphatic hydrocarbon, LLDPE does not conduct electricity, and so is widely used for wire and cable insulation. LLDPE is poorly permeable to water and inorganic gases and only slightly more so to organic compounds, whether liquid or gas.

Mechanical Properties. Mechanical characteristics of ethylene copolymers are functions of their structural characteristics, such as content and type of α-olefin, branching uniformity, molecular weight and width of molecular weight distribution (MWD), and orientation (see Table 5 for properties of films made from three grades of LLDPE).

Catalysts and LLDPE Polymerization Processes

LLDPE resins are produced in industry with three classes of catalysts titanium-based catalysts (Ziegler), metallocene-based catalysts (Kaminsky and Dow), and chromium oxide-based catalysts (Phillips).

Ziegler catalysts account for by far the greatest share of LLDPE resins manufactured. They consist of two components: the first contains as its active ingredient a derivative of a transition metal (usually titanium); the second is an organoaluminum compound such as triethylaluminum. The molar [Al]:[Ti] ratio in these catalyst systems is usually in the 50–500 range. Most commercially important catalysts are heterogeneous; a large

[e] To convert MPa to psi, multiply by 145.

number of them are supported. Both inorganic and organic supports are used, the most important are $MgCl_2$ and silica.

Typical heterogeneous Ziegler catalysts operate at temperatures of 70–100°C and pressures of 0.1–2 MPa (15–300 psi). The polymerization reactions are carried out in an inert liquid medium (e.g., hexane, isobutane) or in the gas phase. Molecular weights of LLDPE resins are controlled by using hydrogen as a chain-transfer agent. Reactivities of α-olefins in copolymerization with ethylene depend on two factors: the size of the alkyl groups attached to their double bonds and the type of catalyst.

Three types of metallocene catalysts are presently used in industry: Kaminsky, ionic, and Dow constrained-geometry catalysts.

Chromium oxide-based catalysts, which were originally developed for the manufacture of HDPE resins, have been modified for ethylene–α-olefin copolymerization reactions. These catalysts use a mixed silica–titania support containing from 2 to 20 wt % of Ti.

Polymerization

The technologies suitable for LLDPE manufacture include gas-phase fluidized-bed polymerization, polymerization in solution, polymerization in a polymer melt under high ethylene pressure, and slurry polymerization. Most catalysts are fine-tuned for each particular process.

Processing

All LLDPE processing technologies involve resin melting; viscosities of typical LLDPE melts are between 5000 and 70,000 Pa·s (50,000–700,000 P). The main factor that affects melt viscosity is the resin molecular weight; the other factor is temperature. Its effect is described by the Arrhenius equation with an activation energy of 29–32 kJ/mol (7–7.5 kcal/mol).

LLDPE melts in the 140–250°C range (a typical processing range) are non-Newtonian liquids; their effective viscosity is significantly reduced when the melt flow speed is increased. This phenomenon is called shear-thinning; it plays an important role in resin processing. The resins with an expressed shear-thinning capability have decreased viscosities and hence a greatly reduced energy demand at high speed processing.

LLDPE is easily processed by most conventional techniques due to its low melting point and high chemical stability.

Most LLDPE produced worldwide is made into thin film, either melt blown or cast from the melt. Blown film is produced by extrusion of LLDPE melt through a circular die with a large diameter, up to 100–120 cm, and a narrow gap, usually less than 1 mm. The tube of molten polymer expands from internal air pressure and forms a bubble of a larger diameter. Typically, the blow-up ratio, the ratio of the final film tube diameter to the circular-die diameter, is between 1.5:1 and 4:1. LLDPE cast film is manufactured by depositing polymer melt on a rotating heated drum with a highly polished surface. Compositional uniform LLDPE resins produced with metallocene catalysts can be easily processed into film by using standard equipment with minor modifications.

Injection molding is used for the manufacture of LLDPE articles of complex shapes. The duration of the molding cycle depends on the melt viscosity and the rate of polymer crystallization. Because LLDPE crystallizes rapidly, molding cycles are short, typically from 10 to 30 seconds. Molds usually accommodate up to 50 or more articles formed in a single shot. Bottles and simple containers are manufactured in large quantities by the blow molding technique. LLDPE resins with high molecular weights and high melt viscosities are used in this method. Large containers and some toys are manufactured from LLDPE powder with a specialized technique called rotational molding. Extrusion applications include resin pelletization after LLDPE synthesis, and manufacture of thick film, sheet, pipe, tubing, and insulated wire.

Health and Safety Factors

LLDPE by itself does not present any health-related hazard on account of its chemical inertness and low toxicity. Consequently, film, containers, and container lids made from LLDPE are used on a large scale in food and drug packaging. Some LLDPE grades produced with unsupported metallocene catalysts have an especially high purity due to high catalyst productivity and a low contamination level of resins with catalyst residue. FDA approved the use of film manufactured from these resins for food contact and for various medical applications. However, if LLDPE articles contain fillers, processing aids, or colorants, their health factors must then be judged separately.

LLDPE can present a certain health hazard when it burns, since smoke, fumes, and toxic decomposition products are sometimes formed in the process.

LLDPE can be disposed of by landfill or incineration. In landfill, the material is completely inert, degrades very slowly, does not produce gas, and does not leach any pollutants into ground water. When incinerated in commercial or municipal facilities, LLDPE produces a large amount of heat (the same as heating fuel) and should constitute less than 10% of the total trash.

Uses

By far the largest application for LLDPE resins (over 60% in the United States) is film. Because LLDPE film has high tensile strength and puncture resistance, it is able to compete with HDPE film for many uses. Bags manufactured from thin LLDPE film have excellent tensile strength, puncture resistance, and seal strength at thin gauges; they can be used either for packaging or as garment bags, laundry and dry-cleaning bags, and ice bags. Several LLDPE films are currently competing for a special film market: elastic stretch film for packaging. Both blown and die-case film can be used for this application. The resins based on ethylene–1-hexene and ethylene–1-octene copolymers are particularly suited for these purposes. A significant volume of LLDPE film is used to manufacture large-size packaging material for food (e.g., grocery sacks) and textiles, in addition to such applications as industrial sheeting and agricultural mulch film. LLDPE bags are thinner than LDPE bags; their thickness can be further reduced to around 25 μm, which makes them price-competitive with paper.

High oxygen-barrier properties of metallocene-derived resins make their film especially attractive for packaging poultry, frozen foods, and vegetables. Such properties, moreover, make these resins and their blends with HDPE suitable for producing film for blood bags, surgical disposable bags, and medical gowns.

An important property recommending the use of LLDPE in many packaging applications is their sealability. Compositionally uniform resins are especially attractive for such use because their melting and softening points are 15–20°C lower than those of commodity LLDPE resins.

Injection molding is the second largest market for LLDPE, accounting for over 10% of its total consumption. Over half of the LLDPE consumed in injection-molding applications is used for housewares.

LLDPE resins formulated for the blow molding applications have superior environmental stress-cracking resistance and low gas permeability. These features opened new bottle markets where such properties are important. A large variety of molded articles with a complex configuration

are manufactured from LLDPE resins, including toys, large square-edged containers, as well as tanks for agriculture and water treatment.

The same qualities that make LLDPE attractive for blow molding applications also play a crucial role in its being adapted for pipe manufacture, an area that accounts for about 1% of the LLDPE market. LLDPE pipes provide flexibility, high burst strength, and high environmental stress-cracking resistance, and a high heat-distortion temperature. LLDPE tubing is used for drip piping, swimming pool tubing, household hoses, and in such specialty markets as medical tubing applications.

LLDPE is also widely used for wire and cable coating in electrical and telephone industry, which amounts to 2.5% of LLDPE production.

POLYPROPYLENE

Propylene polymerization processes have undergone a number of revolutionary changes since the first processes for the production of crystalline polypropylene (PP) were commercialized in 1957 by Montecatini in Italy and Hercules in the United States. These first processes were based on Natta's discovery in 1954 that a Ziegler catalyst could be used to produce highly isotactic polypropylene. The stereoregular, crystalline polymers produced by this technology had sufficiently attractive economic and property performance that they became significant commercial thermoplastics in a remarkably short period.

Properties

Structure and Crystallinity. The stereochemistry of propylene polymers was first studied by Natta, who defined three possible structures of polypropylene by the location of the pendent methyl groups relative to the polymer backbone. Isotactic polypropylene consists of molecules in which all methyl groups have the same stereochemistry as a result of all insertions of propylene monomer being identical. Syndiotactic polypropylene is produced by regular alternating stereochemistry of monomer insertion, resulting in alternating locations of the pendent methyl groups. Atactic polypropylene, which is noncrystalline, is the result of nonstereospecific monomer insertion and random location of the pendent methyl groups (Fig. 1).

Crystallinity of polypropylene is usually determined by x-ray diffraction. Isotactic polymer consists of helical molecules, with three monomer units per chain unit, resulting in a spacing between units of identical conformation of 0.65 nm.

Syndiotactic polypropylene also forms helical molecules; however, each chain unit consists of four monomer units having a spacing of 0.74 nm. The unit cell is orthorhombic and contains 48 monomer units having a crystallographic density of 0.91 g/cm^3.

Molecular Weight. The molecular weight of polypropylene is typically determined by viscosity measurements. The melt viscosity, or melt flow rate, measured under standard conditions, can also be correlated to molecular weight. Because of the distribution of molecular weights in polypropylene, and the relationship of this distribution to important polymer properties, considerable effort has been exerted to measure the molecular weight distribution of these polymers.

Thermodynamic Properties. The thermodynamic melting point for pure crystalline isotactic polypropylene obtained by the extrapolation of melting data for isothermally crystallized polymer is 185°C. Under normal thermal analysis conditions, commercial homopolymers have melting points in the range of 160–165°C. The heat of fusion of isotactic polypropylene has been reported as 88 J/g (21 cal/g). The value of 165 ± 18 J/g has been reported for a 100% crystalline sample.

The value of the glass-transition temperature, T_g, is dependent on the stereoregularity of the polymer, its molecular weight, and the measurement techniques used. Transition temperatures from -13 to 0°C are reported for isotactic polypropylene, and -18 to 5°C for atactic.

Syndiotactic polypropylene has an ultimate melting point of 174°C, and extrapolated heat of fusion of 105 J/g (25.1 cal/g); both lower than those of isotactic polymer. The heat of fusion of the polymer produced using a metallocene catalyst is reported as 79 J/g (19 cal/g).

Physical Properties. Properties of various homopolymer grades are given in Table 6.

Polypropylene polymers are typically modified with ethylene to obtain desirable properties for specific applications. Specifically, ethylene-propylene rubbers are introduced as a discrete phase in heterophasic copolymers to improve toughness and low temperature impact resistance.

Catalysts Used in Manufacture

$TiCl_3$-Based Catalysts. Isotactic polypropylene was first synthesized by Natta in 1954, using a catalyst system consisting of $TiCl_4$ and $Al(C_2H_5)_3$. This system, based on Ziegler's catalyst for polyethylene, produced a large fraction of polymer with poor structural uniformity and properties. These catalysts, activated with $Al(C_2H_5)_2Cl$ or $Al(C_2H_5)_3$, dramatically increased the percentage of isotactic polymer. Although all four crystal forms of $TiCl_3$, α, β, γ, and δ, are active as catalysts, the best results were obtained using δ-$TiCl_3$ activated by $Al(C_2H_5)_2Cl$. These catalysts enabled rapid commercialization of the production of isotactic polypropylene.

$TiCl_3$ catalysts produced by the reduction of $TiCl_4$ with $Al(C_2H_5)_2Cl$, and subsequently treated first with an electron donor (diisoamyl ether), then with $TiCl_4$, are highly stereospecific and four to five times more active than δ-$TiCl_3$. These catalysts were a significant advance over the earlier $TiCl_3$ systems, because removal of atactic polymer was no longer required. They are often referred to as second-generation catalysts. The life of many older slurry process facilities has been extended by using these catalysts to produce "clean" polymers with very low catalyst residues.

$MgCl_2$-Supported Catalysts. Magnesium chloride, in active form as a support for $TiCl_4$, has been found to significantly increase catalyst activity, enabling the design of processes in which removal of catalyst residues from the polymer is not required. The use of electron donors as stereoregularity control agents reduces formation of the undesirable atactic polymer, giving stereoregularity sufficient for commercial production of polypropylene.

[b] To convert kPa to psi, multiply by 0.145.
[c] To convert MPa to psi, multiply by 145.
[d] To convert J/m to ft · lb/in., divide by 53.38.

Active catalyst systems have also been produced using silica as a support for $MgCl_2$, and $TiCl_4$. A number of magnesium-containing compounds such as alkylmagnesium, magnesium hydrocarbyl carbonates, magnesium alkanoates, magnesium alkoxides and aryloxides, and alkyl magnesium chloride, can be used as the source of activated $MgCl_2$ in addition to the alcoholates of $MgCl_2$ or anhydrous $MgCl_2$. In all cases, these systems contain active centers consisting of $TiCl_4$ supported on activated $MgCl_2$.

Metallocene Catalysts. The use of the dicyclopentadienyl titanium dichloride—diethyl aluminum chloride system to catalyze the polymerization of ethylene homogeneously was first reported in 1957. Dramatic improvements in the performance of these metallocene catalysts were obtained by using methylalumoxane as cocatalyst and dicyclopentadienyl zirconium dichloride as catalyst. Modification of the zirconocene by the addition of substituents to the cyclopentadiene rings provided the capacity of achieving high molecular weight polyethylene at economical process temperatures. Modifications of the organic substituents have resulted in the development of metallocene catalysts capable of producing isotactic polypropylene with similar melting points and molecular weights to commercial Ziegler-Natta propylene.

Manufacturing Processes

Early Processes. The first commercial processes for the production of polypropylene were batch polymerization processes using $TiCl_3$ catalysts activated by $Al(C_2H_5)_2Cl$ in a hydrocarbon medium. As the demand for polypropylene increased, these batch polymerization processes were rapidly replaced by continuous ones.

Polymerization in liquid monomer was pioneered by Rexall Drug and Chemical and Phillips Petroleum (United States). Gas-phase polymerization of propylene was pioneered by BASF, who developed the Novolen process which uses stirred-bed reactors. Eastman Chemical has utilized a unique, high temperature solution process for propylene polymerization. In the 1970s, Solvay introduced an advanced $TiCl_3$ catalyst with high activity and stereoregularity.

Montedison and Mitsui Petrochemical introduced $MgCl_2$-supported high yield catalysts in 1975. These third-generation catalyst systems reduced the level of corrosive catalyst residues to the extent that neutralization or removal from the polymer was not required. Stereospecificity, however, was insufficient to eliminate the requirement for removal of the atactic polymer fraction. These catalysts are used in the Montedison high yield slurry process.

Current Processes. The development of superactive third-generation supported catalysts enabled the introduction of simplified processes, without sections for catalyst deactivation or removal of atactic polymer. By eliminating the waste streams associated with the neutralization of catalyst residues and purification of the recycled diluent and alcohol, these processes minimize any potential environmental impact. Investment costs are reduced by approximately one-third over slurry process plants. Energy consumption is minimized by elimination of the distillation of recycled diluent and alcohol. The total plant cost for the production of polymer is less than 130% of the monomer price, when a modern process is used, compared to 175% for a slurry process.

Processing

Polypropylene is produced in a variety of molecular weights, molecular weight distributions, and crystallinities; consequently, it can be used in most polymer processing technologies. The physical and mechanical properties of polypropylene in the end use product are a function of both the molecular structure and the processing conditions. The final crystalline morphology is a function of the melt temperatures, polymer orientation, and cooling temperatures and rates. The most commonly used processes are injection molding, blow molding, extrusion, and thermoforming (see **Plastics**).

Melt Spinning. This process is used to produce a broad range of polypropylene fibers ranging from fine, dtex (one denier) staple coarse continuous filaments. Homopolymers are almost exclusive used to produce fibers, although copolymer blends are used in some special applications. Processing conditions and polymer melt flow vary with the desired fiber type.

Slit and Split Films. Thick industrial-grade yarns are often produced by slitting films, providing a less expensive alternative to melt spun fiber. Cast film is slit in the machine direction by parallel rotary knives. The resulting tape can then be cold drawn in an oven in a manner similar to melt spun fibers to produce the final fiber.

Melt Blowing. The melt blowing process uses very high melt flow polymers, sometimes in excess of 400 dg/min, and extrusion and temperatures above 300°C to produce very fine fibers (<5 μm dia).

Spun Bonded Fabrics. Spun bonded fabrics are produced by depositing extruded, spun filaments onto a collecting belt in a uniform randomized manner. The fibers are separated during the web laying process by air jets and the collecting belt is usually perforated to prevent the air stream from deflecting and carrying the fibers in an uncontrolled manner. Spun bonded fabrics are used in a variety of applications requiring nonwoven fabrics (qv), competing with thermally bonded staple fiber.

Polypropylene (PP) films were first produced by extrusion casting. Polymer is extruded through a slit or tubular die and quenched by cooling on chill rolls or in a water bath. Cast films can be sealed over a wide range of temperatures and do not shrink in a steam autoclave. Polymers with melt flow rates below 5 dg/min are usually used to maintain the stability of the extrudate. Higher clarity films are produced using random copolymers.

Biaxially oriented polypropylene (BOPP) films have higher stiffness than cast films and consequently can be used in much thinner gauges. Homopolymers are used almost exclusively to provide maximum stiffness and water-vapor barrier. Oriented films are produced by the tenter frame and bubble processes.

Polypropylene is subject to attack by oxygen, radiation, and excessive heat causing a loss of molecular weight and physical properties. Stabilizers are added to the polymer to minimize these effects. Small quantities of hindered phenolic antioxidants (qv) are added in the polymerization plant, usually in the drying section, to protect the polymer against degradation during short-term storage. The bulk of the stabilizer is added during pelletization or fabrication to protect the polymer during processing or in the final application.

Uses

Polypropylene is extensively used in injection molding because of the wide range of physical properties and melt flow rates available. The principal markets served include transportation (primarily automotive), appliances, consumer products, rigid packaging, and medical products. Polypropylene use has increased in the automotive industry because of the wide availability of high melt flow rate impact copolymers for use in large thin parts, such as interior trim.

Polypropylene is frequently utilized in the design of container closures, lunchboxes, and similar articles. Polypropylene closures are used on a wide variety of containers, including child-proof caps and screw caps on plastic beverage bottles. Medical devices injection molded from polypropylene include syringes, pans, trays, and a variety of utensils. A large variety of toys, cups, dishes, and other household articles are molded from polypropylene. The development of high melt flow rate copolymer grades for thin-wall injection molding has increased the use of polypropylene in food containers.

Polypropylene blow-molded bottles are used to package a wide variety of products including foods, cleansers, shampoo, pharmaceuticals, and mouthwash.

Improved equipment and polymers have increased the capability to extrude and thermoform polypropylene. Drinking straws are commonly extruded from polypropylene, however most larger diameter tubes, such as pipes and conduits, are predominantly extruded from other thermoplastics. Extruded sheet is thermoformed into food containers and trays; polypropylene is used when microwavability is desired.

Polypropylene fibers are extensively used in carpeting.

Disposable polypropylene nonwoven fabrics are widely used as the cover-stock for disposable baby diapers, baby wipes, adult incontinence, and feminine hygiene products. Use of polypropylene nonwovens in disposable medical apparel, such as surgical gowns, has increased as a means of reducing the spread of infection.

Oriented polypropylene films are widely used in the packaging of snack foods, candy, and other products. The most common method of packaging using these films is the form and fill process in which the package is formed filled with product, and sealed in a continuous process.

Cast films provide a high clarity, heat sealable film and are primarily used as an overwrap for boxes and other packaging. These films have a lower density than cellophane and provide a longer product shelf life.

RICHARD B. LIEBERMAN
Montell Polyolefins

POLYMERS OF HIGHER OLEFINS

Crystalline polymers of α-olefins, i.e., those with carbon numbers of four or higher, are stereoregular, i.e., isotactic or syndiotactic polymers, such as polypropylene (PP). These polymers are produced with a number of different catalysts. Heterogeneous Ziegler-Natta catalysts and some soluble bridged metallocene catalysts produce isotactic polymers, other types of bridged metallocene catalysts produce crystalline syndiotactic polymers whereas nonbridged metallocene catalysts yield amorphous atactic polymers.

The synthesis of isotactic polymers of higher α-olefins was discovered in 1955, syndiotactic polymers of higher α-olefins were first prepared in 1990. The first commercial production of isotactic poly(1-butene) (PB) and poly(4-methyl-1-pentene) (PMP) started in 1965.

Higher α-olefins can also be polymerized with cationic initiators to liquid oligomeric materials with isomerized structures. These liquids are manufactured commercially and used as lubricating oils.

Cycloolefins are polymerized by means of two different mechanisms. In the first, catalysts based on tungsten and molybdenum compounds induce ring-opening polymerization (metathesis) of monocycloolefins with the formation of linear elastomers containing regularly spaced double bonds in polymer chains. If cyclodienes are used in this reaction, these catalysts then produce cross-linked resins. In the second mechanism, metallocene-based catalysts polymerize cycloolefins without ring opening into linear, stereoregular, highly crystalline polymers. Polymers of several cycloolefins, polydicyclopentadiene, polyoctenamers, and norbornene elastomers are all produced commercially.

Monomers

The monomers of the greatest interest are those produced by oligomerization of ethylene and propylene. Some olefins are also available as by-products from refining of petroleum products or as the products of hydrocarbon thermal cracking.

Commercial production of 1-butene, as well as the manufacture of other linear α-olefins with even carbon atom numbers, is based on the ethylene oligomerization reaction.

4-Methyl-1-Pentene is produced commercially by dimerization of propylene in the presence of potassium-based catalysts at 150–160°C and ~10 MPa.

Linear α-olefins, such as 1-hexene and 1-octene, are produced by catalytic oligomerization of ethylene with triethylaluminum or with nickel-based catalysts. Olefins with branched alkyl groups are usually produced by catalytic dehydration of corresponding alcohols.

1-Butene is a colorless, flammable, noncorrosive gas. Because 1-butene has a very low flash point, it poses a strong fire and explosion hazard.

4-Methyl-1-pentene is a light, colorless, flammable liquid. It is an irritant and, in high concentrations, a narcotic. Like 1-butene, this chemical compound has a low flash point and represents a significant fire hazard when exposed to heat, flame, or oxidizing agents.

Higher α-olefins are exceedingly reactive in radical and ionic reactions. These olefins participate in numerous reactions, such as oxidations, hydrogenation, double-bond isomerization, complex formation with transition-metal derivatives, polymerization, and copolymerization with other olefins in the presence of Ziegler-Natta, metallocene, and cationic catalysts. All olefins readily form peroxides by exposure to air.

Polymer Properties

Chemical properties of most polyolefins resemble those of polypropylene. The resins resist most inorganic or organic acids and bases below 90°C as well as most salt solutions, solvents, soaps, and detergents. Properties of polyolefins rapidly deteriorate in contact with strong oxidizing agents. All polyolefins undergo peroxidation, halogenation, and halosulfonation reactions.

Commercially produced crystalline polyolefins, PB, and PMP exhibit high stability to inorganic substances, and excellent resistance in nonoxidative inorganic environments. PMP easily withstands prolonged boiling and autoclave treatment required for medical and pharmaceutical applications. Prolonged exposure of polyolefin specimens under stress to some hydrocarbon solvents and aqueous detergent solutions can cause cracks and eventual failure, a phenomenon usually referred to as environmental stress cracking.

Polymers of α-olefins are susceptible to thermal and thermooxidative degradation. Reactivity in degradation reactions is especially significant in the case of polyolefins with branched alkyl side groups.

Thermooxidative degradation of PMP is noticeable even at 140–150°C, and its photooxidative degradation, especially at wavelengths below 400 nm, also proceeds at a relatively high rate, thus limiting some of its outdoor applications.

Both thermooxidation and photooxidation of polyolefins can be prevented by using the same antioxidants as those employed for the stabilization of polypropylene, i.e., alkylated phenols, polyphenols, thioesters, and organic phosphites in the amount of 0.2–0.5%.

Polybutene can be cross-linked by irradiation at ambient temperature with γ-rays or high energy electrons in the absence of air. PMP is relatively stable to β- and γ-radiation employed in the sterilization of medical supplies.

Highly crystalline isotactic polyolefins are not soluble in organic solvents at room temperature. However, most amorphous polyolefins and oligomers of α-olefins are easily soluble in saturated and aromatic hydrocarbons at ambient temperature. This difference in solubility can be used to separate amorphous atactic components of polyolefins from crystalline isotactic material in crude polyolefins mixtures.

Above 100°C, most polyolefins dissolve in various aliphatic and aromatic hydrocarbons and their halogenated derivatives.

Crystalline PMP is relatively highly permeable to various organic and inorganic gases. Permeabilities to oxygen, nitrogen, and light hydrocarbons are 20–30 times higher than those of HDPE.

Physical Properties. Table 7 lists physical properties of stereoregular polymers of several higher α-olefins.

Thermal Properties. Melting points of stereoregular PO resins depend on the size and shape of side groups in the polymer chains (Table 7). In the case of isotactic polymers of linear α-olefins, the melting points of the crystalline phase rapidly decrease with increasing side-chain length, isotactic poly(1-hexene) is amorphous, and isotactic polyolefins with longer linear side groups derive their crystallinity from the side chains rather than from the polymer backbone. Polymers of α-olefins with branched alkyl groups generally exhibit much higher melting points (Table 7); the melting points of isotactic poly(3-methyl-1-butene) and poly(vinylcyclohexane) are the highest, over 350°C.

Mechanical Properties. The side-group type in the polymer chains determines mechanical properties of stereoregular polyolefins. Resins with long linear side groups have low crystallinities and exhibit mechanical behavior typical for elastomers. On the other hand, PB and most polymers with branched side groups are highly crystalline and exhibit mechanical properties similar or superior to those of isotactic PP. Excellent mechanical and optical properties contribute to the industrial importance of PB and PMP. Although poly(3-methyl-1-butene) and poly(vinylcyclohexane) also exhibit good mechanical characteristics, their high melting points, poor oxidative stability, and brittleness still preclude them from finding industrial application.

All polyolefins have low dielectric constants and can be used as insulators; in particular, PMP has the lowest dielectric constant among all synthetic resins. As a result, PMP has excellent dielectric properties and a low dielectric loss factor, surpassing those of other polyolefin resins and polytetrafluoroethylene (Teflon). These properties remain nearly constant over a wide temperature range. The dielectric characteristics of poly(vinylcyclohexane) are especially attractive: its dielectric loss remains constant between−180 and 160°C, which makes it a prospective high frequency dielectric material of high thermal stability.

Although most polyolefins are highly opaque, isotactic PMP possesses the outstanding feature: it has low haze (1.2–1.5%) and high optical transparency (~90–92%) comparable to that of polystyrene (88–92%) and acrylics (90–92%). Light transmittance of PMP in the near uv region is also excellent, higher than that of glass and inferior only to quartz. Optical clarity accounts for many applications of PMP.

Polymers of monocyclic olefins (cyclopentene, cyclooctene) produced by ring-opening metathesis are linear elastomers. Their properties are somewhat similar to those of poly(*cis*-1,4-butadiene). Polymers of dicyclopentadiene produced with the same catalysts are heavily cross-linked resins displaying high toughness and tensile strength as well as excellent impact strength at low temperatures.

Polymerization of α-Olefins

Ziegler-Natta Catalysts. All isotactic polymers of higher α-olefins are produced with the same type of heterogeneous, titanium-based Ziegler-Natta catalyst systems as that used for the manufacture of isotactic PP.

TABLE 7. PROPERTIES OF POLYOLEFINS

Polymer[a]	Melting point, °C	Crystal type	Helix type	Crystalline density, g/cm^3
		POLYMERS OF α-OLEFINS		
iso-polybutene				
form I	138–142	hexagonal	3_1	0.951
form II	120–130	tetragonal	11_3	0.902

[a] *iso* designates isotactic; *syndio* designates syndiotactic.

The catalyst systems have two components, a solid catalyst containing a titanium compound and a co-catalyst containing an organoaluminum compound. Both 1-butene and 4-methyl-1-pentene are three to four times less reactive in the polymerization reactions with Ziegler-Natta catalysts than propylene. Modern, highly active catalysts are supported on $MgCl_2$. Some contain aromatic esters such as ethyl benzoate. These catalysts are employed with co-catalyst mixtures containing $Al(C_2H_5)_3$ or $Al(i\text{-}C_4H_9)_3$ and aromatic esters, ethyl benzoate or ethyl anisate. Another highly active type of the supported catalysts uses aromatic diesters (phthalates) and mixtures of $Al(C_2H_5)_3$ and phenylalkoxysilanes as co-catalysts.

Polymerization reactions with Ziegler-Natta catalysts are carried out at 40–80°C in pure monomers or in monomer mixtures with aliphatic solvents. Molecular weights of polymers are controlled by the addition of hydrogen, an effective chain-transfer agent. Some Ziegler-Natta catalysts polymerize linear α-olefins, such as 1-hexane or 1-decene, into linear polymers with ultrahigh molecular weights which are used as drag-reducing agents for hydrocarbon flow.

All higher α-olefins, in the presence of Ziegler-Natta catalysts, can easily copolymerize both with other α-olefins and with ethylene. In these reactions, higher α-olefins are all less reactive than ethylene and propylene.

Isotactic PB and PMP are produced commercially in slurry processes in liquid monomers or monomer mixtures (optionally diluted with light inert hydrocarbons) at 50–70°C.

Metallocene Catalysts. Higher α-olefins can be polymerized with catalyst systems containing metallocene complexes. The first catalysts of this type (Kaminsky catalysts) include metallocene complexes of zirconium such as biscyclopentadienylzirconium dichloride, activated by methylaluminoxane. These catalysts polymerize α-olefins with the formation of amorphous atactic polymers. Polymers with high molecular weights are produced at decreased temperatures and have rubber-like properties.

Zirconocene complexes containing two indenyl or tetrahydroindenyl groups bridged with short links such as $-CH_2-CH_2-$ or $-Si(CH_3)-$ produce isotactic polymers of higher α-olefins. To synthesize syndiotactic PO, bridged zirconocene complexes with rings of two different types are required, one example of which is isopropyl(cyclopentadienyl)(1-fluorenyl)zirconocene. These complexes are used for the synthesis of syndiotactic PB, PMP, and poly (4-methyl-1-hexene).

Cationic Polymerization Reactions. α-Olefins with linear and branched alkyl groups can be readily polymerized with cationic initiators. Olefins containing linear alkyl groups (1-pentene, 1-hexene, 1-octene, 1-decene, etc) and their mixtures are oligomerized by using BF_3, mixtures of BF_3 and alcohols, as well as $AlCl_3$ or $AlBr_3$-HBr systems at low temperatures with the formation of low molecular weight oils of an irregular structure. These oligomers are used as base stocks for synthetic lubricating oils.

Polymerization of Cycloolefins

Depending on the type of catalyst used, polymerization of cycloolefins proceeds through either ring opening or by opening of the double bond with the preservation of the ring.

Ring-Opening Polymerization. Ring-opening polymerization of cycloolefins in the presence of tungsten- or molybdenum-based catalysts proceeds by a metathesis mechanism.

Dicyclopentadiene is also polymerized with tungsten-based catalysts. Because the polymerization reaction produces heavily cross-linked resins, the polymers are manufactured in a reaction injection molding (RIM) process, in which all catalyst components and resin modifiers are slurried in two batches of the monomer. The first batch contains the catalyst (a mixture of WCl_6 and $WOCl_4$), additives, and fillers; the second batch contains the co-catalyst (a combination of an alkylaluminum compound and a Lewis base such as ether), antioxidants, and elastomeric fillers. Mixing two liquids in a mold results in a rapid polymerization reaction.

Metallocene Catalysts. Polymerization of cycloolefins with combinations of metallocenes and methylaluminoxane produces polymers with a completely different structure. The reactions proceeds via the double-bond opening in cycloolefins. If the metallocene complexes contain bridged and substituted cyclopentadienyl rings, such as ethylene(bisindenyl)zirconium dichloride, the polymers are stereoregular and have the *cis*-diisotactic structure.

Processing

Both PB and PMP melts exhibit strong non-Newtonian behavior: their apparent melt viscosity decreases with an increase in shear stress. Melt viscosities of both resins depend on temperature. Equipment used for PP processing is usually suitable for PB and PMP processing as well; however, adjustments in the processing conditions must be made to account for the differences in melt temperatures and rheology.

Extrusion. The main applications of this method include the production of film, sheet, pipe, and tubing. PB is usually extruded by using the same equipment (single- or twin-screw extruders) as that used for PP and HDPE, at melt and die temperatures of 170–190°C. PMP is processed on extruders with a high length-to-diameter ratio at temperatures of 240–300°C.

Injection molding of PB is carried out under conditions similar to those for PP at 145–190°C. Injection molding of PMP is carried out at melt temperatures of 260–330°C, mold temperatures of 30–80°C, injection pressures of around 30 MPa (300 atm), and at relatively low injection rates.

Film. The blown film process is most commonly used in the production of PB film from resins with melt indexes from 0.3 to 10 g/10 min at a melt temperature of 200–215°C using conventional equipment. Mechanical properties of blown PB film depend on the degree of orientation and other processing parameters. PB film can be sealed at 160–220°C. Another technique for the PB film production consists of film casting from the melt on polished chilled rolls and co-extrusion or lamination with other films.

Health and Safety Factors

Polymers and higher α-olefins are not toxic; their main potential health hazards are associated with residual monomer, antioxidants, and catalyst residues. In particular, PB and PMP are inert materials and usually present no health hazard. PMP is employed extensively for a number of medical and food packaging applications.

Uses

Polybutene. The largest share of commercially produced crystalline PB is used for manufacturing pipe and tubing. The advantages of PB in pipe applications include high flexibility, toughness, and high resistance to creep, environmental stress-cracking, wet abrasion, and various chemicals. Pipes manufactured from PB retain their properties at temperatures up to 85°C. PB pipe is used in residential and commercial hot- and cold-water plumbing (including chlorine-containing hot water), water wells, water manifolds, and fire sprinklers. Black-pigmented pipe grades are suitable for outdoor use.

Blown film manufactured from PB has a high tensile strength and exhibits good resistance to tear, impact, and puncture.

Poly(4-methyl-1-pentene). Most PMP applications capitalize on the resin's high optical transparency, excellent dielectric characteristics, high thermal stability, and good chemical resistance. The manufacture of medical equipment comprises about 40% of PMP production, including such articles as hypodermic syringes, needle hubs, blood collection and transfusion equipment, pacemaker parts, blood analysis cells, and respiration equipment. It is also used in chemical and biomedical laboratory equipment, e.g., cells for spectroscopic and optical analysis, laboratory ware, and animal cages, and in a variety of injection-molded articles, such as caps for enclosures, ink cartridges for printers, light covers, tableware, and sight-glasses. PMP is suitable also for microwave oven cookware and service, and is used in food packaging (qv). In many applications, PMP replaces stainless steel trays. PMP is also utilized for wire and cable coating, as well as for film and paper coatings with good release properties.

Synthetic Lubricating Oils. Liquid oligomers of higher linear α-olefins such as 1-decene are produced with cationic initiators. They are the most versatile of all synthetic lubricants. They exhibit not only good lubricating properties over a wide temperature range (including excellent low temperature properties), but also high frictional and oxidative stability as well as low volatility, and are miscible with all mineral oils and most synthetic lubricants. They have found wide application as synthetic base oils in the formulation of various lubricants, including lubricating oils for cars, transformer oils, transmission and crankcase fluids, hydraulic fluids, and compressor oils. See **Lubrication and Lubricants**.

Polymers of Cycloolefins. Polyoctenamer elastomers are processed by extrusion, injection molding, and calendering into hoses, rubber coatings, and tire components. They are mostly used as components in rubber-, PVC-, and PS-based compositions.

Cured liquid-molding resins based on polydicyclopentadiene are uses in the manufacture of automotive parts for trucks, snowmobiles, wheel loaders, recreational vehicles, and also in other areas that require toughness and good all-weather impact resistance.

Mobil Chemical Company

OLEFINS, HIGHER

Higher olefins are versatile chemical intermediates for a number of important industrial and consumer products, providing a better standard of living with low environmental impact (qv) in many commercial uses. These uses can be characterized by carbon number and by chemical structure.

The even-numbered carbon alpha olefins (α-olefins) from C_4 through C_{30} are especially useful. For example, the C_4, C_6, and C_8 olefins impart tear resistance and other desirable properties to linear low and high density polyethylene; the C_6, C_8, and C_{10} compounds offer special properties to plasticizers used in flexible poly (vinyl chloride). Linear C_{10} olefins and others provide premium value synthetic lubricants; linear C_{12}, C_{14}, and C_{16} olefins are used in household detergents and sanitizers. In addition, many carbon numbers from C_4 to C_{30+} are also utilized in specialty applications such as sizing agents to produce longer-lasting paper.

The C_6–C_{11} branched, odd and even, linear and internal olefins are used to produce improved flexible poly (vinyl chloride) plastics.

Physical Properties

For a listing of selected physical properties of linear alpha olefins, see Table 8.

Chemical Properties

The general reactivity of higher α-olefins is similar to that observed for the lower olefins. However, heavier α-olefins have low solubility in polar solvents such as water; consequently, in reaction systems requiring the addition of polar reagents, apparent reactivity and degree of conversion may be adversely affected. Reactions of α-olefins typically involve the carbon-carbon double bond and can be grouped into two classes: (1) electrophilic or free-radical additions; and (2) substitution reactions.

Commercial Olefin Reactions. Some of the more common transformations involving α-olefins in industrial processes include the oxo reaction (hydroformylation), oligomerization and polymerization, alkylation reactions, hydrobromination, sulfation and sulfonation, and oxidation.

Commercial α-Olefin Manufacture

Most linear α-olefins are produced from ethylene.

Ethylene oligomerization can be accomplished in the following commercial processes: (1) stoichiometric chain growth on aluminum alkyls followed by displacement (Albemarle); (2) catalytic chain growth on aluminum alkyls (Chevron-Gulf); (3) catalytic chain growth using a nickel ligand catalyst (Shell); and (4) catalytic chain growth using a modified zirconium catalyst (Idemitsu). In the Albemarle (formerly Ethyl) process, stoichiometric quantities of aluminum alkyls are used with subsequent displacement of α-olefins from the aluminum, followed by separation of the α-olefins from the aluminum alkyls. In the Chevron-Gulf process, catalytic amounts of aluminum alkyl are used. The operating temperatures

TABLE 8. PROPERTIES OF C_4 TO C_{20} LINEAR 1-OLEFINS

Compound	Mol wt	Density, g/mL 20°C	Viscosity, mm²/s(= cSt) 20°C	Viscosity, mm²/s(= cSt) 100°C	Free energy of formation, kJ/mol[a]

[a] To convert kJ/mol to kcal/mol, divide by 4.184.
[b] f = frozen.

are higher than those in the stoichiometric process, thus favoring displacement reactions after a finite amount of chain growth. In the Shell process, a three-phase system is employed, which gives a high linearity at higher carbon numbers. A nickel ligand catalyst dissolved in a solvent forms one liquid phase, the produced olefins form a second liquid phase, and the ethylene forms a third. Once formed, the olefins usually do not engage in further reactions because most of them are not in contact with the catalyst. Shell practices isomerization and disproportionation to produce a narrow range of internal linear olefins for feed to their oxo-alcohol unit. In the Idemitsu process, a zirconium oligomerization catalyst is modified by adding an aluminum alkyl and a Lewis base or an alcohol in a solvent. Variations in the catalyst mix thus offer a variety of carbon-number distributions, some of which resemble those in the catalytic processes, others approaching those in the stoichiometric process. Although operating at lower pressures than the other ethylene-based oligomerizations, the Idemitsu process still produces high quality linear α-olefins.

Vista has offered for license a stoichiometric process, which has not yet been commercialized, although the related primary alcohol process has been described.

One-Step Ziegler Process. Gulf Research and Development Corp. developed the one-step Ziegler process. This process is now owned by Chevron, which has two plants at Cedar Bayou, Texas. Plants based on licensing the technology are operated by Mitsubishi in Japan and at Neratovice in the Czech Republic. Chevron further improved the process around 1990 by reducing paraffin impurities.

Uses

The principal outlets for higher olefins are in the polymer, surfactant, and detergent industries. See also **Alcohols, Higher Aliphatic-Synthetic Processes**. Generally, higher olefins are seldom incorporated directly into a product as an ingredient; rather, they are processed through at least one chemical reaction step before appearing in a finished product.

Polymers. The manufacture of alcohols from higher olefins via the oxo process for use in plasticizers is a significant outlet for both linear α-olefins and branched olefins such as heptenes, nonenes, and dodecenes. These olefins are converted into alcohols containing one more carbon number than the original olefin. The alcohols then react with dibasic anhydrides or acids to form PVC plasticizers. The plasticizers produced from the linear olefins have superior volatility and cold-weather flexibility characteristics, making them an ideal product to use in flexible PVC for automobile interiors.

Detergents. The detergent industry consumes a large quantity of α-olefins through a variety of processes. Higher olefins used to produce detergent actives typically contain 10–16 carbon atoms because they have the desired hydrophobic and hydrophilic properties.

Lubricants. Lubricants represent a significant and growing outlet for higher olefins. Both basestocks and lube additives are produced from higher olefins by a variety of processes. See **Lubrication and Lubricants**.

Other Uses. A small but growing outlet for C_{16} and higher linear olefins is the production of alkenylsuccinic anhydride (ASA) for the paper industry. ASA is an effective alkaline sizing agent and competes with alkylketene dimer (AKD) in this application.

Additional uses for higher olefins include the production of epoxides for subsequent conversion into surface-active agents, alkylation of benzene to produce drag-flow reducers, alkylation of phenol to produce antioxidants, oligomerization to produce synthetic waxes (qv), and the production of linear mercaptans for use in agricultural chemicals and polymer stabilizers. Aluminum alkyls can be produced from α-olefins either by direct hydroalumination or by transalkylation. In addition, a number of heavy olefin streams and olefin or paraffin streams have been sulfated or sulfonated and used in the leather (qv) industry.

Health and Safety Factors

Toxicological Information. The toxicity of the higher olefins is considered to be virtually the same as that of the homologous paraffin compounds. Based on this analogy, the suggested maximum allowable concentration in air is 500 ppm. Animal toxicity studies for hexene, octene, decene, and dodecene have shown little or no toxic effect except under severe inhalation conditions.

Handling. The main hazard associated with these olefins, especially the lighter homologues, is their low flash point. Although no special precautions are necessary with regard to fire extinguishing, these olefin products should be stored and shipped under an inert atmosphere to maintain product purity.

OLEIC ACID. [CAS: 112-80-1]. $CH_3(CH_2)_7CH{:}CH(CH_2)_7 \cdot COOH$, formula weight 282.45, colorless liquid, mp 14°C, bp 286°C, sp gr 0.854. Sometimes referred to as red, oil, elaine oil, or octadecenoic acid, this compound is insoluble in H_2O, but miscible with alcohol or ether in all proportions. Oleic acid solidifies into colorless needle crystals.

Oleic acid differs from stearic acid chemically by possessing 33 instead of 35 hydrogen atoms in the radical $C_{17}H_{33} \cdot COOH$ (oleic acid), $C_{17}H_{35}COOH$ (stearic acid). It is possible to convert oleic acid and oleate esters into stearic acid and stearate esters by treatment with hydrogen gas in the presence of finely divided nickel as a catalyzer at 250°C under pressure as in the hydrogenation of oils and fats. Either by careful oxidation, or by addition of ozone and splitting, oleic acid yields products of 9 carbon atoms, thus leading to the conclusion that the double bond is in the center of the carbon chain. Oleic acid adds bromine or iodine in definite amounts to confirm the conclusion that one double bond is contained. Nitric acid converts oleic acid into elaidic acid, $C_{17}H_{33}COOH$, mp 51°C (oleic and elaidic acids are related, cis- and trans-, as maleic and fumaric acids).

Oleic acid may be obtained from glycerol trioleate, present in many liquid vegetable and animal nondrying oils, such as olive, cottonseed, lard, by hydrolysis. The crude oleic acid after separation of the water solution of glycerol is cooled to fractionally crystallize the stearic and palmitic acids, which are then separated by filtration, and fractional distillation under diminished pressure. Oleic acid reacts with lead oxide to form lead oleate, which is soluble in ether, whereas lead stearate or palmitate is insoluble. From lead oleate oleic acid may be obtained by treatment with H_2S (lead sulfide, insoluble solid, formed). With sodium oleate, a soap is formed. Most soaps are mixtures of sodium stearate, palmitate, and oleate.

Representative esters of oleic acid are: methyl oleate, $C_{17}H_{33}COOCH_3$, bp 190°C at 10 millimeters pressure; ethyl oleate, $C_{17}H_{33}COOC_2H_5$, bp 205°C at 10 millimeters pressure; glyceryl trioleate (triolein), $C_3H_5(COOC_{17}H_{33})_3$, bp 240°C at 18 millimeters pressure.

Oleic acid is used in the preparation of metallic oleates, such as aluminum oleate for thickening lubricating oils, for water-proofing materials, and for varnish dryers. The glyceryl ester of oleic acid is one of the constituents of many vegetable and animal oils and fats.

See also **Vegetable Oils (Edible)**.

OLEORESIN. Any of a number of mixtures of essential oils and resins characteristic of the tree or plant from which they are derived. Most types are semi-solid and tacky at room temperature, becoming soft and sticky at high temperatures. They have various distinctive odors. See also **Balsam**; **Oils, Essential**; and **Rosin**.

OLEUM. The Latin word for oil, applied to fuming sulfuric acid. (Sulfuric acid was originally called oil of vitriol.)

OLIVINE. The mineral olivine is a silicate of magnesium and ferrous iron corresponding to the formula $(Mg,Fe)_2(SiO)_4$. Olivine is the group name for the isomorphous series forsterite, Mg_2SiO_4, and fayalite, Fe_2SiO_4. The ratio of magnesium to iron varies considerably but the more common olivines are richer in Mg than in Fe. Olivine crystallizes in the orthorhombic system, usually in flattened prismatic forms, also granular and massive. It has a conchoidal fracture and is rather brittle; hardness, 6.5–7; specific gravity, 3.22–4.39; luster, vitreous; color, olive to gray-green; may be yellowish-brown from the oxidation of the iron. It is transparent to translucent. Olivine occurs both in igneous rocks as a primary mineral as well as in certain rocks of metamorphic origin. It has also been discovered in meteorites.

Olivine crystallizes from magmas that are rich in magnesia and low in silica and which form such rocks as gabbros, norites, peridotites and basalts. The metamorphism of impure dolomites or other sediments in which the magnesia content is high and silica low seems to produce olivine.

Transparent olivines of good color are sometimes used as a gem, often called *peridot*, the French word for olivine; it is also called chrysolite from the Greek meaning gold, and stone. Olivine occurs in the lavas of Vesuvius and Monte Somma and in the Eifel district of Germany. Gem material comes from St. John's Island in the Red Sea, Upper Burma, and from Minas Geraes, Brazil. In the United States olivine localities are Orange County, Vermont; Webster and Jackson counties, North Carolina. Arizona and New Mexico have also furnished some gem material.

See also **Peridotite**.

ONSAGER, LARS (1903–1976). A Norwegian chemist who won the Nobel prize for chemistry in 1968. He studied and wrote on the theory of electrolytic conduction and theory of dielectrics. He also worked with superfluids and crystal statistics and reciprocal relations in irreversible processes. After receiving his doctorate in Norway, he came to the U.S. and became a citizen. See also **Dielectric Theory**.

OPACITY. The optical density of material, usually a pigment; the opposite of transparency. A colorant or paint of high opacity is said to have a good hiding power or covering power, by which is meant its ability to conceal another tint or shade over which it is applied. See also **Paints and Coatings**.

OPAL. The mineral opal, long classified as an amorphous mineral gel, has been found by X-ray analysis to consist of a microcrystalline aggregate of crystallites of cristobalite. On this basis, opal may be considered as a variety of cristobalite bearing the same relationship to that mineral as chalcedony does to quartz. Opal is hydrous silica, $SiO_2 \cdot nH_2O$, with variable water content. It never occurs in crystal form; usually as irregular veins or masses, or as pseudomorphous replacements after wood or fossilized material such as bones and shells. Opaline silica occurs in many forms: geyserite from geyser deposits, siliceous sinter (fiorite) form siliceous waters of hot springs, and diatomite (diatomaceous earth) from siliceous shells of diatoms and comparable microscopic species. It has a conchoidal fracture; hardness 5.5–6.5; specific gravity 2.1–2.3; luster, vitreous or greasy to dull; color very variable, colorless, white, milky-blue, gray, red, yellow, green, brown, and black. Often a beautiful play of colors may be observed in the gem varieties. The color play in opals is attributed to three different mechanisms: finely divided pigmentation of foreign material; light interference by open-spaced grid of cristobalite crystallization; and reflected light. It may well be that two or all three causes may contribute to the color effect in any given opal specimen. Before a more complete understanding of opal color is established these phases seem to be of prime significance.

Besides the gem varieties, which show the delicate play of colors, there are other kinds of common opal, such as: the milk opal, a milky bluish to greenish kind; resin opal, which is honey-yellow with a resinous luster; wood opal, resulting from the replacement of the organic matter of wood by opal, and hyalite, a colorless glass-clear opal sometimes called Muller's Glass. Opal is deposited at relatively low temperatures and may occur in the fissures of almost any type of rock. Hungary, Australia, Honduras, Mexico and in the United States Nevada and Idaho, have been sources of gem opals. Hyalite comes from Czechoslovakia, Mexico, Japan and British Columbia. Other common varieties of opal are widespread in their occurrence. The word opal is derived from the Latin *opallus*.

OPTICAL BRIGHTENER. Also referred to as optical bleach; colorless dye; fluorescent brightener. A colorless fluorescent, organic compound that absorbs UV light and emits it as visible blue light. The blue light masks the undesirable yellow of textiles, paper, detergents, and plastics. Some examples are derivatives of 4,4′-diaminostilbene-2,2′-disulfonis acid, coumarin derivatives such as 4-methyl-7-diethylaminocoumarin.

OPTICAL CRYSTAL. A comparatively large crystal, either natural or synthetic, used for infrared and ultraviolet optics, piezoelectric effects, and shortwave radiation detection. Examples are sodium chloride, potassium iodide, silver chloride, calcium fluoride, and (for scintillation counters) such organic materials as anthracene, naphthalene, stilbene, and terphenyl.

OPTICAL EMISSION SPECTROCHEMICAL ANALYSIS. In this analytical technique, an optical device is used to analyze radiation from electrically excited sample atoms. The analyzing device provides monochromatic images whose intensities are measured and related to the concentration of the elements within the sample that produces the specific radiation measured. The technique is precise and rapid, and adaptable to solid, powder, or liquid samples.

More than seventy elements may be detected by standard procedures. Atomic gases, such as O, N, H, He, Ar, Ne, Kr, Xe, and Rn and the halogens are excluded. Nonmetallic substances, such as C, S, and Se, require vacuum path spectrometers for optimum detection and measurement. Analytical ranges may extend from fractional parts per million to about 40% concentration. Computer-controlled photoelectric optical emission spectrometers will output printed percent concentrations for 30 to 50 elements per sample in just a few minutes. This form of analytical instrumentation is used widely in production and quality control, as well as for research studies.

A schematic diagram of an optical emission spectrometer is given in Fig. 1. Various means are used to introduce the sample, whether solid or liquid, into an excitation stand where energy is imparted to it by some form of excitation source. The atoms composing the sample are excited and therefore emit their characteristic radiations, which are then separated by a grating in the spectrometer into line spectra. The light of selected element lines is isolated by slits and focused on phototubes. The sensitivity is adjusted by attenuating the high voltage from the high voltage supply. The intensity of a spectrum line can be correlated with the concentration of the element producing it. It is therefore necessary to measure intensities with very high precision.

Sample atoms may be excited by absorbing specific energies from an electric discharge. These atoms, raised to higher-than-usual energy levels, are unstable, and revert to their stable states by emitting the absorbed radiation according to the relation:

$$E_2 - E_1 = hv = hc/l \qquad (1)$$

where E = energy, eV
h = Planck's constant (6.624×10^{-27} erg-second)
v = frequency, Hz
$\lambda = c/v$ = wavelength (in Å $= 10^{-8}$ centimeter)
c = velocity of light (3×10^{10} centimeters/second).

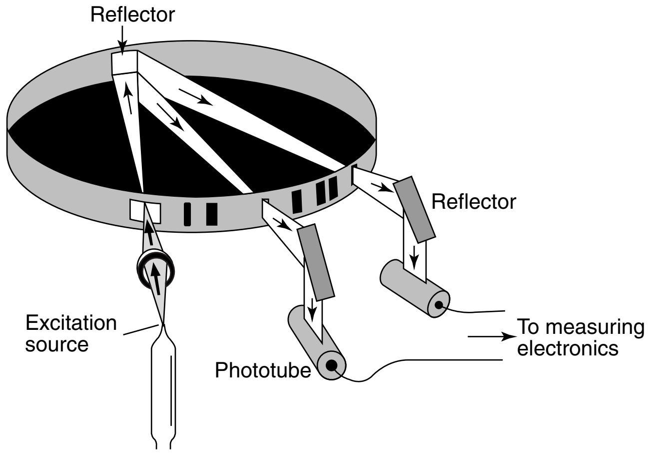

Fig. 1. Operating principle of optical emission spectrometer

Atomic transitions may be expressed in terms of wavelength, and qualitative analysis may be performed by wavelength determination and identification.

The commonly used dispersive device is the diffraction grating, which produces spectra by light interference according to the relation:

$$N\lambda = d(\sin\alpha \pm \sin B) \tag{2}$$

where N = an integer
λ = wavelength
d = grating constant (width of single groove)
α = angle of incident light
B = angle of diffracted light.

For constant a and the same sin B, integer values of N produce spectra of $\frac{1}{2}\lambda$, $\frac{1}{3}\lambda$, etc., called *spectral orders*.

A grating ruled on a spherical surface combines the properties of the diffraction grating with the focusing ability of the optical surface. Such a device, with radius of curvature R, focuses spectra as images of the entrance (primary) slit on the circumference of a circle of diameter R, when the entrance slit is also located on the circumference of the circle.z

The usual measure of how well a grating separates individual wavelengths is given by the reciprocal linear dispersion, in angstroms per millimeter, as follows:

$$\text{Å/mm} = \frac{d\cos B}{Nf} \tag{3}$$

Thus, dispersion is governed by the fineness of the grating ruling d and the focal length f of the focusing element.

The concentration C of an irradiating element is related to the intensity I of the emitted spectral line, according to the relationship:

$$I = kC^n \tag{4}$$

where k and n depend on the excitation conditions employed. Accuracy and precision are improved by use of an internal standard reference line of another element of constant concentration. The relationship becomes:

$$\frac{I_x}{I_r} = k_1 C_x^{n_1} \tag{5}$$

where I_x and I_r are the intensities of spectral lines emitted by elements x and r; C_x is the concentration of element x; and k_1 and n_1 are constants depending on the line pair and on the excitation conditions. The relative intensities of lines having different excitation energies depend on the temperature of the spark discharge column.

The source unit must vaporize and excite a portion of the sample, which is generally used as one of the electrodes between which the electric discharge takes place. No single excitation source is ideally suited for all applications of emission spectrochemistry. Trace impurities in metals, alloying constituents in high concentrations, biological substances, ceramics, slags, oils, nonconductors, refractories—all may require different excitation techniques and sample preparation procedures. Table 1 summarizes the important characteristics of the commonly used spectrochemical source units.

Photographic radiation detection may be used, but film emulsion response is not linear. Film calibrations are required to relate measured densities with the intensities producing these densities before *intensity* versus *concentration* working curves can be formulated. Although quite general in application at one time, the photographic technique is slower than photoelectric radiation detection wherein each beam whose intensity is to be measured is directed onto a photomultiplier detector through a suitably sized exit (secondary) slit. The output of the detectors is transmitted to the measuring console, where it is translated into the readout format of the system.

Many dramatic changes in the development of readout electronics have occurred over the last 15 to 20 years. Modern systems use integrated circuit and digital computing devices. The engineer is no longer required to design complex circuitry to perform the basic tasks of control. Software now becomes the tool by which timing, sequencing, and logic control are accomplished.

Generally, spectrometer systems fall into two major functional categories—system control and data handling. The digital controller with its controlling and computing capabilities is ideal for handling both tasks with a minimum of effort required by the circuit design engineer.

Particularly during the last decades, several new analytic techniques have been developed that, when appropriate, have a tendency to displace former traditional methodologies.

OPTICAL FIBER SYSTEMS. Optical fibers are hair-thin structures (usually cylindrical in shape) capable of transmitting light signals with extremely low signal loss and at very high digital pulse rates. Fibers are available in a variety of sizes and material compositions and with a wide range of optical performance. Although commercially available fibers are solid structures, they function as "light pipes" that guide rays of light and are therefore sometimes called *lightguides*. When used to connect a light

TABLE 1. SPECTROCHEMICAL EXCITATION SOURCE UNITS

Type	Voltage	Current, A	Characteristics
Dc arc	220	3–30	Most sensitive, least reproducible, quantitative analysis; trace element quantitative analysis.
Ac arc	2500 5000	5 2–5	Good sensitivity, more reproducible, best use for self-electrode metal analysis.
High-voltage spark interrupted auxiliary gap	15–40,000	3–20 RF	Least sensitive, most precise, ±1% or better. Excites higher energy lines. Parameter selection allows variations between arc-like and spark-like in spectral excitation.
Multisource	1000	Peak discharge currents from 5 to in excess of 500 A at time constants ranging from 8 to less than 1 ms.	Sensitive and precise. Parameter selection allows wide variety of controlled unidirectional and oscillatory charges variable from arc-like to spark-like in spectral excitation.

source to a light receiver (photodetector) to form a communication system, the fiber carries *photons* instead of the *electrons* used in traditional metal-conductor communication links. Although a laser light source containing a narrow range of optical wavelengths is preferred for carrying signals the farthest and fastest, light-emitting diodes (LEDs) are also used, especially for short distance communication links within buildings. Thus, the three key elements of a lightwave communication system are the light source, the optical fiber, and the photodetector.

Fiber-Optic Systems in Perspective

As early as 1841, D. Colladon demonstrated light guiding by a jet of water, and in the following year J. Babinet showed the phenomenon in a bent glass rod. However, these experiments did not receive wide publicity until John Tyndall duplicated and popularized the same effect in 1854. In 1880, shortly after the telephone was invented, Alexander Graham Bell proposed telecommunications using lightwaves. See Fig. 1. Patented as the "Photophone," the concept depended on the free propagation of light through the atmosphere. Of course, a century ago Bell had no powerful steady light source such as the laser, and even on very clear days atmospheric disturbances severely limited the practical distance over which undisturbed light could travel.

These experiments were followed by the development of light pipes to illuminate homes (W. Wheeler), bent glass rods to illuminate body cavities for dentistry and surgery (Roth and Reuss), and surgical lamps (D. Smith).

As early as 1910, the possibility of guiding electromagnetic waves by internal reflection within long cylinders of dielectric material was investigated on a theoretical basis (D. Hondros and P. Debye). The first quantitative experimental investigations took place in 1920. Although some interest was shown in conducting light by glass rods, a serious rekindling of interest in lightwave communication had to await the first laboratory demonstration of a laser in 1960 (T.H. Maiman, Hughes Aircraft Company). Earnest efforts to devise shielded waveguide structures were made shortly thereafter. Because the glasses available in the early 1960s possessed prohibitively large absorption and scattering losses, some early experimental lightguides consisted of gas-filled underground conduits (some 20 centimeters (7.87 inches) in diameter) that incorporated lenses at various intervals to refocus the light and change its direction when required. These systems were unsatisfactory on several counts: bulk, expense, and the extreme sensitivity to temperature and alignment of the components.

In the mid-1960s, Charles K. Kao of STL Laboratories, determined that the fundamental limit on glass transparency was less than 20 decibels (dB) per kilometer (km), which is low enough to make glass fibers practical for communications. (A loss of 20 dB/km means that the optical power after 1 km is 1% of the amount at the beginning.) This spurred investigators to explore methods for making purer glass. In 1970, fibers with attenuation less than 20 dB/km were made and demonstrated in the laboratory (Maurer, Keck and Schultz, Corning), and this was reduced to 4 dB/km by 1972.

Combining these fibers with emerging semiconductor lasers with lifetimes reaching 1000 hours (Bell Labs, 1973) and photodetectors, enabled lightwave communications to become practical in the mid-1970s. The first nonexperimental fiber-optic link became operational in Dorset, England (1975) to service a police station. In early 1976, Bell Labs started tests at 45 million bits per second on multimode fibers installed in Norcross, Georgia. Fibers continued to improve as their attenuation decreased to 0.47 dB/km (M. Horiguchi).

In 1980, video signals were carried by optical fibers $2\frac{1}{2}$ miles (4 kilometers) for the Winter Olympic Games in Lake Placid, New York. The first long-haul intercity installations (AT&T, Washington-New York; New York-Boston) were made in 1983. After that, the capacity of fiber optic transmission systems increased exponentially. Despite this progress, the fundamental limits predicted by the physics of photonics materials, devices, and systems have not yet been approached (Kogelnik). The challenge of future research and development continues to be a fuller exploitation of the ultimate capacity of optical fibers.

Fig. 2 shows a schematic history of the development of optical communication systems.

Seldom does a new technology have as many practical advantages as found in optical fiber systems and become available in only a decade of concentrated research and development. As solid state physics and semiconductors created the electronics industry, fiber-optic systems have revolutionized the telecommunications industry.

Fiber optic systems are more economical than their alternatives—copper wire, radio relay, and satellite. The regeneration of signals sent on copper cables is necessitated at several mile intervals, whereas the distance on optical fibers can be over a thousand miles by using optical amplifiers approximately every 50 miles.

The first fiber optic systems used light in the 850 to 875 nanometer (nm) wavelength region (the so-called "first window"), and were followed with systems operating near 1300 nm (the "second window") where fiber loss is smaller, and then near 1550 nm (the "third window") where fiber loss is even smaller. In the year 2000, fibers were carrying digital signals at 10 billion bits per second on one or more (as many as 40) wavelengths in the 1550 nm window.

Because optical fibers are nonconducting, fiber optic systems provide excellent electrical isolation and immunity from electrical interference. Signal losses are much lower in fibers (as low as 0.20 dB/km) compared to other guided transmission media, such as twisted copper pairs, coaxial cable, and metallic waveguides. In addition, the bandwidth or information carrying capacity of fibers is far greater. When one or more optical fibers are packaged into cables, the cables are smaller and more flexible than their metallic counterparts.

In 1984, British Telecom laid the first submarine fiber optic cable to carry regular traffic, to the Isle of Wight. In 1988, service began on the first transatlantic fiber-optic cable (TAT-8) from Tuckerton, New Jersey to France and England. Similar undersea communication links between Japan and Guam and other Pacific locations began in 1989. With the development of optical fiber technology proceeding at such a rapid rate, decisions as to whether or not to delay undersea cables for further advancements sometimes are difficult to make.

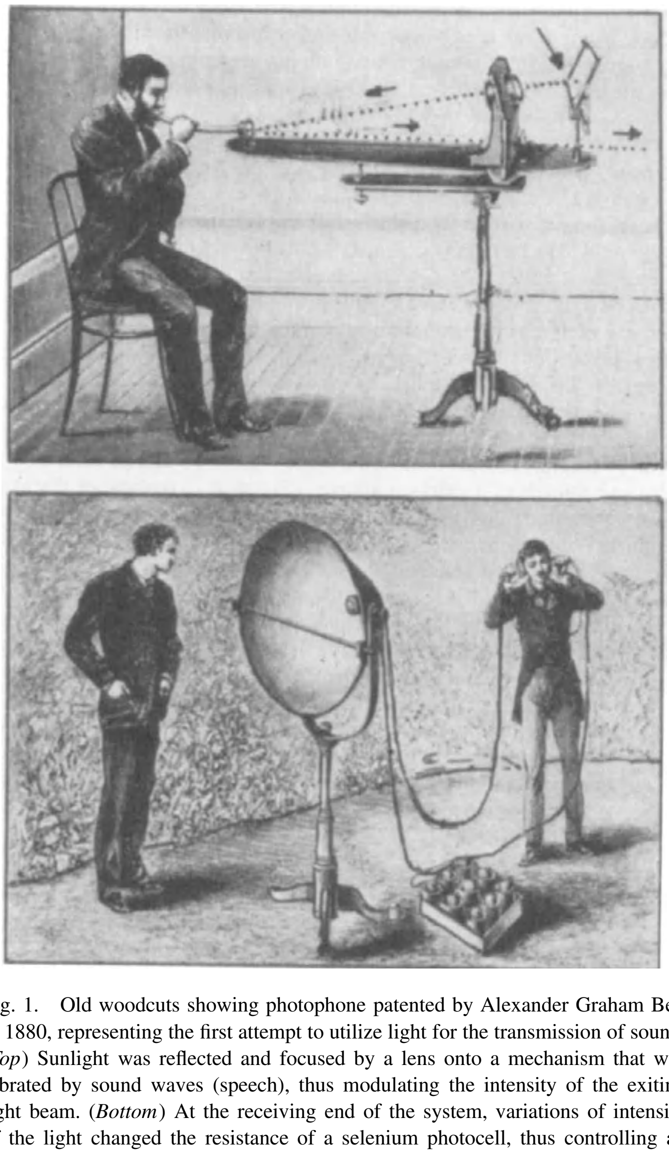

Fig. 1. Old woodcuts showing photophone patented by Alexander Graham Bell in 1880, representing the first attempt to utilize light for the transmission of sound. (*Top*) Sunlight was reflected and focused by a lens onto a mechanism that was vibrated by sound waves (speech), thus modulating the intensity of the exiting light beam. (*Bottom*) At the receiving end of the system, variations of intensity of the light changed the resistance of a selenium photocell, thus controlling an electric current input to the receiving telephone

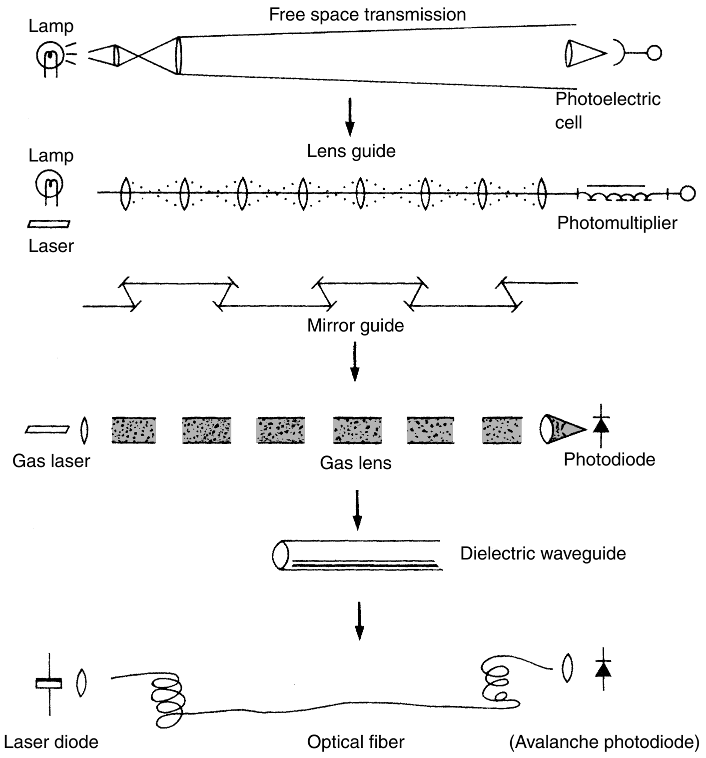

Fig. 2. Schematic representation of the development of optical communication systems. (*Adapted from Suematsu and Iga*)

Earlier "fantastic" claims that 24,000 simultaneous telephone calls on a single pair of fibers at rates of up to 1.7 billion bits per second could be made, that full-length motion pictures such as *Gone with the Wind* could be fed to a home memory unit in one second, or that major symphonies, such as Beethoven's Fifth, could be transmitted in less than 1/50 of a second have already been surpassed. For example, here is listing of some "hero" experiments illustrating an optical fiber's capability as of the year 2000.

- Using 160 wavelengths of light with each wavelength carrying 40 billion bits per second of information, NEC researchers transmitted 6.4 trillion bits of information per second over a special fiber 186 kilometers long.
- Using a single wavelength of light on an experimental TrueWave® fiber, Bell Labs scientists transmitted 320 billion bits of information per second over a distance of 200 kilometers.
- Bell Labs demonstrated 3.28 trillion bits per second over a 300 km of experimental TrueWave fiber. This experiment used 82 wavelengths of light with each operating at 40 billion bits per second.

Types of Optical Fibers

Optical telecommunications fibers fall into two main categories: *multimode fiber*, and *single-mode* (also called *monomode*) *fiber*. Multimode fibers receive their name because they can propagate many (hundreds) of light modes, which can be thought of as paths taken by the light as it travels in the fiber. Single-mode fibers, on the other hand, propagate only one mode. Multimode and single-mode fibers can be further divided into subset categories. For example, multimode fibers can be either *step-index* or *graded-index*, and single-mode fibers can be *dispersion-unshifted, dispersion-shifted,* or*nonzero-dispersion shifted.* Each of these, in turn, can be further differentiated. For example, two types of graded-index multimode fibers have either 50 micron or 62.5 micron core diameters. Two types of dispersion-unshifted fiber have either depressed clad or matched clad refractive index profiles. Or they may have a typical high loss at the "water peak" wavelength near 1385 nm or low loss at this wavelength, such as with Lucent's AllWave™ fiber.

Single-mode fibers have many advantages over multimode fibers. See Fig. 3. Compared to the 50 or 62.5 micron core diameter of typical graded-index multimode fibers, some single-mode fibers have a core diameter near 8 micrometers. Single-mode fibers also have a core-cladding refractive index difference of a few tenths of a percent compared to 1 or 2% for multimode fibers. Their smaller core diameter and refractive index difference allow single-mode fibers to propagate light in only one clearly defined path (or mode). Because this reduces multipath effects that spread the arrival times of a short input pulse, single-mode fibers have high bandwidth, meaning that they can carry signals at higher bit rates than multimode fibers.

Various types of optical fibers are used for specific applications. For example, multimode fibers are used primarily in enterprise systems: buildings, offices, campuses. Special single-mode transmission fibers exist for submarine applications, and for metropolitan and long-haul terrestrial applications. And in addition to these transmission fibers, there are various "specialty" fibers for performing dispersion compensation (dispersion compensating fiber), optical amplification (erbium-doped fiber), and other special functions.

Characteristics Affecting Optical Fiber Performance

Phase Index of Refraction. Phase index of refraction is the ratio of the phase velocity of light in a vacuum to its velocity in another medium, such as glass. The value of this parameter depends on wavelength, and the composition, temperature and pressure of the medium. The higher the refractive index of a material, the lower the phase velocity of light in the material, and the more a light ray is bent as it enters the material from air.

Numerical Aperture (NA). Numerical aperture describes an angle just outside the a fiber's end face that determines the largest angle that a light ray can have to the fiber axis and still be captured and propagate within the fiber. The formula from Snell's law governing the numerical aperture number of a fiber is

$$NA = \sqrt{n_1^2 - n_2^2}$$

where n_1 and n_2 are the phase refractive indices of the fiber's core and cladding, respectively.

Most optical fibers have numerical apertures between 0.15 and 0.4, and these correspond to light acceptance half-angles of about 8 and 23 degrees. Typically, fibers having high *NAs* exhibit greater loss and lower bandwidth.

Light Loss or Attenuation through a Fiber. The amount of light at the output of a fiber is smaller than at the input. This attenuation is expressed in decibels per kilometer (dB/km), which is a relative power unit according to the formula

$$\alpha(dB) = -10 \log \frac{P_o}{P_i}$$

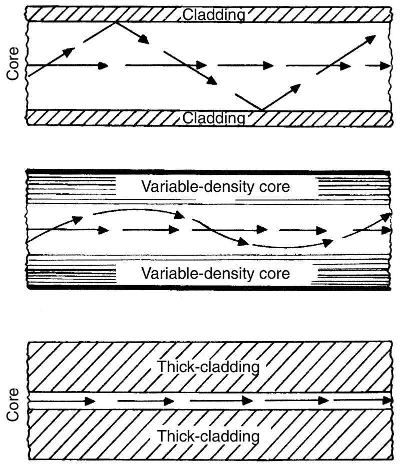

Fig. 3. Fundamental classes of optical fibers: (**a**) Step-index fiber made up of glasses of two different densities, the core and the cladding. Lightwaves travel in a zig-zag fashion down the core, bouncing off one side and then the other side of the core-cladding interface; (**b**) Graded-index fiber where the glass in the core varies in density—hence the light travels in a smooth, curving path, causing less distortion of transmitted information; and (**c**) single- or monomode fiber where the core is very small relative to the wavelength of the transmitted light causing the light to move down the fiber in a straight line—hence resulting in very low distortion. In modern designs, the distortion has been reduced to almost the theoretical low limit

where P_o/P_i is the ratio of optical power at the output to the optical power launched into the fiber at the input. This ratio is smaller than 1, and the logarithm of a number smaller than 1 is negative. Consequently, the minus sign in the equation makes the attenuation value a positive number. A comparison of the ratio of output power to input power in percent to the quantity in dB is as follows:

$$80\% \text{ transmission} = \text{a loss of}: 1 \text{ dB}$$

$$50\% \text{ transmission} = \text{a loss of } 3 \text{ dB}$$

$$10\% \text{ transmission} = \text{a loss of}: 10 \text{ dB}$$

$$1\% \text{ transmission} = \text{a loss of}: 20 \text{ dB}$$

Bandwidth. Bandwidth is a measure of information-carrying capacity. An optical fiber's bandwidth can be expressed either in the time domain as pulse dispersion in nanoseconds per kilometer (ns/km), or in the frequency domain as frequency passband in megaHertz-kilometers (MHz-km). Light pulses spread or broaden as they pass through a fiber depending on the material used and its design. A fiber's bandwidth limits the rate at which optical pulses can be transmitted and decoded without error at the terminal end of the optical fiber. In general, optical fibers with small core diameter and low numerical aperture have higher bandwidth and lower loss.

Glass Processing

Depending on a fiber's application, a number of glass compositions may be used. However, for low-loss applications, the options become increasingly limited. Multicomponent glasses containing a number of oxides are not suited to making very low-loss fibers. Multicomponent glasses are prepared by essentially standard optical melting procedures, but with special attention given to details for increasing transmission and controlling defects from later fiber drawing steps. In contrast, low-loss fibers are usually made from pure fused silica doped with minor constituents. These require special manufacturing techniques.

Several methods have been used for manufacturing low-loss optical fibers, including the rod-in-tube method, the double-crucible method, and the more recent and widely used chemical vapor deposition (CVD) methods. CVD methods can be divided into two main categories: inside processes and outside processes. With the inside processes, such as modified chemical vapor deposition (MCVD) and plasma-activated chemical vapor deposition (PCVD), the chemical reactions that form the glass occur inside a glass starting tube (sometimes called a "substrate" tube). This starting tube serves as a containment vessel during deposition and eventually becomes part of the fiber. With outside processes, such as outside vapor deposition (OVD) and vapor axial deposition (VAD), vapor deposition occurs on the outside surface of a starting rod, and the reaction that forms the glass occurs near a burner.

With all CVD methods, silica and other glass-forming oxides and dopants are deposited at high temperatures on an object. In the inside processes, the object is collapsed and becomes part of the fiber, whereas in the outside processes, the object is removed and the resultant *soot blank* is dried and sintered. This produces a thick cylindrical *preform*. A long, thin fiber can then be drawn from this preform at high temperature, or the preform can first be made larger by either depositing more glass on its outer surface or by placing the preform in a glass overclad tube.

There are numerous variations on these processes and these are considered proprietary by most manufacturers. See Fig. 4.

Fig. 4. Experimental optical fiber designs are tested by creating glass preforms, heating them in a special furnace located above the research fiber drawing tower (as shown) and drawing the fiber from the preform onto a collection drum shown in the foreground. The fiber is then used in tests conducted with light generators (lasers and LEDs) and photodetectors. The single-mode fiber is rated for high-capacity transmission, while lower-capacity multimode fibers are well matched to various economical sources and detectors. (*AT&T Bell Laboratories*)

Improvements in Lasers

Just a few years ago, the so-called C^3 laser (cleaved-coupled-cavity) appeared, wherein the alignment of two conventional semiconductor lasers yields a beam of exceptional purity that enables communication systems to send signals at rates as great as billions of bits, or binary digits per second. Just as recently as the late 1980s, commercial lightwave systems were limited to somewhat less than 2 million bits per second, but nevertheless a rate that permits the transmission of 24,000 simultaneous telephone calls on a single pair of fibers.

The cleaved-coupled-cavity laser developed by W.T. Tsang and colleagues (AT&T Bell Laboratories) was designed especially for use in fiber optics telecommunication systems and probably as much as the optical fibers themselves will contribute to the gross claims, as mentioned earlier in the article, made for faster, higher-capacity optical links.

Traditionally, semiconductor lasers have been used in optical communication systems. They are about the size of a grain of salt and produce pulses of light from pulses of electric current. Their electrical requirements are minimal (generally a few mA at 1 or 2 V). These lasers can generate infrared (IR) light where optical fibers are most nearly transparent. Unlike a gas laser, for example, the semiconductor laser is mechanically stable and reliable.

For comparison, a simple semiconductor laser is illustrated and briefly described in Figs. 5 and 6. A buried-heterostructure laser is shown in Fig. 7. The alignment of two lasers to form the C^3 laser is shown in Fig. 8. The turnability of a C^3 laser is illustrated in Fig. 9.

As observed in Tsang, the C^3 laser configuration offers at least three advantages in optical communication systems: (1) The exceedingly monochromatic output of the laser eliminates the problem of chromatic dispersion in optical fibers. This facilitates the transmission of digital information in a single-mode fiber at a wavelength of 1.55 micrometers, that is, the wavelength at which a silica fiber is most nearly transparent to electromagnetic radiation. In a test, using the C^3 laser, scientists at AT&T Bell Laboratories transmitted digital information in an optical fiber more than 120 kilometers long at a rate of one gigabit (10^9 bits) per second without reamplification along the path. The frequency of error was less than two bits in 10^{10}. (2) By coupling several C^3 lasers, each tuned to a different wavelength, to a single optical fiber, wavelength-division multiplexing can make it possible to carry several independent messages on the fiber. (3) As proposed by Tsang, at rates on the order of a billion

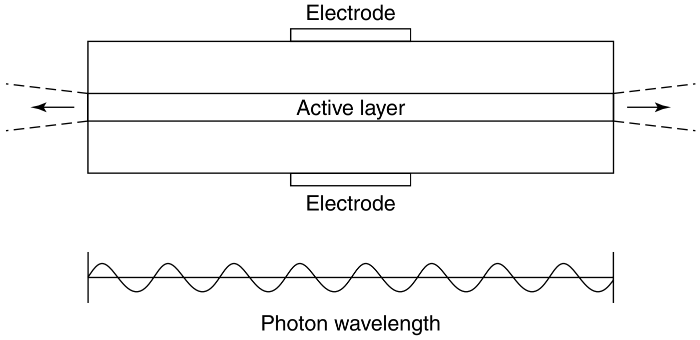

Fig. 5. A simple semiconductor laser. It is a p–n junction in a semiconductor crystal the end faces of which are flat and perfectly parallel. Thus, the faces form a pair of semireflecting mirrors that bounce photons back and forth through the *active layer* of the crystal. Current injection causes photons to arise by spontaneous emission. Those photons traversing the semiconductor cause an avalanche of *stimulated* emission. Reflections at the mirrors are self-reinforcing provided that the wavelength of the photon fits evenly into the *length* of the laser. See also Fig. 6

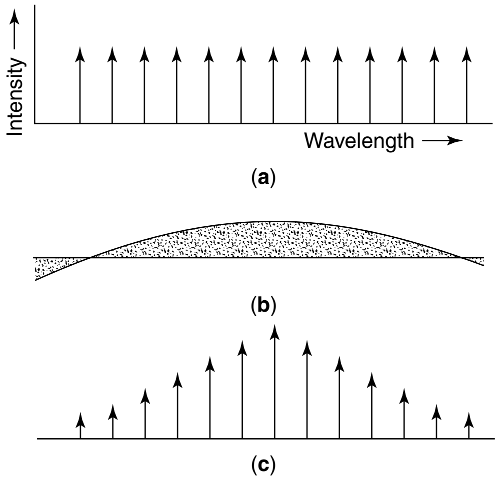

Fig. 6. Simple semiconductor laser energy diagram. This schematic diagram illustrates why the output beam of the laser jumps randomly among several wavelengths. Fundamentally, the laser resonates at the *infinite number* of wavelengths that fit evenly into the length of the laser as indicated in (**a**). On the other hand, the p–n junction produces photons in only a narrow range of wavelengths—the *gain profile*, as indicated in (**b**). Therefore, the beam emitted by the laser includes only the resonant wavelengths positioned within the profile, as shown in (**c**). (*After Tsang*)

switchings per second, it is possible to shunt the output wavelength of a C^3 laser among as many as 15 modes spaced about 2 nm apart. Thus, the single-wavelength transmission of data, with high-power and low-power pulses representing the binary digits 1 and 0, respectively, yields to multiple-wavelength transmission.

In the future, it is expected that the C^3 laser may become part of optical logic circuitry. This will be feasible because of the laser's tunability and from the electrical isolation of the two half-lasers. See Fig. 10.

One problem of the past results from the fact that much energy is wasted at the beginning of an optical link. H.M. Presby (Bell Laboratories) asserts in connection with the loss of about half the laser light, "It seemed like an awful waste, like throwing away half a tank of gas." Through redesigning the tips of optical fibers into carefully sculpted microlenses, a surprising amount of light was captured. Optical problems could be solved by designing an aspheric, hyperbolic shape. In a process that is akin to shaping a piece of metal in a lathe, the researchers rotate silicon fibers in and around a carbon dioxide laser beam.

Researchers also have been investigating microlasers. These lasers range from 1 to 5 microns in diameter and are "carved" from a multilayered

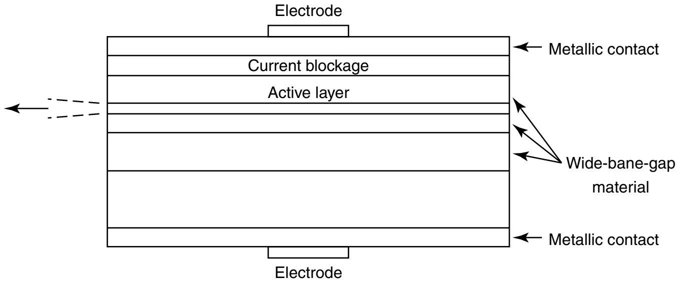

Fig. 7. In an effort to improve the performance of the basic semiconductor laser, researchers developed the buried-heterostructure laser. In this configuration, the p–n junction is reduced to a "tube" that runs the length of the semiconductor crystal. This tube is surrounded by layers of semiconductor whose wide band gap raises the electrical barrier confining charge carriers within the tube. The wide-band-gap material also confines the photons produced at the junction. The laser beam spreads because of diffraction occurring where the beam emerges from the face of the device

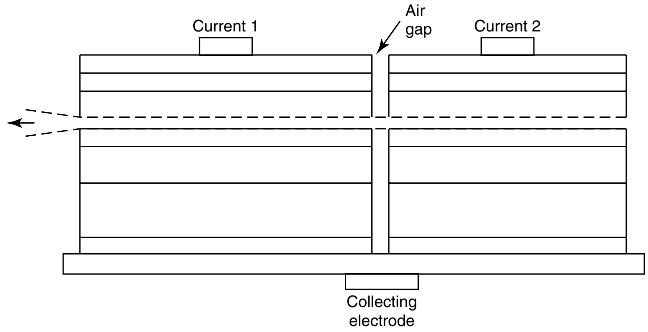

Fig. 8. The C^3 laser consisting of two aligned lasers. The half-lasers have different lengths and thus their resonant wavelengths are differently spaced. Only a few of them match. The mismatches are suppressed. Among the matches, only one is near the peak gain. Thus, the C^3 laser beam is made up almost exclusively of that wavelength. Tests have shown that the probability of the beam "jumping" to another wavelength is less than 1 in 10 billion beam samplings

semiconductor substrate. It is estimated that a million such lasers occupy but a square centimeter on a chip. See Fig. 11.

Light-Emitting Diode for Telecommunications

In telecommunications, a light-emitting diode (LED) operates similarly to a laser in that it sends pulses of light signals representing speech or data through an optical fiber. Lasers are powerful and are preferred for sending light signals over great distances, such as between cities. Lasers require a measurable amount of power and require temperature regulation. An LED system developed by GTE Laboratories (LOC-LED System) operates on less than one-tenth the power required for a typical laser transmitter and requires no temperature control or means to adjust light signals, thus greatly simplifying the circuitry. The LOC-LED system generates sufficient optical power to fulfill most needs of fiber optic systems over a range of about 6 to 8 miles (9.7–12.9 km), which is a typical span for a local service loop. The system has been tested at temperatures from −4 to +185°F (−20 to +85°C). No prior commercially available LED device generates as much power while using so little energy as the LOC-LED.

Erbium-doped Fibers for Amplification

The use of repeaters to amplify signals dates back to the earliest days of telegraphy and telecommunications. Although optical fibers offered numerous improvements over copper wire communications, the need to use repeaters was not overcome. Since the serious introduction of optical fibers in the mid-1980s, long-range research has been directed toward maintaining signals over long distances and minimizing the requirement for repeater stations. As aptly pointed out by E. Corcoran, "Repeaters have become as endemic—and as constraining—on the telecommunications freeway as tollbooths on a turnpike." Lightwaves, of course, are capable of many frequencies, but electronic repeaters can handle only one frequency at a

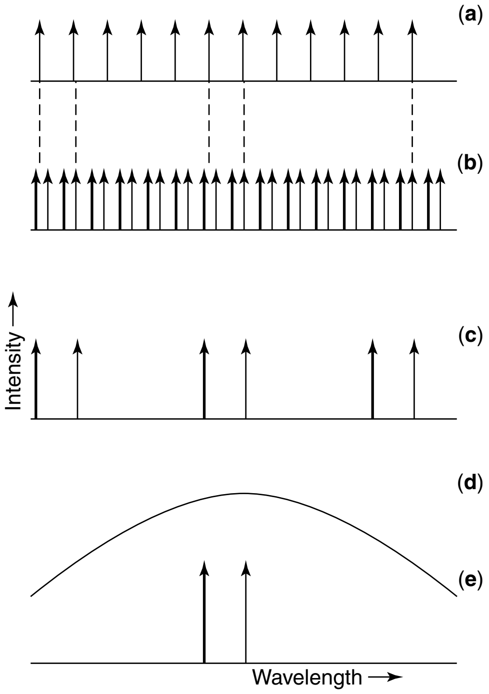

Fig. 9. The energy diagram of the C^3 laser illustrates its tunability by current injection. As explained by Tsang, the current to one of the half-lasers elevates it above its *lasing* threshold. Thus, its resonant modes are fixed as indicated in (**a**). The other (second) half-laser is maintained below its lasing threshold. Thus, it still has resonant modes, as shown by the thin black lines in (**b**). But, some of the resonant modes [thin black lines in (**c**)] match the modes of the light-emitting half-laser. The match at the peak of the laser's gain profile (**d**) determines the wavelength of the C^3 laser's output (**e**). Now the current applied to the second half-laser is changed. The change alters its resonant modes [heavy black lines in (**b**)]. Thus, a new set of matching resonances is established [heavy black lines in (**c**)] and with it a new output wavelength [heavy black line in (**e**)]. (*After Tsang*)

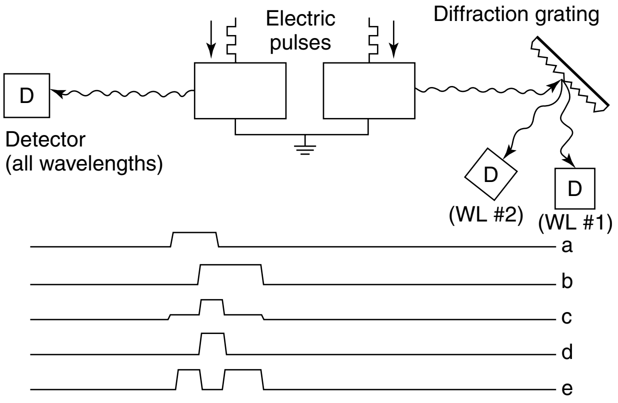

Fig. 10. Use of the C^3 laser in an optical logic circuit. The laser's tunability and the electrical isolation of the two half-lasers make this application possible. Visualize the application of independent trains of electric pulses applied to the half-lasers, as indicated in (**a**) and (**b**). Simultaneous pulses cause the emission of light at wavelength #1. A pulse to one of the half-lasers causes the emission of light at wavelength #2. Detection of light at both wavelengths is equivalent to the logic operation OR (**c**). Detection of wavelength #1 is equivalent to the logic operation AND (**d**). Detection of wavelength #2 is equivalent to the logic operation EXCLUSIVE OR (**e**). (*After Tsang*)

time and thus decrease data throughput through a network. Elias Snitzer (Rutgers University) found that erbium-doped glass fibers could be used to provide optical amplification and thereby increase the number of light frequencies that can be amplified. When pumped with a light source, more erbium ions in these fibers are forced to a higher energy level (known as *population inversion*) than remain at lower levels. As a transmission signal carrying information enters the erbium fiber, some of the excited erbium ions give up their energy to the information signal—thereby amplifying them. The amplification is purely optical. The information signal does not first need to be converted to an electrical signal.

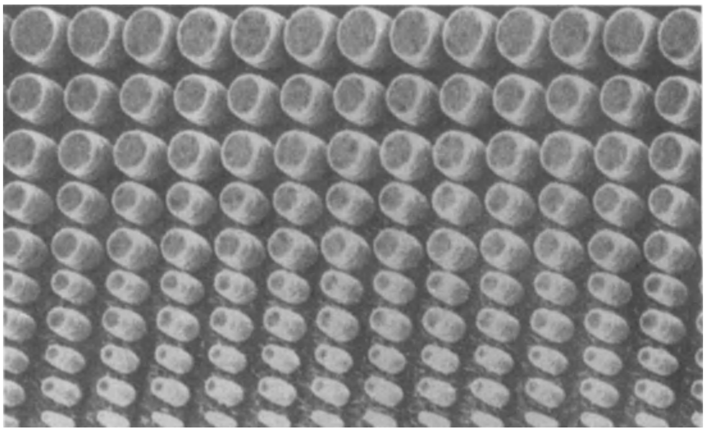

Fig. 11. An array of microscopic lasers sculpted from a multi-layered semiconductor substrate. The lasers range from 1 to 5 microns in diameter, and a million of them occupy a square centimeter on a chip. (*AT&T Bell Laboratories*)

Researchers (AT&T Bell Laboratories) have demonstrated that erbium-doped devices (Fig. 12) can "boost signals traveling at any bit rate, transmission networks can be upgraded by simply changing the transmitters (and receivers). Virtually any video data or voice signal can be dumpled 'like marbles' into one end of the 'transparent light pipes' and roll out intact at the other end."

Earlier research on the erbium-doped principle had been conducted by University of Southampton, U.K., and Japanese communications engineers. Currently, scientists envision that the new devices will be applied first to cable television and transoceanic telecommunications network. As pointed out by E. Corcoran, "Fiber amplifiers could enable a video broadcaster to lay one cable from the transmission center to a neighborhood, then split up the signal, amplify it and route the fibers directly into the homes." The Japanese already are at work on an all-optical network under the Pacific Ocean to be operable by 1996. For local communications loops, L.J. Andrews (GTE) observes, "Cost is the critical issue." John Mellis (BTD, Ipswich, U.K.) says, "The challenges are all engineering now... Because optical amplifiers are being seriously considered in transoceanic submarine systems, they will certainly happen, if not in this decade then the next." Another professional in the field observes, "There's absolutely no doubt that this is the thing to work on. It's changed how we think about fiber-optic systems."

There are three different locations in which optical amplifiers can be located in a network. See Fig. 13. Used immediately after a laser, booster amplifiers deliver output powers higher than 100 mW, and can therefore increase the output power of a laser by more than an order of magnitude. Preamplifiers increase the strength of an optical signal before it enters a conventional receiver.

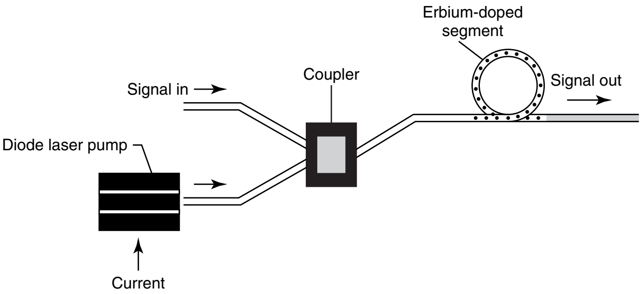

Fig. 12. Erbium-doped light amplifier. Light from a diode laser pump excites erbium ions in segment of an optical fiber. These ions then emit light and thus boost a passing optical signal. (*After AT&T Bell Laboratories*)

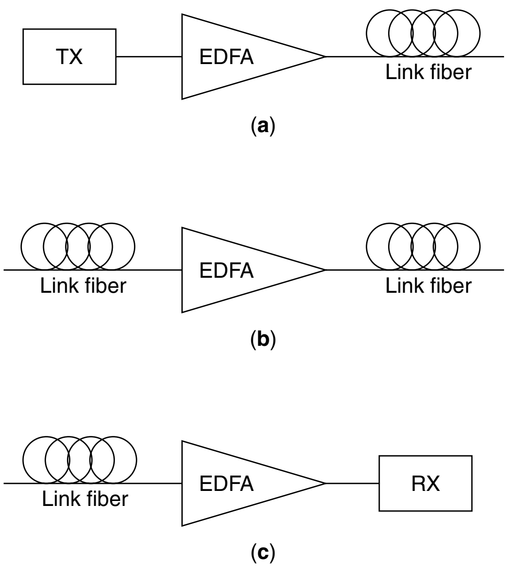

Fig. 13. Three types of optical amplifier as distinguished by their location in a network: (**a**) Postamplifier (booster), (**b**) in-line amplifier, and (**c**) optical preamplifier. (*From J. AugÉ*)

Solitons. A *soliton* may be defined as a wave that retains its shape indefinitely. Bright-pulse solitons are pulses of light that travel over long distances without dispersing or broadening. Each of the wavelengths that comprise an *ordinary* light pulse tend to travel at a slightly different speed. D.R. Grischkowsky (IBM Thomas J. Watson Research Center) observes that a pulse can be prevented from dispersing by taking advantage of an optical property of glass fibers—that is, proportional to the received light intensity. This output current is AC coupled to the load to deliver the RF signal.

Optical Fibers in Aircraft

Traditionally, communications and control in modern aircraft have been accomplished by as much as 240 km (in a typical wide-body jet) of electric wires, adding significantly to the weight of the craft. Even with insulation and shielding, such wire connections constantly are subject to electromagnetic interference (EMI), not to mention increased vulnerability to lightning during storm conditions and other sources of electromagnetic radiation of particular note to military aircraft. The potential of an "electronic blizzard" over a war zone long has been recognized as a hazard by military planners. Numerous crashes of the Sikorsky Aircraft Black Hawk helicopter have been attributed to EMI. R.J. Baumbick (National Aeronautics and Space Administration, Cleveland, Ohio) notes, "Wires are becoming the dominant antennae in aircraft." By replacing copper lines with optical fibers, the weight of cabling required can be reduced by an estimated 50%. See Fig. 14.

For the use of light systems in aircraft, researchers recognize the need for developing improved light sources for transmitters. Lasers do not serve well because of the high temperatures encountered in supersonic flight and of intense heat from aircraft engines. Powerful light-emitting diodes are required. A difficult problem is that of using optical components in place of traditional electric control of hydraulic actuators (control of flaps, rudders, and other flight-control surfaces). Sensors that heat a small amount of hydraulic fluid and thus build up pressure that can be amplified by the actuator's hydraulic system are being developed and tested.

Fiber Optics in Biomedicine

Sensors incorporating glass or plastic optical fibers have demonstrated several advantages over electrosensors for biomedical applications. These sensors involve no electrical connections and hence are safe from that standpoint; the leads are quite small and flexible: they can be incorporated in catheters for multiple sensing; where required, they can be implanted for relatively long periods. The fibers are considerably less than 1 millimeter in diameter. Where designed for simplicity, they often can be considered disposable.

As reported by Peterson (National Institutes of Health) and Vurek (Sorenson Research Corp.), there are three principal types of *in vivo* fiber-optic sensing configurations—*photometric* (or bare-ended fiber), *physical parameter sensors* in which a transducer at the end of a fiber alters the light signal in accordance with the values of the parameter measured, and *chemical probes*. In the latter, a suitable reversible reagent fixed at the end of a fiber provides spectrophotometric or fluorometric analysis. The earliest use of fiber optic sensors was in connection with reflectometry, spectrophotometry, and fluorometry where no transducer was used. In oximetry, the hemoglobin content of blood is measured spectrophotometrically. Where dyes are injected into the blood, fiber optic sensors can be used for measuring blood flow, cardiac output, and perfusion. When a microtransducer is attached at the end of a fiber optic conductor, temperature and pressure measurements can be made. A notable application is the use of a temperature sensor in connection with the hyperthermal treatment of cancer. Accuracy of $\pm 0.1^{\circ}$C can be obtained. Sometimes such devices are used in multiple locations. For example, a layer of liquid crystals at the end of optical fibers will produce changes in light scattering due to temperature change. Fiber optic sensors have been designed for monitoring intracranial and intracardiac pressure. Chemical sensors have been developed to measure pH, PO_2, PCO_2, and glucose, among other chemical variables. The details of these biomedical applications for fiber optic sensors are well developed in the Peterson-Vurek paper (reference listed).

Fiber Optic Communications in Botany

It has been known for centuries that the position of a plant relative to its source of light will affect the manner in which the plant grows and develops, including its shape. Thus, there arose expressions such as "a plant seeks or reaches for the light." Horticulturists and farmers carefully lay out their greenhouses and fields so that maximum advantage can be taken of available sunlight or, in some cases, artificial light. Only in recent years, however, has it been suspected that plants may possess means for further utilizing the radiation which they receive. Researchers Mandoli (Stanford University) and Briggs (Carnegie Institution) have observed that, in addition to depending upon light as a source of energy (photosynthesis), light is also used as a means of communication. For example, the tissues of plant seedlings can guide light through distances measured in centimeters (a distance of 4.5 centimeters has been demonstrated in the laboratory). The exact method of light transmission within plants has not been fully established, but researchers suspect that natural fibers are involved—so called "light pipes."

In the initiation and control of several physiological processes in plants, lightwave communications may serve in a way comparable to the nervous

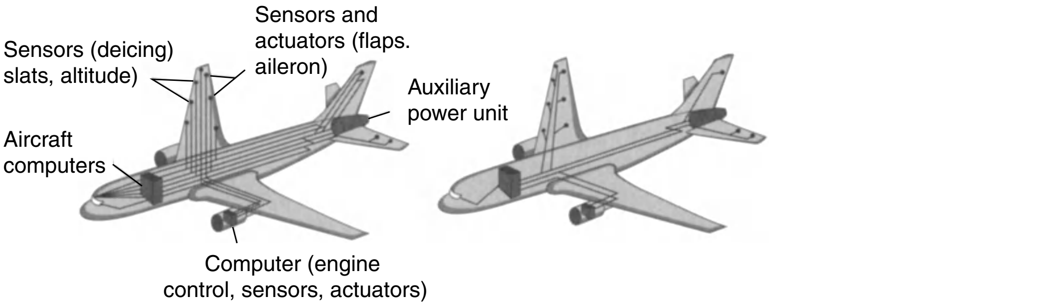

Fig. 14. Contrast of (left) hard-wire aircraft communications and controls and (right) use of fiber optics. (*After United Technologies Research Center*)

system of animals. Some of the factors influenced by light receptors include the time for a seed to germinate, the angle a shoot should take to counter gravitational forces, the rate with which a leaf should develop, and the time when a plant should bloom. Laboratory findings show that the amount of energy needed for light signaling is several orders of magnitude less than the light used for photosynthesis.

Light-sensitive detectors are pigment cells, of which the molecules making up a substance known as *phytochrome* are among the most important. These photoreceptors are sensitive to various parts of the light spectrum and thus play distinctive roles in managing different parts of a plant's physiology. In addition to the spectral distribution of light as received by the photosensitive cells, other important factors include the amount of light received, the direction from which the light is received, and the duration of the light signal.

This relatively recent area of botany and biology admittedly is in an early stage of development.

Fiber Optics in the Private Network

Private Networks, new and existing, must be well planned and carefully structured. Their network cabling solution may require a balance of both copper and fiber to cost effectively meet today's needs and support the high-bandwidth applications of the future, such as multimedia and full motion digital video-conferencing. Lucent Technologies, SYSTIMAX® SCS product families, supports these new and existing networks.

Rapidly evolving applications and technologies will drastically increase the speed and volume of traffic on LAN/WAN networks. Ensuring that your structured cabling solution is designed to accommodate the higher transmission rates associated with these evolving bandwidth intensive applications will be critical. Some examples include:

- Multimedia workstation
- Networked Scientific Modeling
- Imaging, Radiography, Computer Aided Design/Computer Aided Manufacturing (CAD/CAM)
- Asynchronous Transfer Mode (ATM)
- High-Definition Television (HDTV)
- Array processor workstations
- Mass memory database transfer
- Videophone
- Photonic (lightwave) switches and processors.

Local Area Networks (LANs). A LAN is a data communications system that enables users to access common data processing (PCs, minicomputers, and mainframe computers) and peripheral equipment (printers and fax machines). LANs, are created by using workstations with adapter cards and connecting them to file servers (where the operating system/software resides) and printers. Gateways are used to connect LANs to other LANs or operating systems like large mainframes where there is a need to share departmental or corporate computing systems. A LAN can be as simple as a few workstations working off a file server or as complex as putting hundreds of workstations on a network that runs between floors of a building or between a number of buildings in a campus environment. LANs, which were originally designed so that users could share and access a few expensive printers or controllers, have expanded into essential telecommunications networks. Today, LANs are used for file and printer sharing, electronic mail, shared databases, point-of-sale, and order entry systems.

LANs deployed on different floors or buildings are typically connected with multimode fiber. However, newer high-speed LAN topologies like full motion video do utilize single-mode fiber in some long-distance route applications where the excellent transmission characteristics of single-mode fiber are required.

LAN Topologies. SYSTIMAX SCS offers cabling architecture options for Fiber-to-the-Desktop installations: the traditional **Hierarchical Star architecture** and the new **Single Point Administration architecture**.

The traditional **Hierarchical Star architecture** is designed for maximum flexibility. Cross-connect facilities are provided in both the telecommunications closets and the main equipment room. The riser backbone cables can be sized with low counts which allow only distributed active equipment, or for greatest flexibility, with high counts which permit both distributed and centralized active equipment. The horizontal cross-connect facility helps ensure the greatest life span for the system by allowing the active equipment to be located closer to the work areas. The short horizontal runs can support applications at higher speeds than the longer combined horizontal/riser runs used with centralized active equipment. Also, this architecture is standards-compliant with both riser design approaches.

Single Point Administration architecture is designed for simplicity and cost-effectiveness for centralized equipment. This approach provides direct connections from all work areas (offices) to the cross-connect in the main equipment room, forming a single point of administration optimized for centralized active equipment. The single point of administration provides the simplest circuit management possible by eliminating the need to cross-connect circuits in multiple places. It also provides the ability to connect users in different areas of a building directly to the same LAN segment, reducing traffic on bottleneck-prone bridges and routers. Single point administration also provides three cost benefits. First, it eliminates the need for horizontal cross-connects, saving passive hardware costs. Second, it consolidates active equipment, reducing the number of idle ports in the system, thereby saving active equipment costs. Finally, this type of architecture eases network administration and maintenance, reducing technical support staff effort.

The LAN topology is the physical layout of a LAN—how the controllers, workstations (primarily PCs), and other equipment are connected by the cable. The three basic LAN topologies are: Bus; Star; and Ring.

The bus topology has all the workstations on the network attached (via the information outlet) to a single cable that carries the signal in both directions through the network. The bus network, can be expanded by adding several segments together with bridges, routers, and repeaters. The Institute of Electrical and Electronics Engineers Inc. (IEEE) Standard 802.3 is an example of a bus topology. In a star topology, all of the nodes or workstations are connected with unshielded twisted pair (UTP) or fiber optic cable to a centrally located common controller or concentrator. The central control point permits centralized network administration, management, and troubleshooting. StarLAN is an example of a star topology, as is IEEE 802.3. In a ring topology, the network forms a ring. A token carries data through the network. Workstations are connected as in a star topology to a central administration point, such as a multistation access unit (MAU). Token Ring (IEEE 802.5) is an example of a ring topology.

The LANs, which were introduced back in the 1980s, were based on copper cable, with very few fiber applications being used. Most of the more recently introduced LANs (FDDI, 10BASE-F, and DFON) primarily use fiber optics but offer interfaces (bridges and routers) with the older copper-based networks. The more recent trend is in the use of "smart hubs" or concentrators, which allow both bus and ring (Ethernet and Token Ring) topologies to be mixed in the same electronics within the communications closet. In addition, the backbone network, which links the hubs/concentrators together, could be on a higher speed LAN topology such as FDDI running at 100 Mbps.

The advent of new lower cost optoelectronics for LAN applications has spurred a growing interest in using fiber all the way to the workstation. These total fiber networks offer easy migration to even higher speed applications like ATM.

Fiber Optics in Industrial Instrumentation and Networks

The combination of light-transmitting optical cable and miniature silicon sensors has resulted in the development of a new measurement technology for various industrial processes. Three variables may be measured with this technique—temperature, pressure, and refractive index. The new systems are immune to electromagnetic and radio-frequency interference, they provide more accuracy in electrically noisy environments, and their miniature size improves response and causes minimal process disturbances.

The fiber optic sensors utilize an extrinsic Fabry-Perot interferometer to spectrally modulate light in proportion to pressure, temperature, or refractive index variations. Because they are based on spectral modulation instead of amplitude modulation, they are not affected by such common problems as fiber bending, connector losses, and aging.

Pressure Sensing. As shown by Fig. 15, a cavity resonator is constructed using a float-bottom pocket-etched into a refractory glass substrate. The pocket is 2–3 wavelengths deep and covered with a diaphragm. The two reflecting surfaces (bottom of pocket and the diaphragm) form an interferometer. The cavity is evacuated, thus permitting the diaphragm to deflect. This deflection is a function of absolute pressure. In effect, the path

length changes. A parallel can be made with the action of a soap bubble. As the bubble changes size and hence film thickness, interference effects occur. These reinforce reflected light at certain wavelengths, enhancing transmission of light through the film at other wavelengths. Color (frequency) changes occur as a result.

The cavity resonator (sensor) is 0.015 in (0.4 mm) in all three dimensions. The resonator is joined to a multimode fiber by a glass capillary 0.032 in (0.8 mm) in diameter. The light source's spectrum is centered at 850 nm. As the effective cavity depth changes as a function of the measured variable, the cavity's reflectance spectrum shifts. This spectral shift modulates (skews) the incoming light spectrum. A dichroic filter and photodiodes are then used to discern differences in the returning light's spectrum strength within two wavebands.

Temperature Sensing. As shown in Fig. 16, a layer of silicon (whose refractive index changes with temperature) is placed in the optical path in place of the evacuated cavity, as previously described. The second reflector (glass) is rigid. The effective path length thus changes with temperature.

Refractive Index. This property is the ratio of the velocity of light in a vacuum to the velocity of light in a transparent material. The property is used extensively in the processing industries for measuring component concentrations or for tracking changes in molecular makeup, such as materials that are reacting. The hydrogenation of food oils is an example of such a process.

The extent of hydrogenation (the degree of saturation of a double bond in the ester chain of an edible oil) may be indicated by conventional laboratory titrations of the iodine number. This is a time-consuming, grab-sampling method. Continuous measurement and control via refractive index measurement is far more efficient. As shown by Fig. 17, the fluid of interest is drawn by capillary action into a duct through a glass substrate, and the effective path length varies in proportion to the refractive index of the fluid. Excellent correlation of refractive index with the iodine number of hydrogenated oil is shown in Fig. 18.

Note: The foregoing information on fiber optic sensors was furnished by Gene Yazbak, Foxboro, MA.

Optical Fiber Terminology

An abridged glossary of terms used to describe optical fiber products and processes would include:

Absorption—A physical mechanism in fibers that attenuates light by converting it into heat-thereby raising the fiber's temperature. In practice the temperature increase is slight and difficult to measure. Absorption arises from tails of the ultraviolet and infrared absorption bands, from impurities such as the OH−ion, and from defects in the glass structure.

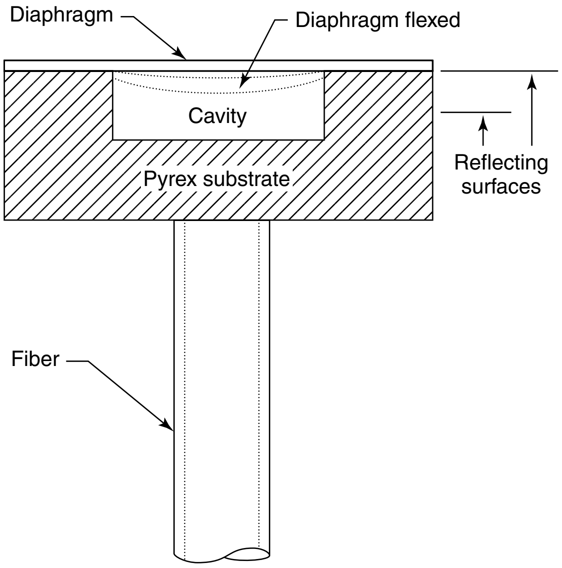

Fig. 15. Fiber-optic pressure sensor. As light passes into a cavity resonator formed by a glass substrate and a flexible diaphragm, it is reflected from both surfaces, forming an interference pattern that changes as the diaphragm flexes with pressure changes. (*Yazbak, Foxboro, Massachusetts*)

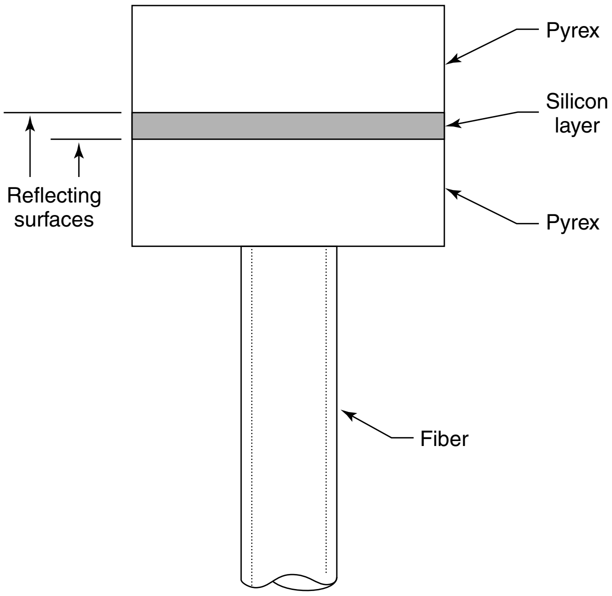

Fig. 16. Fiber-optic temperature sensor. A thin layer of silicon placed in the optical path exhibits a large change in refractive index with temperature, changing the effective path length. (*Yazbak, Foxboro, Massachusetts*)

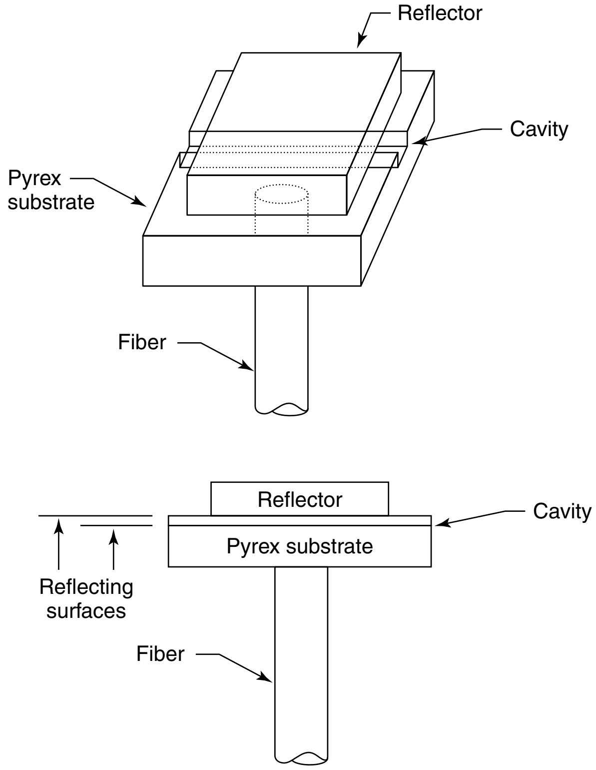

Fig. 17. Fiber-optic refractive index sensor. Fluid of interest is drawn by capillary action into a duct through a glass substrate. The effective path length varies in proportion with the refractive index. (*Yazbak, Foxboro, Massachusetts*)

Adapter Loss—The power loss suffered when coupling light from one optical device to another.

Aramid Yarn—Strength elements that provide tensile strength and provide support and additional protection of the fiber bundles. Kevlar is a particular brand of aramid yarn.

Armor—Additional protective element beneath outer jacket to provide protection against severe outdoor environments. Usually made of plastic-coated steel, it may be corrugated for flexibility.

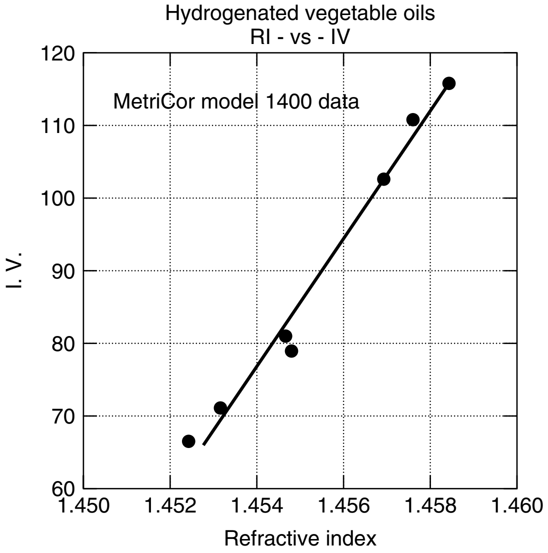

Fig. 18. Correlation of refractive index with iodine number of hydrogenated oil. (*Yazbak, Foxboro, Massachusetts*)

Attenuation—The decrease in magnitude of power, of a signal in transmission between points. A term used for expressing the total loss of an optical system, normally measured in decibels (dB) at a specific wavelength.

Attenuation Coefficient—The rate of optical power loss with respect to distance along the fiber, usually measured in decibels per kilometer (dB/km) at specific wavelength. The lower the number, the better the fiber's attenuation. Typical multimode wavelengths are 850 and 1300 manometers (nm); single-mode wavelengths are 1310 and 1550 nm. Note: When specifying attenuation, it is important to note whether the value is average or nominal.

Avalanche Photodiode (APD)—A photodiode designed to take advantage of avalanche multiplication of photocurrent. As the reverse-bias voltage approaches the breakdown voltage, hole-electron pairs created by absorbed photons acquire sufficient energy to create additional hole electron pairs when they collide with ions; thus a multiplication or signal gain is achieved.

Axial Ray—A light ray that travels along the axis of an optical fiber.

Beamsplitter—A device used to divide an optical beam into two or more separate beams.

Cable—An assembly of optical fibers and other material providing mechanical and environmental protection.

Central Member—The center component of a cable. It serves as an antibuckling element to resist temperature induced stresses. Sometimes serves as a strength element. The central member material is either steel, fiberglass, or glass-reinforced plastic.

Chromatic Dispersion—Spreading of a light pulse caused by the difference in refractive indices at different wavelengths.

Cladding—The dielectric material surrounding the core of an optical fiber.

Composite Cable—A cable containing both fiber and copper media per article 770 of the National Electric Code (NEC).

Core—The central region of an optical fiber through which light is transmitted.

Dielectric—Nonmetallic and, therefore, nonconductive. Glass fibers are considered dielectric. A dielectric cable contains no metallic components.

Ferrule—A mechanical fixture, generally a rigid tube, used to protect and align a fiber in a connector. Generally associated with fiber optic connectors.

Fiber—Any filament or fiber, made of dielectric materials, that guides light.

Fiber Bend Radius—Radius a fiber can bend before the risk of breakage or increase in attenuation.

Fiber Optics—The branch of optical technology concerned with the transmission of radiant power through fibers made of transparent materials such as glass, fused silica, or plastic.

Fresnel Reflection—The reflection of a portion of the light incident between two homogeneous media having different refractive indices. Fresnel reflection occurs at the air/glass interfaces at entrance and exit ends of an optical fiber.

Fresnel Reflection Losses—Reflection losses that are incurred at the input and output of optical fibers due to the differences in refraction index between the core glass and immersion medium.

Index Matching Fluid—A fluid with an index of refraction close to that of glass that reduces reflections caused by refractive-index differences.

Index Matching Material—A material, often a liquid or cement whose refractive index is nearly equal to the core index. Used to reduce Fresnel reflections from a fiber end face.

Intermediate Cross-Connect (IC)—A secondary crossconnect in the backbone cabling used to mechanically terminate and administer backbone cabling between the main cross-connect and horizontal cross-connect.

Irradiance—Power density at a surface through which radiation passes at the radiating surface of a light source or at the cross section of an optical waveguide. The normal unit is Watts per centimeters squared, or W/cmu2d.

Laser Diode (LD)—Light Amplification by Stimulated Emission of Radiation. An electro-optic device that produces coherent light with a narrow range of wavelengths, typically centered around 780 nm, 1320 nm, or 1550 nm. Lasers with wavelengths centered around 780 nm are commonly referred to as CD Lasers.

Lasing Threshold—The lowest excitation level at which a laser's output is dominated by stimulated emission rather than spontaneous emission.

Light—In the laser and optical communication fields, the portion of the electromagnetic spectrum that can be handled by the basic optical techniques used for the visible spectrum extending from the near ultraviolet region of approximately 0.3 micron, through the visible region and into the mid infrared region of about 30 microns.

Lightwaves—Electromagnetic waves in the region of optical frequencies. The term "light" was originally restricted to radiation visible to the human eye, with wavelengths between 400 and 700 manometers (nm). However, it has become customary to refer to radiation in the spectral regions adjacent to visible light (in the near infrared from 700 to about 2000 nm) as "light" to emphasize the physical and technical characteristics they have in common with visible light.

MDPE—Abbreviation used to denote medium density polyethylene. A type of plastic material used to make cable jacketing.

Material Dispersion—The dispersion associated with a non-monochro matic light source due to the wavelength dependence of the refractive index of a material or of the light velocity in this material.

Microbending—Curvatures of the fiber which involve axial displacements of a few micrometers and spatial wavelengths of a few millimeters. Microbends cause loss of light and consequently increase the attenuation of the fiber.

Micrometer (gm)—One millionth of a meter; 10–6 meter. Typically used to express the geometric dimension of fibers, for example, 62.5 μm.

Modal Dispersion—Pulse spreading due to multiple light rays traveling different distances and speeds through an optical fiber.

Mode Field Diameter—The diameter of the one mode of light propagating in a single-mode fiber. The mode field diameter replaces core diameter as the practical parameter in single-mode fiber.

Modified Chemical Vapor Deposition (MCVD) Technique—A process in which deposits are produced by heterogeneous gas/solid and gas/liquid chemical reactions at the surface of a substrate. The MCVD method is often used in fabricating optical waveguide preforms by causing gaseous material to react and deposit glass oxides. Typical starting chemicals include volatile compounds of silicon, germanium, phosphorus, and boron, which form corresponding oxides after heating with oxygen or other gases. Depending on its type, the preform may be processed further in preparation for pulling into an optical fiber.

Monochromatic—Consisting of a single wavelength. In practice, radiation is never perfectly monochromatic but, at best, displays a narrow band of wavelengths.

Multimode Fiber—An optical waveguide in which light travels in multiple modes. Typical core/cladding size (measured in micrometers) is 62.5/125.

Nanometer (nm)—A unit of measurement equal to one billionth of a meter; 10–9 meters. Typically used to express the savelength of light, for example, 1300 nm.

Near Field Radiation Pattern—Distribution of the irradiance over an emitting surface; in other words, over the cross section of an optical waveguide.

Optical Waveguide—Dielectric waveguide with a core consisting of optically transparent material of low attenuation (usually silica glass) and with cladding consisting of optically transparent material of lower refractive index than that of the core. It is used for the transmission of signals with lightwaves and is frequently referred to as fiber. In addition, there are planar dielectric waveguide structures in some optical components, such as laser diodes, which are also referred to as optical waveguides.

Optoelectronic—Pertaining to a device that responds to optical power, emits or modifies optical radiation, or utilizes optical radiation for its internal operation. Any device that functions as an electrical-to-optical or optical-to-electrical transducer.

PE—Abbreviation used to denote polyethylene. A type of plastic material used for outside plant cable jackets.

PVC—Abbreviation used to denote polyvinyl chloride. A type of plastic material used for cable jacketing. Typically used in flame-retardant cables.

PVDF—Abbreviation used to denote polyvinyl difluoride. A type of material used for cable jacketing. Often used in plenum-rated cables.

Preform—A glass structure from which an optical fiber waveguide may be drawn.

Prefusing—Fusing with a low current to clean the fiber end. Precedes fusion splicing.

Single-Mode Fiber—Optical fiber with a small core diameter (typically 9 μm) in which only a single-mode, the fundamental mode, is capable of propagation. This type of fiber is particularly suitable for wideband transmission over large distances, since its bandwidth is limited only by chromatic dispersion.

Spontaneous Emission—This occurs when there are too many electrons in the conduction band of a semiconductor. These electrons drop spontaneously into vacant locations in the valence band, a photon being emitted for each electron. The emitted light is incoherent.

Step Index Fiber—A fiber having a uniform refractive index within the core and a sharp decrease in refractive index at the core/cladding interface.

Stimulated Emission—This occurs when photons in a semiconductor stimulate available excess charge carriers to the emission of photons. The emitted light is identical in wavelength and phase with the incident coherent light.

OPTICAL GLASS. Glass to be useful for lenses, prisms and other optical parts through which light passes, as distinguished for mirrors, must be completely homogeneous. This includes freedom from bubbles, striae, seeds, strains, etc. In order to reduce aberrations, the optical designer needs many different kinds of glass. A few typical types are described in Table 1. The v-number is the reciprocal of the dispersive power of the glass.

TABLE 1. VARIOUS GLASSES

	Type	n_D	v-Number
Borosilicate	Crown	1.5170	64.5
Barium	Crown	1.5411	59.5
Spectacle	Crown	1.5230	58.4
Light	Flint	1.5880	53.4
Ordinary	Flint	1.6170	38.5
Dense	Flint	1.6660	32.4
Extra dense	Flint	1.7200	29.3

OPTICAL ISOMER. Either of two kinds of optically active three-dimensional isomers (stereoisomers). One kind is represented by mirror-image presence of one or more asymmetric carbon atoms in the compound (glyceraldehyde, lactic acid, sugars, tartaric acid, amino acids). The other kind is exemplified by diastereoisomers, which are not mirror images. These occur in compounds having two or more asymmetric carbon atoms; thus, such compounds have 2_n optical isomers, where n is the number of asymmetric carbon atoms.

See also **Optical Rotation**.

OPTICAL MICROSCOPE. A magnifying lens system that utilizes light in the visible wavelength range of the electromagnetic spectrum (5000 Å). A convex glass lens bends or focuses light waves because of the difference in density between glass and air. Invented in 1590 by the Janssen brothers and later improved by van Leeuwenhoek, the compound microscope has three lenses: a condenser lens, which concentrates the incident light; an objective lens, which gives an enlarged reverse image of the specimen; and a projector lens, which further enlarges the image and return it to normal position. Its maximum resolving power is 0.5 micron, compared with 100 microns for the human eye. The compound microscope is particularly useful in studying bacterial and other microorganisms in their natural state without interfering with their behavior. It has been of untold benefit to biologists and bacteriologists and also has innumerable uses in chemical and metallurgical research, as well as in forensic chemistry.

OPTICAL ROTATION. The change of direction of the plane of polarized light to either the right of the left as it passes through a molecule containing one or more asymmetric carbon atoms, e.g., sugars. The direction of rotation, it to the right, is indicated by either a plus sign (+) or a *d*-; if to the left, by a minus sign (−) or an *l*-. Molecules having a right landed configuration (D) usually are dextrorotatory, D(+), though they may be levorotatory, D(−); those having a left-handed configuration (L) are usually levorotatory, L(−), but may be dextrorotatory d(+). Compounds having this property are said to be optically active and are isomeric. The amount of rotation varies with the compound but is the same for any two isomers, though in opposite directions.

See also **Optical Isomer**.

ORBITALS. This article embraces both atomic and molecular orbitals.

Atomic. From spectroscopic studies, it is known that when an electron is bound to a positively charged nucleus only certain fixed energy levels are accessible to the electron. Before 1926, the old quantum theory considered that the motion of the electrons could be described by classical Newtonian mechanics in which the electrons move in well defined circular or elliptical orbits around the nucleus. However, the theory encountered numerous difficulties and in many instances there arose serious discrepancies between its predictions and experimental fact.

A new quantum theory called wave mechanics (as formulated by Schrödinger) or quantum mechanics (as formulated by Heisenberg, Born and Dirac) was developed in 1926. This was immediately successful in accounting for a wide variety of experimental observations, and there is little doubt that, in principle, the theory is capable of describing any physical system. A strange feature of the new mechanics, however, is that nowhere does the path or velocity of the electron enter the description. In fact it is often impossible to visualize any classical motion that could be consistent with the quantum mechanical picture of the atom.

In this theory the electron is viewed as a three-dimensional standing wave. The pattern of the wave is described by a wave function ϕ (analogous to the amplitude of a water wave). This one-electron wave function is called an atomic orbital. Since the wave function can be positive or negative (and real or complex) it does not describe an observable property of the electron. However, the square of the wave function (ϕ^2 or ϕ times its complex conjugate) is always positive and real, and can be identified with the probability of finding the electron at any point. This was first suggested by Born, but has now received ample experimental support. Hence, when the wave function is calculated for any electron we can determine the regions in space where the electron is most likely to be found, though we cannot say what type of motion results in that particular probability pattern.

Atomic orbitals are usually labeled by a set of designating numbers called quantum numbers. The one that determines the energy of the resulting state (for hydrogen) is given the symbol n and called the "principal quantum number." It assumes the values 1, 2, 3, 4, 5, ... to infinity, with increasing electron energies. The second quantum number is given the symbol l. It can be identified with the angular momentum of the electron due to its orbital motion, and assumes values of 0, 1, 2, 3, ... to $(n - l)$. For historical reasons the orbitals with these values are referred to as *s, p, d, f,* ... orbitals respectively. Hence a $3d$ orbital is one for which $n = 3$ and $l = 2$. The third quantum number is usually given the symbol m and is difficult to define in the absence of an external field. However, under all conditions it can assume $2l + 1$ values.

From the rules given in the previous paragraph it can easily be shown that for $n = 1$, 2 and 3 there are a total of 14 allowed orbitals. For an isolated hydrogen atom all orbitals must be spherically symmetrical and have the shapes shown in series (a) of Fig. 1. These are plots of the probability function (ϕ^2) for the orbitals and hence the darkest areas represent regions where the electron is most likely to be found. Though there are actually three $2p$ orbitals, three $3p$ orbitals and five $3d$ orbitals, in the absence of an external field the orbitals within a given set are identical in shape and energy, and are said to be degenerate. If a direction is defined by the presence of a magnetic field or the approach of another atom, the degeneracy is removed. The shapes of the allowed orbitals under these conditions are shown in series (b) of Fig. 1. The quantum number m is well defined for these orbitals and its value is given beside each orbital. For the discussion of bonding in polyatomic molecules another set of orbitals is useful. These are shown in series (c) of Fig. 1. The quantum number m is not well-defined for these orbitals, and they are usually labeled according to the axis along which they lie.

In addition to the orbitals shown in Fig. 1 there are "hybrid" orbitals that are not stationary states for the electron in an isolated atom. They can be obtained by taking a linear combination of the standard orbitals in Fig. 1. Since the electron distribution is "off center" they are useful only for atoms that are perturbed by an electric field (Stark-effect) or by the approach of other atoms as occurs in chemical-bond formation.

In addition to the three quantum numbers discussed above, experimental evidence requires an additional quantum number m_s, which by analogy to classical mechanics is attributed to an intrinsic (i.e., position-independent) property of the electron called "spin." Unlike the other quantum numbers, however, it can assume only two values ($\pm\frac{1}{2}$). As we shall see, this fact determines the orbital population of the many-electron atom.

It is an unfortunate consequence of the mathematical complexity of the quantum mechanical equations that the hydrogenic atom (i.e., one-electron atom) is the only system for which an exact probability distribution (ϕ^2) can be obtained. Approximate methods must be used to calculate the wave functions for the many electron atoms. We begin with the natural assumption that the wave function for such a more complex atom (ψ) can be obtained by taking a product of the appropriate one electron functions (ϕ). However, even if we ignore for the moment the coulombic repulsion between electrons, there are two fundamental postulates of quantum mechanics that complicate the picture. One is that electrons are indistinguishable. Hence, when their positions are interchanged, the probability function (ψ^2) must remain unchanged. This means that the wave function (ψ) must either remain the same or only change signs when electron positions are interchanged. A second postulate (called the Pauli principle) is that the total wave function must change signs when electron positions are interchanged. From these requirements it can be seen that when two electrons are placed in the same orbital (i.e., assigned the same orbital wave function ϕ) the total wave function will change signs (as required by the Pauli principle) only if the electrons have different spin quantum numbers ($+\frac{1}{2}$ and $-\frac{1}{2}$). It is hence a general rule that hydrogenic orbitals can only be occupied by a maximum of two electrons and these must have opposite spin.

If we begin with the most tightly bound orbital and add two electrons to each orbital the so called "ground state configuration" of the atom is obtained. For example the electronic configuration of the silicon atom is written $1s^2, 2s^2, 2p^2; 3s^2, 3p^2$. The orbital shapes and energies are, however, considerably altered by electron-electron repulsion, especially between electrons whose orbitals overlap appreciably. This has several marked effects. For a given value of n, all the orbitals no longer have the same energy. The binding energy now decreases with increasing values of the quantum number l. Secondly, because of the coulombic repulsion between electrons, they will tend to occupy separate orbitals whenever feasible (for example the $3p$ orbitals configuration in the silicon atom is actually $3p^1, 3p^1$). Furthermore, when electrons are forced together into the region of one hydrogenic orbital it is quite likely that electron-electron

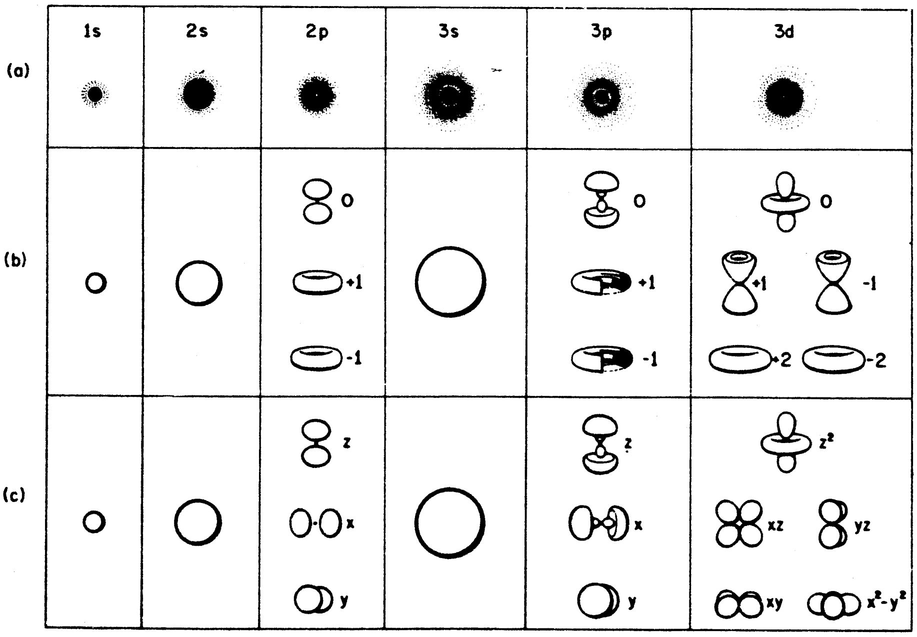

Fig. 1. Hydrogen atomic orbitals: (a) for isolated atoms; (b) with one direction defined; (c) with three directions defined.

repulsion (always greater than 25 kcal) leads, in effect, to slightly different orbitals for each electron.

For chemical purposes we are most interested in the shapes of orbitals in which the valence (outermost) electrons reside. By assuming that the inner electrons act only to screen some of the positive charge on the nucleus the valence electrons can be shown to assume the shape of the appropriate hydrogenic orbital, with the insignificant difference that the inner nodes in the orbitals shown in Fig. 1 are drawn in closer to the nucleus because the shielding is poorer in this region. It is worth noting that for the many-electron atom, the indistinguishability of electrons has the effect of making only the total probability function physically meaningful. For this reason and because of the repulsion between electrons, the individual one-electron wave functions are so correlated that, though the "independent orbital concept" remains a very useful approximation, it is not fundamental to the problem.

Molecular. By analog with atomic orbitals, the wave function (ψ) for one electron in a molecule is called a molecular orbital, and the probability of finding the electron at any point is similarly given by the value of ψ^2 at that point. Just as in the case of atomic orbitals, an exact solution of the equations is possible only for the one-electron molecule (H_2^+) and it is only for this species that accurate molecular orbitals can be obtained.

The shapes of 10 of the most tightly bound orbitals of H_2^+ are shown in Fig. 2. Three quantum numbers can be used to label these orbitals. The one that is always well defined is given the symbol λ and can be identified with the component of the orbital angular momentum along the internuclear axis. It can take on values 0, 1, 2, 3 ... for which the orbitals are called $\sigma, \pi, \delta, \ldots$ respectively. The other two quantum numbers are defined differently depending on the nuclear separation. When the internuclear distance is short, as the case of H_2^+, it is convenient to consider the atomic orbital that would result from a given molecular orbital if the two nuclei were made to coalesce (in our imaginations). In the case of homonuclear diatomic molecules, for example, the molecular orbital designated $3d\ \sigma$ has $\lambda = 0$ and correlates to a $3d$ atomic orbital when the nuclei coalesce (i.e., the atomic quantum numbers n and l become well-defined at short internuclear distance). On the other hand, when the internuclear distance is large, a more useful and significant label is one which identifies the atomic orbitals with which a given molecular orbital correlates when the distance between the two nuclei approaches infinity. For this "separate atom" designation an additional symbol must be used to distinguish between the two molecular states that can arise from a given pair of atomic states. Chemists find it most useful to use the superscript * to indicate the higher energy (antibonding) orbital and the absence of * to indicate the lower energy (bonding) orbital. When the difference in symmetry between the two states is important the symbols g (gerade-symmetric) and u (ungerade-symmetric) are used. Thus, the orbital $\sigma^*(2p_x)$ is an antibonding orbital with $\lambda = 1$ that correlates with two $2p_x$ orbitals on the separated atoms. Similarly, a $\sigma_g 2(\text{sp})$ orbital is a bonding orbital with $\lambda = 0$ that correlates with two atomic orbitals on the separated atoms. It is worth noting that the "antibonding" orbitals possess a nodal surface (i.e., a region of zero electron-probability density) between the two nuclei.

Exact solutions such as those given above have not yet been obtained for the usual many-electron molecules encountered by chemists. The approximate method which retains the idea of orbitals for individual electrons is called "molecular-orbital theory" (M. O. theory). Its approach to the problem is similar to that used to describe atomic orbitals in the many-electron atom. Electrons are assumed to occupy the lowest energy orbitals with a maximum population of two electrons per orbital (to satisfy the Pauli exclusion principle). Furthermore, just as in the case of atoms, electron-electron repulsion is considered to cause degenerate (of equal energy) orbitals to be singly occupied before pairing occurs.

It has not proved mathematically feasible to calculate the electron-electron repulsion that causes this change in orbital-energies for many-electron molecules. It is even difficult to rationalize the qualitative changes in sequence on the basis of the shapes of the H_2^+ orbitals. Greater success has been achieved by an approximate method which begins with orbitals characteristic of the isolated atoms present in the molecule, and assumes that molecular orbital wave functions can be obtained by taking linear combinations of atomic orbital wave functions (abbreviated L.C.A.O.). For

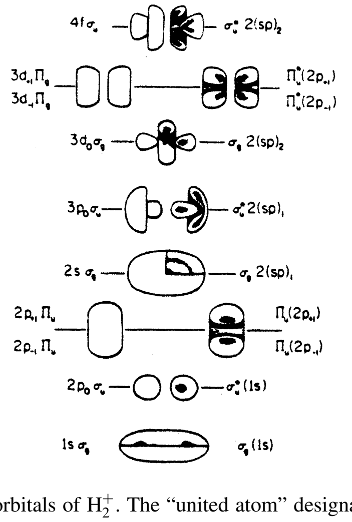

Fig. 2. Molecular orbitals of H_2^+. The "united atom" designation is given on the left-hand side and the "separate atom" designation on the right-hand side.

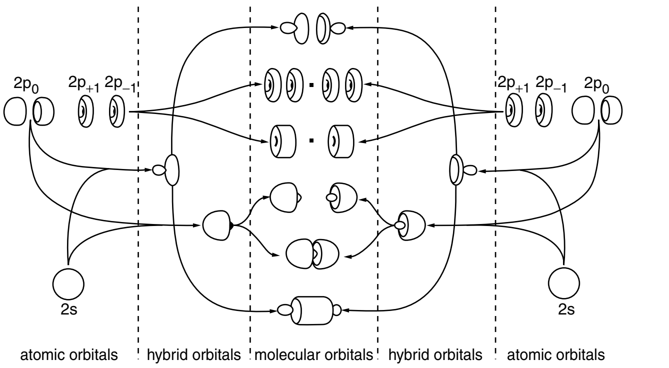

Fig. 3. L.C.A.O. method of obtaining molecular orbitals for N_2. Arrows indicate the combinations of atomic orbitals used to generate molecular orbitals. The stabilities of the orbitals increase from top to bottom.

homonuclear diatomic molecules, the atomic orbitals used are normally those with which a given molecular orbital correlates. An example of how molecular orbitals are manufactured in the L.C.A.O. approximation is shown in Fig. 3. According to this theory, the relative molecular-orbital energies will depend on (a) the spread of orbital energies on the individual atoms (since this determines the extent of hybridization) and (b) on the internuclear distance which is largely determined by the relative number of bonding and antibonding orbitals that are filled.

The L.C.A.O. approximation has also proved useful for the description of heteronuclear diatomic molecules, although valence-bond theory has been somewhat more successful in its quantitative calculations of bond energies. For these molecules the selection of appropriate atomic orbitals to be used in linear combination is governed by considerations of symmetry, energetics and overlap. These considerations also apply to the formation of molecular orbitals in polyatomic molecules by the L.C.A.O. approximation. In the case of polyatomic molecules it is always possible to develop either (a) molecular orbitals that extend between only two atoms (localized M.O.*s*) or (b) molecular orbitals that extend over the entire molecule (delocalized M.O.*s*). In the case of saturated molecules, the two descriptions are practically equivalent. However, for molecules with conjugated double bonds and especially for aromatic compounds, delocalized molecular orbitals which extend over several atoms must be used. When the L.C.A.O. method is used to develop molecular orbitals in complexes between metal ions (possessing *d* orbitals) and ligands such as CO, OH^-, NH_3, CN^- etc., the procedure is called Ligand Field Theory.

A thorough test of the L.C.A.O. molecular orbitals has been possible only for H_2^+ where both the wave functions and orbital energies are known accurately. Such a comparison shows that though the shapes of the wave functions are reasonably represented by the approximation, their energies can be appreciably in error, especially for excited state. Nevertheless, the L.C.A.O. approximation has proved the most fruitful method of obtaining molecular orbitals that has been developed to date.

ORDER-DISORDER THEORY AND APPLICATIONS. Phase transitions in binary liquid solutions, gas condensations, order-disorder transitions in alloys, ferromagnetism, antiferromagnetism, ferroelectricity, antiferroelectricity, localized absorptions, helix-coil transitions in biological polymers and the one-dimensional growth of linear colloidal aggregates are all examples of transitions between an ordered and a disordered state.

The two quantities which apparently must be used to explain or describe these phenomena are the presence of a potential between the particles or spins and a small volume which must be assigned to each particle so that two particles or spins cannot occupy the same space. All the above phenomena may be semi-quantitatively treated by a single statistical model called the Ising model which consists of a lattice in space, each site of which possesses either a 0 or a 1. Thus two rows of a two dimensional lattice might look like

$$\ldots 011000011011110011 \ldots$$

$$\ldots 110110010100110111 \ldots$$

The 0's and 1's represent different particles or spins depending upon the system being studied and their definition will be given below for different systems. The disordered state corresponds to a random array of 0's and 1's. The ordered state is described by an ordered arrangement of the 0's and 1's. The total number of lattice sites equals N. The number of 0's and 1's on the lattice are respectively n_0 and n_1 and $n_1 + n_0 = N$.

The dimensionality of the lattice depends on the physical nature of the phase. For transitions in linear biopolymers and associative colloids, a one-dimensional lattice is used because these materials become ordered in a one-dimensional manner even though they actually exist in three dimensions. For absorption of gas onto a surface, a two-dimensional lattice is sufficient. For bulk phase changes, however, a three-dimensional lattice must be used.

The great advantage of this model is that it gives essentially the same explanation for a large number of seemingly completely diverse physical and chemical phenomena, often with quantitative success. This permits a deeper insight into the statistical thermodynamic behavior of different types of matter.

The calculation of the thermodynamic properties begins by selecting values for w_{00}, w_{11}, w_{10}, which are the potential energies between like and unlike particles or spins occupying nearest neighbor sites. Since two particles cannot occupy one lattice point, the energy of repulsion of two particles on the same site is considered infinite. The energy of a given configuration is then given by

$$E_{\text{Conf}} = n_{11}\ w_{11} + n_{10}\ w_{10} + n_{00}\ w_{00} \tag{1}$$

where n_{11}, n_{00} and n_{10} are the number of nearest neighbor pairs. The probability of a given configuration is given by Boltzmann's theorem as

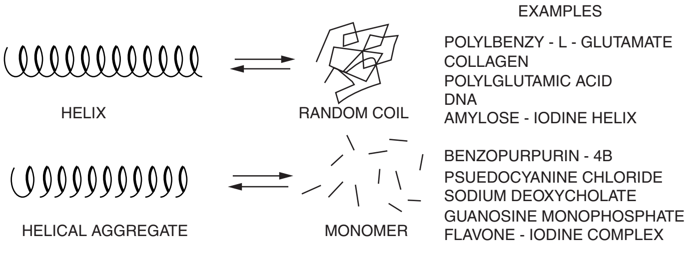
$$P(E_{\text{Conf}}) = \frac{e^{(-E_{\text{Conf}}/kT)}}{\sum\limits_{\text{Conf}} e^{(-E_{\text{Conf}}/kT)}} \tag{2}$$

where the summation occurs over all possible configurations, keeping the number of 0's and 1's constant. The restriction of a constant number of 0's and 1's may be removed by letting the lattice interact with its surroundings. The probability that the lattice possesses a given number of 1's and a configurational energy, E_{Conf}, is given by

$$P(E_{\text{Conf}}, n_1) = \frac{e^{-Xn_1/kT}\, e^{-E_{\text{Conf}}/kT}}{\sum\limits_{n_1=0}^{N} e^{-Xn_1/kT} \sum\limits_{\text{Conf}} e^{-E_{\text{Conf}}/kT}} \tag{3}$$

where X is a suitable thermodynamic quantity such as the chemical potential or magnetic field, etc.

For a lattice gas, the 0 and 1 stand for an empty and filled site respectively. Consequently, w_{11} is the attractive potential energy between two gas molecules when they occupy adjacent sites on the lattice, and $w_{00} = w_{10} = 0$.



Diagrammatic illustration of the helix-coil transitions in biopolymers (*top*). Helix-monomer transition in associative biocolloids (*bottom*)

For binary solutions including linear associative colloids, the 0 and 1 represent solvent and solute respectively; w_{11} and w_{00} are the potential energies between like molecules and w_{10} is the potential energy between unlike molecules.

For a ferromagnet the 0 and 1 represent spins of $-\frac{1}{2}$ and $+\frac{1}{2}$ respectively. It is generally assumed that the potential energy between like spins is always the same, i.e., $w_{11} = w_{00}$. To show how the quantity, X of Eq. (3), is obtained, consider a ferromagnet interaction with an external magnetic field. The total energy is

$$E = (n_0 - n_1)H \cdot d + E_{\text{Conf}}$$

where H is the magnetic field strength, and d is the magnetic dipole moment of a spin. Thus for a ferromagnet $X = 2H \cdot d$ since $N - 2n_1 = n_0 - n_1$.

The above described order-disorder transitions are all three-dimensional phase transitions and occur with essentially infinite sharpness unless the condensed phase exists in a colloidally dispersed state. Recently, it has been shown that certain polymers and associative colloids, particularly those of biological interest, have one-dimensional order-disorder transitions which may be explained in exactly the same terms that describe the three-dimensional phase changes discussed above. However, because the condensed state is colloidally dispersed and the ordering occurs only in one dimension, it may be shown that such transitions cannot be infinitely sharp.

The accompanying figure illustrates the transition from an ordered helical to a disordered state which occurs in a large number of colloidal systems. For the helix-coil transition in polymers, the 1 and 0 represent, respectively, a hydrogen bonded turn of the helix and an unhydrogen bonded section of randomly fluctuating polymer. In an associative colloid, the 0 or 1 represent respectively a cell containing a solvent or colloid monomer. In either case, there exists an energy of attraction between 1's which leads to the formation of a one dimensional ordered helix. The fact that the transition tends to be rather sharp comes about because the 01 and 10 configurations which always occur at the beginning and end of a helical sequence are energetically unfavorable. This means that configurations with

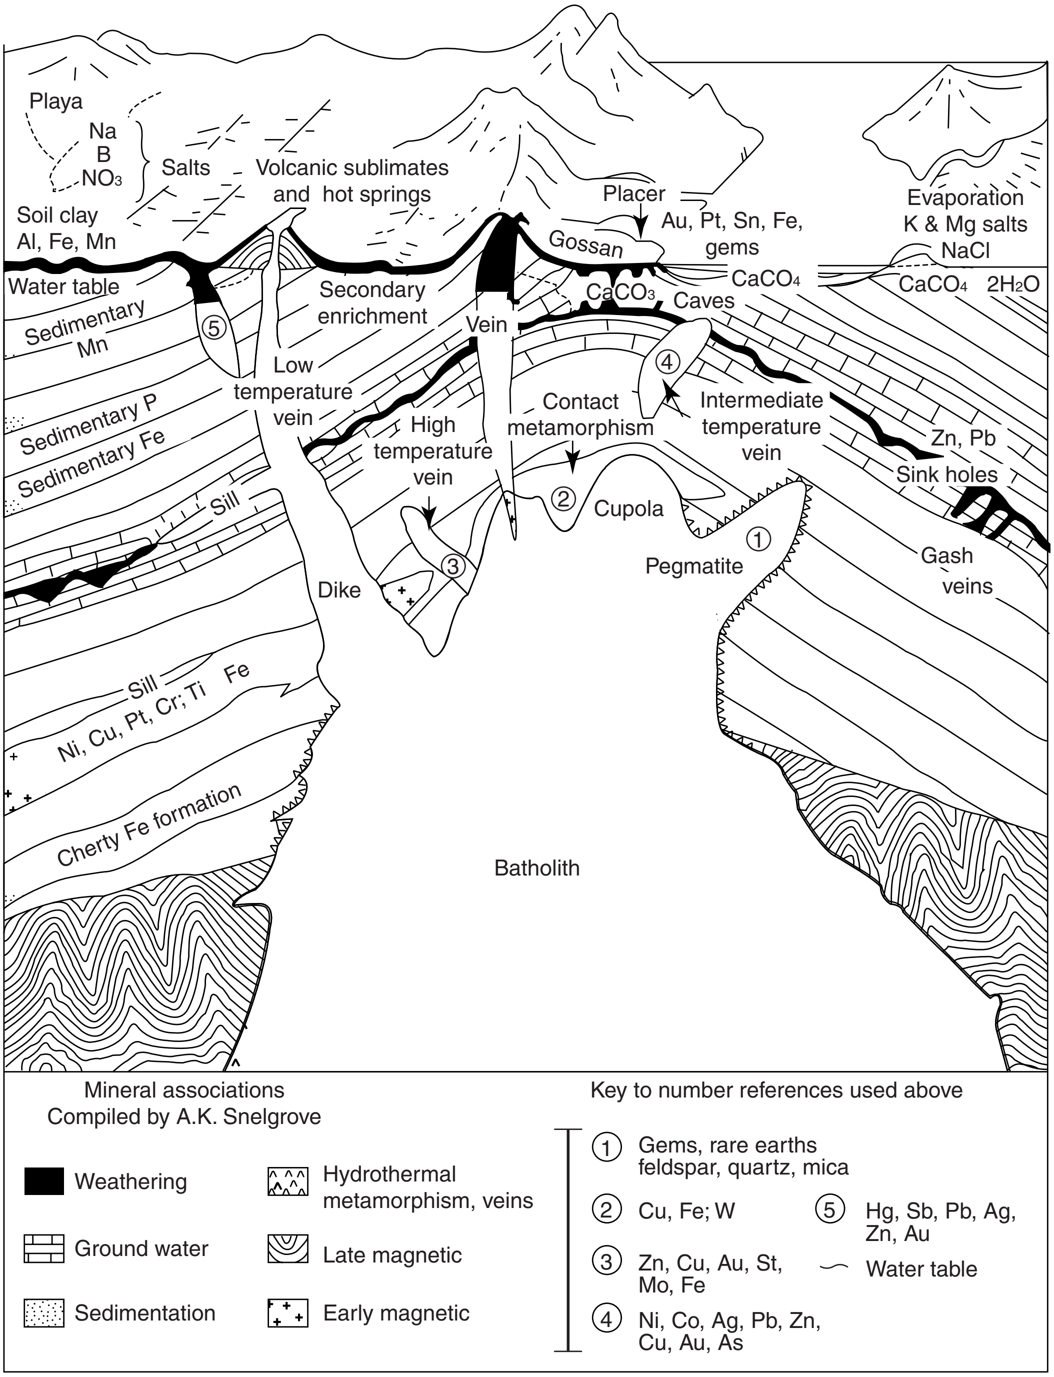


Fig. 1. Diagrammatic illustration of the origin of ore deposits. (*Field*)

a lot of ends containing many short segments are suppressed since the configurational energy is large when n_{10} is large and this leads to a small Boltzmann factor for this configuration.

The fact that so many diverse phenomena can be correlated and explained by such a simple model makes it possible to develop tables of equivalent thermodynamic properties. This was first done by Yang and Lee who showed the equivalence between the properties of the lattice gas and Ising ferromagnet. Hill extended their analogies to the case of binary liquid mixtures. After the development of the helix-coil transition theory by Zimm and Bragg and others, Peticolas gave a corresponding table of equivalent thermodynamic properties between polymers and associative colloids. Thus the force-length curve for a helical polymer is the one dimensional analogue of the three dimensional pressure-volume curve for gas condensation and is equivalent to the chemical potential-mole-fraction curve for the associative linear colloid.

ORES. Mineral aggregates in which the valuable metalliferous minerals are sufficiently abundant to make the aggregates worth mining. Types and origins of ore deposits are illustrated in Fig. 1. See also **Copper**; and **Iron**.

ORGANELLE. A portion of a cell having specific functions, distinctive chemical constituents, and characteristic morphology; it is a unit subsystem of a cell. Examples are mitochondria and chromosomes. Organelles are often closely associated with enzymes. The lysosome (an enzyme-bearing organelle) has been synthesized.

ORGANIC CHEMISTRY. The term *organic*, which means *pertaining to plant or animal organisms*, was introduced into chemical terminology as a convenient classification of substances derived from plant or animal sources. Early it was believed that organic compounds could arise only through the operation of a vital force inherent in the living cell. However, Wöhler discovered in 1828 that the organic compound urea (see also **Wöhler, Friedrich (1800–1882)**), identified in urine by Rouelle in 1773, could be produced by heating the inorganic salt ammonium cyanate:

$$\underset{\text{Ammonium cyanate}}{NH_4{}^+OCN^-} \longrightarrow \underset{\text{Urea}}{H_2NCONH_2}$$

Subsequently, the association of organic compounds only with living organisms was discontinued.

The term *organic* has persisted, but the modern definition of *organic chemistry* has changed to mean the *chemistry of carbon compounds*. Sometimes a few carbon compounds are excluded from this category, such as carbon dioxide, CO_2; metal carbonates, e.g., Na_2CO_3; carbonyls, e.g., $Ni(CO)_4$; cyanides, e.g., KCN; carbides, e.g., CaC_2; and a few others, but this exclusion is somewhat arbitrary. The designation *organic* is still pertinent because the chemistry of carbon compounds is more important to everyday life than that of any other element.

The uniqueness of carbon stems from its ability to form strong carbon-carbon bonds that remain strong when the carbon atoms are simultaneously bonded to other elements. Whereas both the carbon-hydrogen and carbon-fluorine compounds CH_3CH_3 and CF_3CF_3 are highly stable and relatively unreactive, the corresponding compounds in which the carbon atoms are replaced by boron, silicon, phosphorus, and others either are thermodynamically unstable or highly reactive.

Theoretically, an infinite number of different carbon compounds can exist. Carbon atoms alone or in combination with other atoms, such as oxygen, nitrogen, etc., can join to form linear, branched, and cyclic chains of nearly any length. One, two, or three bonds may be shared between two carbon atoms. In most stable organic compounds, the total number of bonds to each carbon atom is four.

Classification of Organic Compounds

A subject with the wide scope that characterizes organic chemistry requires a logical approach to its organization so that knowledge can be gathered and applied manageably. Molecular structure has become the key method for classifying this subject. Scientists use two-dimensional diagrams or three-dimensional models to depict molecular structures. Although these analogies are sometimes crude representations of actual molecules, they are useful for communicating information about the molecules. Structural diagrams characteristic of some basic types of organic molecules are shown in Table 1. A more detailed discussion on naming organic compounds is given later.

The compounds shown in Table 1 contain only carbon and hydrogen and are called hydrocarbons. Most organic compounds that contain other kinds of atoms in addition to carbon and hydrogen are considered as formally derived from hydrocarbons in which a hydrogen atom has been replaced by another atom or collection of atoms. However, these derivatives usually are not formed directly from the hydrocarbons. The other atoms usually are referred to as functional groups. A group of compounds having the same functional group is referred to as a family. Table 2 shows a number of such families. The R and R' in the formulas of Table 2 represent any hydrocarbon in which a hydrogen atom has been removed from the position to which the functional group is attached.

Molecules with common features also are grouped into more specialized families. The compounds in one such family, carbohydrates, contain only carbon, hydrogen, and oxygen. The hydrogen and oxygen atoms are in the same ratio as in water (2H:1O), hence the suffix *-hydrate*. Other specialized families include terpenes, alkaloids, steroids, lipids, proteins, enzymes, vitamins, and organometallic compounds.

Although these classifications are important for education and documentation in organic chemistry, research usually is rather specialized.

It is often oriented in a practical way, not to the structure of compounds or to the kinds of atoms they contain, but to the manner in which the compounds are used. A partial list of such uses includes plastics, pharmaceuticals, insecticides, fungicides, herbicides, paints, petroleum, fuels, dyes, photography, and adhesives. See Fig. 1.

An important area of organic chemistry is that which deals with life and living substances. Organized under the title biochemistry, this is a subfield of organic chemistry, since most of the compounds involved contain carbon. Numerous advances have been made recently in biochemistry, and of all the areas of organic chemistry it probably will produce the greatest progress in the next decade. Noteworthy advances can be expected in the areas of biochemistry relating to medicine and human health. Some of the categories along which the study of biochemistry is organized are proteins, peptides, amino acids, nucleoproteins, enzymes, nucleotides, carbohydrates, lipids, steroids, carotenoids, porphyrins, nucleic acids, vitamins, and hormones. These topics are described in detail elsewhere in this volume.

Theoretical organic chemistry is another field that has progressed rapidly in recent years. Chemists have derived molecular orbital symmetry rules that allow understanding and predicting the stereochemistry and relative rates of organic reactions in electronic ground and excited states. In a ground state molecule, all electrons are in their lowest energy levels, whereas, in an excited state molecule, at least one electron is in a higher energy level. For example, the Woodward-Hoffman orbital symmetry rules for concerted reactions predict that ground state (thermal) cycloaddition reactions involving $4n + 2$ (where n is an integer) π-electrons, and excited state (photochemical) cycloaddition reactions that involve $4n$ π-electrons, may occur via a concerted process (Scheme 1).

A concerted process or reaction occurs without the involvement of an intermediate. The stereochemistry of the reactants is retained in the product, and the reaction is usually more facile than a comparable nonconcerted reaction. The other combinations of ground state, excited state, $4n + 2$, $4n$ reactions cannot be concerted reactions.

Another area that has received increased attention is environmental organic chemistry. Reactions that organic compounds undergo when they are released to the environment are becoming as significant as the reactions by which the compounds are prepared or the reactions that take place in the use of the compounds. Some environmentally important types of reactions are hydrolysis, oxidation, sunlight-initiated photochemical decomposition, and biodegradation by microbes.

Only a limited discussion of the large field of organic chemistry can be given in the space allotted for this article. Consult alphabetical index for further information on specific topics. The reader is also directed to the references at the end of this article for examples of more detailed treatments of organic chemistry. Refs. Schmerling; Richey; and Morrison et al. represent texts that treat organic chemistry at elementary, intermediate, and advanced levels, respectively.

Nomenclature of Organic Compounds

With the foregoing review in mind, the reader will appreciate the difficulties associated with naming organic molecules. Originally, chemical names

TABLE 1. EXAMPLES OF STRUCTURAL DIAGRAMS OF HYDROCARBONS

Type of compound	Formula	Name
Linear alkane	 or $CH_3CH_2CH_2CH_2CH_2CH_3$ or $CH_3(CH_2)_4CH_3$ or n-C_6H_{14} or	*n*-Hexane
Branched alkane	 or 	2-Methylpentane
Monocyclic alkane	 or 	Cyclohexane
Bicyclic alkane		Bicyclo[2.2.1] heptane or Norbornane
Polycyclic alkane		Pentacyclo [5.3.0.0.^{2,5} – 0^{3,9}0^{4,8}]decane or 1,3-Bishomocubane
Alkene	 or 	*trans*- 2-Pentene
Alkyne	$CH_3C \equiv CCH_2CH_3$ or 	2-Pentyne
Aromatic	 or 	Benzene
Polymer	$X(CH_2)_n$ Y ($n \geq 1000$, X and Y vary according to how polymer was prepared)	Polymethylene or Polyethylene

TABLE 2. EXAMPLES OF SOME MAJOR FAMILIES OF ORGANIC COMPOUNDS

Family	General structure	Family	General structure
Alcohol, phenol	ROH	Isocyanate	RN=C=O
Ether	RoR′	Thiol	RSH
Aldehyde	O ‖ RCH	Sulfide	RsR′
Ketone	O ‖ RCR′	Sulfoxide	O ‖ RSR′
Carboxylic acid	O ‖ RCOH	Sulfone	O ‖ RSR′ ‖ O
Ester	O ‖ RCOR′	Sulfonic acid	O ‖ RSOH ‖ O
Amine	RNH_2	Chloride	RCl
Amide	O ‖ $RCNH_2$	Bromide	RBr
Nitrile	$RC \equiv N$	Iodide	RI
Isonitrile	$R\overset{+}{N} \equiv \overline{C}$	Organolithium	Rli
Nitro compound		Heterocycle	
Nitroso compound	RN=O	(Y is an atom othan than carbon such as N, O, Si, P, S, etc.: Y is bonded to R at two or more positions.) Examples:	
Imine	NH ‖ RCR′		
Azo compound	RN=NR′		 , pyridine;
Diazo compound	$RR'C{=}\overset{+}{N}{=}\overline{N}$		
Diazonium salt	$RN \equiv N^+X^-$ (anion)		 , thiophene.

were indicative of the sources of compounds. For example, *catechol* was the name given to a compound isolated from the natural product *gum catechu*. Chemists have coined other nonsystematic names such as *cubane* or *basketene* to pictorially describe molecules. These nonsystematic names are called common or trivial names. The names *phenol, acetic acid*, and *styrene* are also nonsystematic but are widely understood in chemistry.

As the number of known organic molecules increased, a systematic approach to nomenclature was required. To minimize confusion in communicating chemical information, a name should be consistent with other systems in use and should clearly define the structure of a molecule. Specialists in organic chemistry have developed nomenclatures that are logical for their disciplines, thus devising systems for naming alcohols, antibiotics, carboxylic acids, etc.

Systematic nomenclature on a worldwide scale began in 1892 when a committee of the International Chemical Congress established a set of standards known as the Geneva Rules for naming organic compounds. The International Union of Pure and Applied Chemistry (IUPAC) http://www.iupac.org/dhtml_home.html was formed in 1919 and further developed this nomenclature system. In 1886 in the United States, the American Chemical Society (ACS) established a Committee on

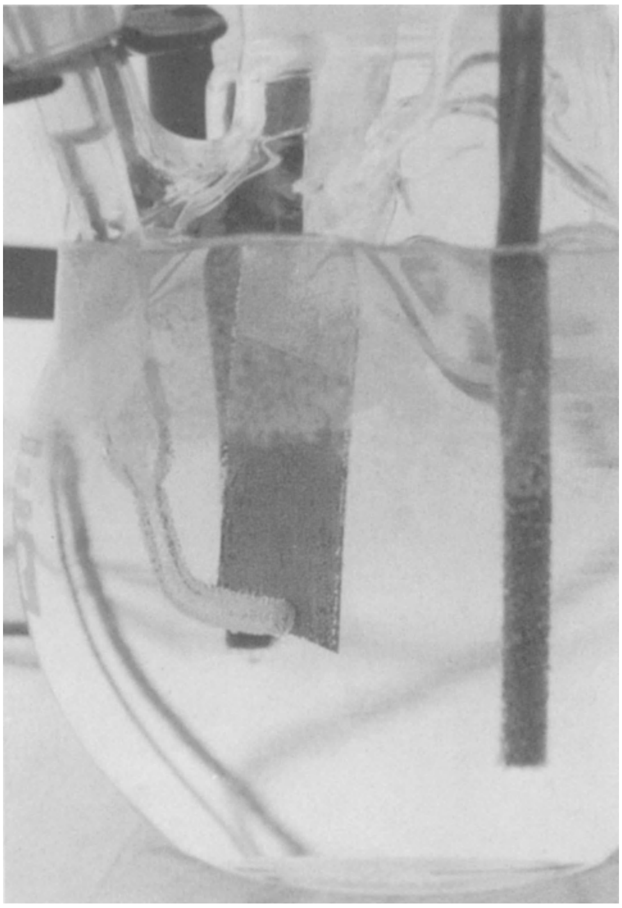

Fig. 1. Apparatus for testing corrosion of metal coated with a plastic. (*The Dow Chemical Company*)

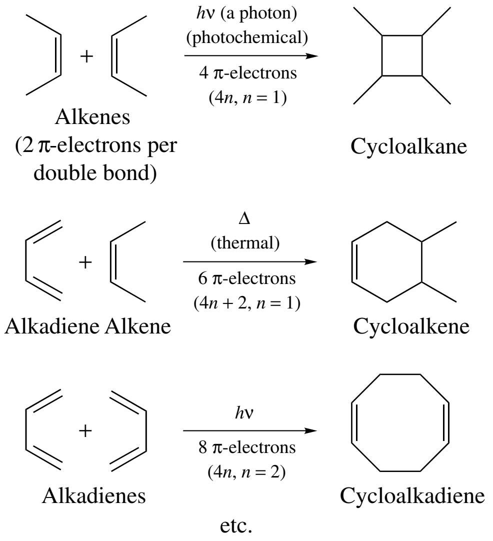


Scheme 1

Nomenclature. The ACS and IUPAC have developed parallel rules for naming organic compounds.

Alternative rules within the latter system may allow assigning more than one unambiguous name to a compound. The controlled alphabetic listing in the *Chemical Substances Index* of Chemical Abstracts Service (CAS), a part of the ACS, requires that each compound have a unique name. This convention ensures that all information for a single compound such as $H_2n{-}CH_2{-}CH_2{-}OH$, which can be unambiguously named 2-aminoethanol, 2-aminoethyl alcohol, 2-hydroxyethylamine, etc., will appear in the index under one name: ethanol, 2-amino-. Because universal nomenclature systems are complex and sometimes inconvenient, some chemists have retained the older methods of naming molecules. These older names are used in the parts of this section that do not deal specifically with nomenclature.

The following paragraphs introduce some basic areas of organic chemical nomenclature. Further details can be found in *Chemical Substances Index Names* and *Nomenclature of Organe Chemistry* listed and end of this entry.

In addition to trivial names, some of the other categories of organic compound names are:

Generic name: one that indicates a class of compounds; e.g., *alkanes, esters*.
Parent name: a base from which other names are derived; e.g., *ethanol*, from *ethane; butanoic acid*, from *butane*.
Systematic name: a name composed of syllables defining the structure of a compound; e.g., *chlorobenzene*, 2-*methylhexane*.
Substitutive name: one describing replacement of hydrogen by a group or element; e.g., 1-*methylnaphthalene*, 2-*chloropropane*.
Replacement name: a name describing compounds that have carbon replaced by a hetero atom; also called “a” nomenclature; e.g., 2-*azaphenanthrene*.
Subtractive name: one that indicates removal of specified atoms; e.g., in the aliphatic series names ending in *-ene* or *-yne*, such as *ethene* or *ethyne*, and names involving *anhydro-*, *dehydro-, deoxy-, nor-,* etc.
Additive name: one that signifies addition between molecules and/or atoms without replacement of atoms; e.g., *styrene oxide*.
Conjunctive name: a combination of two names, one of which represents a cyclic structure and the other an acyclic chain, with one hydrogen atom removed from each; e.g., *benzenemethanol*.
Fusion name: a combination that results from linking with an “o” two names of cyclic systems fused by two or more common atoms; e.g., *benzofuran*.
Multiplicative name: nomenclature describing the symmetrical repetition of radicals about a central unit; e.g., 2, 2′-*oxybis* (*ethanol*).
Hantzsch-Widman name: a name devised by Hantzsch and Widman for describing heterocyclic systems, in which the prefix denotes a hetero atom(s) and the suffix denotes the ring size and degree of saturation; e.g., *oxirene, aziridine*.
Von Baeyer name: a name that describes alicyclic bridged systems; e.g., *bicyclo* [2.2.1]*heptane*.

The procedure for naming a compound involves some or all of the following steps, depending on the structure of the molecule under study: (1) the type of nomenclature to be used (conjunctive, multiplicative, etc.) is chosen; (2) the parent structure is named; (3) the prefixes, suffixes, and names of functional and substituent groups that were not included in (2) are attached; (4) the numbering is completed.

Hydrocarbons

Acyclic Hydrocarbons. A knowledge of the structural features of hydrocarbon skeletons is basic to the understanding of organic chemical nomenclature. The generic name of saturated acyclic hydrocarbons, branched or unbranched, is *alkane*. The term *saturated* is applied to hydrocarbons containing no double or triple bonds.

The simplest saturated acyclic hydrocarbon is called methane. Names of the higher, straight-chain (*normal*) homologs of this series contain the termination “-ane,” as shown in Table 3. The structures of the first four members of the series in Table 3 are: CH_4, $CH_3{-}CH_3$, $CH_3{-}CH_2{-}CH_3$, and $CH_3{-}CH_2{-}CH_3$. The structures of subsequent members of this series are formed by inserting additional CH_2 units.

Univalent groups derived from the preceding acyclic hydrocarbons by removal of one hydrogen atom from a terminal carbon atom are named by replacing the ending “-ane” with “-yl.”

EXAMPLES: ethyl $CH_3{-}CH_2{-}$
butyl $CH_3{-}CH_2{-}CH_2{-}CH_2{-}$

A saturated branched acyclic hydrocarbon is named by numbering the longest chain from one end to the other, and the positions of the side chains are indicated by the lowest possible numbers. The numbers precede the group, and are separated from them by a hyphen.

TABLE 3. EXAMPLES OF SATURATED ACYCLIC HYDROCARBONS

Molecular formula	Name	Molecular formula	Name
CH_4	methane	$C_{18}H_{38}$	octadecane
C_2H_6	ethane	$C_{19}H_{40}$	nonadecane
C_3H_8	propane	$C_{20}H_{42}$	icosane
C_4H_{10}	butane	$C_{21}H_{44}$	henicosane
C_5H_{12}	pentane	$C_{22}H_{46}$	docosane
C_6H_{14}	hexane	$C_{23}H_{48}$	tricosane
C_7H_{16}	heptane	$C_{30}H_{62}$	triacontane
C_8H_{18}	octane	$C_{31}H_{64}$	hentriacontane
C_9H_{20}	nonane	$C_{32}H_{66}$	dotriacontane
$C_{10}H_{22}$	decane	$C_{40}H_{82}$	tetracontane
$C_{11}H_{24}$	undecane	$C_{50}H_{102}$	pentacontane
$C_{12}H_{26}$	dodecane	$C_{100}H_{202}$	hectane
$C_{13}H_{28}$	tridecane	$C_{101}H_{204}$	henhectane
$C_{14}H_{30}$	Tetradecane	$C_{102}H_{206}$	dohectane
$C_{15}H_{32}$	pentadecane	$C_{110}H_{222}$	decahectane
$C_{16}H_{34}$	hexadecane	$C_{120}H_{242}$	icosahectane
$C_{17}H_{36}$	heptadecane	$C_{132}H_{266}$	dotriacontahectane
		$C_{200}H_{402}$	dictane

EXAMPLES:

1 2 3 4 5
$CH_3—CH(CH_3)—CH_2—CH_2—CH_3$

2-methylpentane (not 4-methylpentane)

6 5 4 3 2 1
$CH_3—CH(CH_3)—CH_2—CH(CH_3)—CH(CH_3)—CH_3$

2,3,5-trimethylhexane (not 2,4,5-trimethylhexane)

If two groups are attached to the same carbon atom, the number is repeated.

EXAMPLES:

1 2 3 4 5
$CH_3—CH_2—C(CH_3)_2—CH_2—CH_3$

3,3-dimethylpentane (not 3-dimethylpentane)

For some purposes, such as alphabetical listing of basic skeleton names, inverted word order is used.

EXAMPLES: pentane, 2-methyl-
benzene, chloro-

The two propyl groups are distinguished by calling them *normal*-propyl or *n*-propyl, $CH_3{-}CH_2{-}CH_2{-}$, and isopropyl or i-propyl, $[(CH_3)_2{-}CH{-}]$, in common usage. The latter is called 1-methylethyl in systematic nomenclature. The butyl groups are named as follows:

Structure	*Systematic name*	*Trivial name*
$CH_3{-}CH_2{-}CH_2{-}CH_2{-}$	butyl	*n*-butyl
$CH_3—CH(CH_3)—CH_2—$	2-methylpropyl	*i*-butyl
$CH_3—CH_2—CH(CH_3)—$	1-methylpropyl	*s*-butyl (*s* = secondary)
$CH_3—C(CH_3)_2—$	1,1-dimethylethyl	*t*-butyl (*t* = tertiary)

Hydrocarbons that contain one or more double bonds are called "unsaturated," and are named by replacing the ending "-ane" of the corresponding saturated hydrocarbon with the ending "-ene," "-adiene," or "-atriene," etc. The generic names of unsaturated hydrocarbons are *alkene, alkadiene, alkatriene*, etc. The double bonds receive the lowest possible numbers.

In the following examples, the names listed in the *Chemical Substances Index* of the CAS system are given first. Other names are given in parentheses.

EXAMPLES:

2-butene (2-butylene): 1 2 3 4 $CH_3—CH{=}CH—CH_3$

1,4-hexadiene: 1 2 3 4 5 6 $CH_2{=}CH—CH_2—CH{=}CH—CH_3$

ethene (ethylene): $CH_2{=}CH_2$

2-methyl1-1,3-butadiene (isoprene): 1 2 3 4 $CH_2{=}C(CH_3)—CH{=}CH_2$

Hydrocarbons containing one or more triple bonds are named by replacing the ending "-ane" of the corresponding saturated hydrocarbon with the ending "-yne," "-adiyne," "-atriyne" etc. The triple bonds receive the lowest possible numbers. Double bonds take precedence over triple bonds when there is a choice in numbering.

EXAMPLES:

1-butyne: 1 2 3 4 $CH{\equiv}C—CH_2—CH_3$

1-hexane-3,5-diyne: 1 2 3 4 5 6 $CH_2{=}CH—C{\equiv}C—C{\equiv}CH$

Unsaturated branched acyclic hydrocarbons are numbered in the same manner as alkanes. The longest chain is chosen as the parent. If the alkene or alkyne contains two or more chains of equal length, the chain containing the maximum number of double bonds is chosen as the parent.

Univalent or multivalent groups derived from alkenes and alkynes are named as follows:

EXAMPLES:

ethenyl (vinyl): 2 1 $CH_2{=}CH—$

ethynyl: 2 1 $CH{\equiv}C—$

2-propynyl: 3 2 1 $CH{\equiv}C—CH_2—$

methylidyne: $CH{\equiv}$

ethylidene: $CH_3{-}CH{=}$

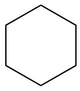
ethylidyne: $CH_3{-}C{\equiv}$

Alicyclic Hydrocarbons. Saturated monocyclic hydrocarbons, or "cycloalkanes," are named by attaching the prefix "cyclo" to the name of the acyclic unbranched alkane.

EXAMPLES:

cyclopropane

cyclohexane

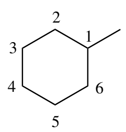


Univalent groups derived from unsubstituted cycloalkanes are named *cyclopropyl, cyclohexyl*, etc., in a manner analogous to that used for naming acyclic alkanes. The carbon atom with the free valence is numbered as 1.

EXAMPLES:

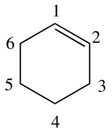
cyclopropyl

cyclohexyl

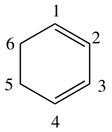


Unsaturated monocyclic hydrocarbons are named by substituting "-ene," "-adiene," "-atriene," "-yne," "-adiyne," etc., in the name of the corresponding cycloalkane. Double and triple bonds are given numbers as low as possible.

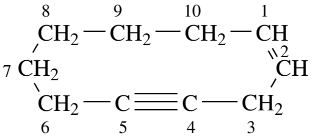
EXAMPLES: cyclohexene



1,3-cyclohexadiene

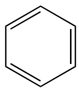


1-cyclodecen-4-yne

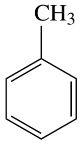


Aromatic Hydrocarbons. Aromatic hydrocarbons generally are considered those which have the characteristic chemical properties of benzene. Many such compounds are known more commonly by their trivial names than by their systematic names.

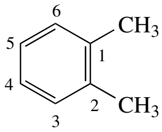
EXAMPLES: benzene



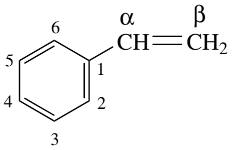
methylbenzene (toluene)



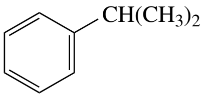
1,2-dimethylbenzene (*o*-xylene)



ethenylbenzene (styrene)



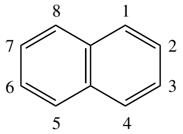
(1-methylethyl)benzene (cumene)



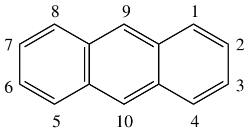
The terms *ortho, meta*, and *para* (abbreviated *o, m*, and *p*) refer to the location of substituents on the benzene ring and are equivalent to 1,2-, 1,3-, and 1,4-substitution in systematic nomenclature, respectively. The lowest numbers possible are given to substituents.

Fused aromatic systems are named by prefixing the largest parent trivial names with combining forms such as benz(o)- and naphth(o)-. Hydrocarbons that contain five or more fused benzene rings in a linear arrangement are named from a numerical prefix followed by "-acene."

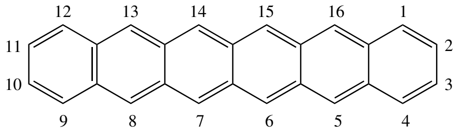
EXAMPLES: naphthalene



anthracene

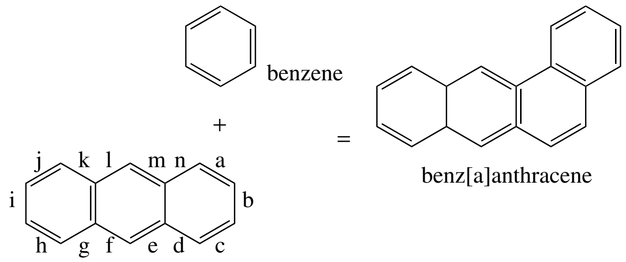


hexacene



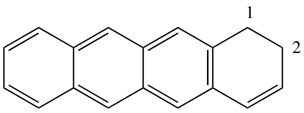
Fusion prefixes are used to designate to which side of the parent hydrocarbon a substituent ring is attached.

EXAMPLES:

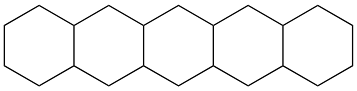


Hydrogenation products of complex aromatic ring systems that are not treated as alicyclic hydrocarbons are named by prefixing "dihydro," "tetrahydro," etc., to the parent name. The lowest locants are used. "Perhydro" is used in trivial nomenclature to indicate a fully hydrogenated compound.

EXAMPLES: 1,2-dihydronaphthacene

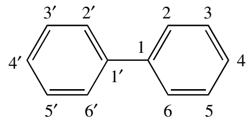


docosahydropentacene (perhydropentacene)

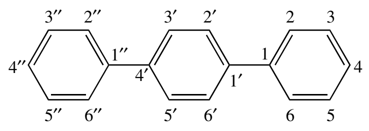


Multiple unsubstituted assemblies of benzene rings are named by using the appropriate prefix with the radical name "phenyl."

EXAMPLES: 1,1′-biphenyl

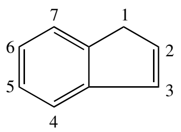


1,1′:4′,1″-terphenyl (*p*-terphenyl)



Indicated hydrogen in aromatic systems is assigned to angular or nonangular positions when needed to accommodate structural features in systematic nomenclature. The lowest locants are used.

EXAMPLE: 1-*H*-indene (not 3*H*-)

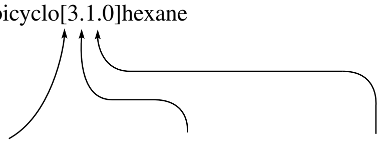


Bridged Hydrocarbon Ring Systems. These compounds are named by prefixing the parent ring with "bicyclo," "tricyclo," etc., or in some complex

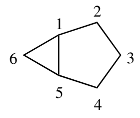
cases by using prefixes that denote the nature of the bridges. The three numbers in brackets denote the number of carbon atoms in each of the three bridges in descending order.

EXAMPLES:

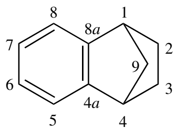
bicyclo[3.1.0]hexane



3 C-atoms (C2,3,4) between bridgeheads C1 and C5	1 C-atom (C6) between bridgeheads C1 and C5	0 C-atoms between bridgeheads C1 and C5

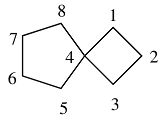


1,2,3,4-tetrahydro-1,4-methanonaphthalene

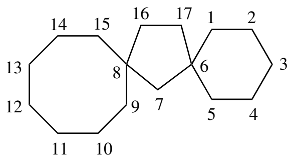


Spiro Hydrocarbon Ring Systems. Spiro systems contain pairs of rings or ring systems that have only one atom (a "spiro atom") in common. The name of the simplest monospiro system is formed by prefixing the acyclic hydrocarbon name with "spiro" and numerals separated by periods. The numerals are given in ascending order to define the number of atoms in each ring linked to the spiro atom. Numbering begins at the atom next to the spiro atom in the smallest ring for monospiro systems.

EXAMPLES: spiro[3,4]octane



dispiro[5.1.7.2]heptadecane



Carboxylic Acids and Their Anhydrides

Acids are named according to the Geneva ("-oic") or "-carboxylic" system. They are regarded as derived from parent hydrocarbons having the same number of carbon atoms so that CH_3 is replaced by COOH. The carbon atom of the carboxyl group is assigned number one in aliphatic monocarboxylic acids. In an alternative numbering system, the Greek letters *alpha, beta*, etc., are assigned to the second, third, etc., carbon atoms, respectively, leading away from the −COOH group. When chain branching is present, the longest chain containing the carboxylic acid group at one end is chosen for naming the molecule. Unsaturated aliphatic acids are named so the longest chain includes the maximum number of unsaturated linkages. Double bonds are given preference over triple bonds. Trivial names are retained for some common molecules.

EXAMPLES:

formic acid — HCOOH

acetic acid — $\overset{2}{CH_3}\ \overset{1}{C}OOH$

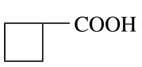
hexanoic acid (caproic acid) — $CH_3(CH_2)_4COOH$

octadecanoic acid (stearic acid) — $CH_3(CH_2)_{16}COOH$

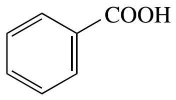
2-propenoic acid (acrylic acid) — $\overset{3}{CH_2}{=}\overset{2}{C}H\overset{1}{C}OOH$

2-methylbutanoic acid — $\overset{4}{CH_3}\overset{3}{CH_2}\overset{2}{C}H\overset{1}{C}OOH$ (with CH_3 on C2)

cyclobutanecarboxylic acid



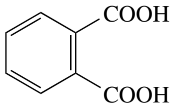
benzoic acid



ethanedioic acid (oxalic acid) — HOOC−COOH

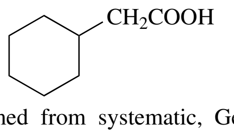
butanedioic acid (succinic acid) — $HOOC{-}CH_2CH_2{-}COOH$

1,2-benzenedicarboxylic acid (phthalic acid)



Conjunctive nomenclature may be used for naming cyclic acids. It is applied to any ring system attached by a single bond to one or more acyclic hydrocarbon chains, each of which bears only one principal functional group.

EXAMPLE: cyclohexaneacetic acid

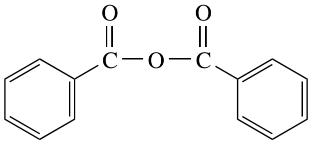


Acid anhydride names are formed from systematic, Geneva, trivial, conjunctive, or other type of acid names.

EXAMPLES: propanoic acid anhydride (propionic anhydride)

CH_3CH_2CO
\
O
/
CH_3CH_2CO

benzoic acid anhydride (benzoic anhydride)



See also **Carboxylic Acids**.

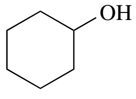
Alcohols

Monohydric alcohols are named by adding "-ol" to a molecular skeleton name. Carbon chains, unsaturation, etc., are numbered in a manner analogous to that used for carboxylic acids. (See preceding section.)

EXAMPLES:

methanol (methyl alcohol) — CH_3OH

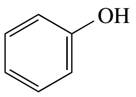
cyclohexanol (cyclohexyl alcohol)



2-propen-1-ol (allyl alcohol) — $\overset{3}{CH_2}{=}\overset{2}{C}H\overset{1}{C}H_2OH$

See also **Alcohols**.

The simplest aromatic hydroxy compound is called phenol:



Esters

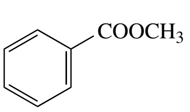
Simple esters are named on the basis of their alcohol and acid functions. Carbon chains, unsaturation, etc., are numbered in a manner analogous to that used for carboxylic acids.

EXAMPLES:

ethyl acetate (inverted name: acetic acid, ethylester) — $CH_3COOC_2H_5$

propyl 2-butenoate — $\overset{4}{C}H_3\overset{3}{C}H{=}\overset{2}{C}H\overset{1}{C}OOCH_2CH_2CH_3$

methyl benzoate



See also **Esters, Organic**.

Ethers

Alkoxy compounds are commonly called ethers. In current CAS nomenclature they are named as derivatives of functional parent compounds, hydrocarbons, etc., by use of "oxy" radicals.

EXAMPLES:

1,1′-oxybis(ethane) (ethyl ether or diethyl ether)	$C_2H_5OC_2H_5$
(hexyloxy)cyclopropane (cyclopropyl hexyl ether)	
methoxybenzene (anisole)	
See also **Ethers**.

Aldehydes are named from the corresponding acids by use of "-carboxaldehyde" and "-al" suffixes.

EXAMPLES:

acetaldehyde	CH_3CHO
2-butenal	$\overset{4}{C}H_3\overset{3}{C}H=\overset{2}{C}H\overset{1}{C}HO$
3-methylbenzaldehyde	
See also **Aldehydes**.

Ketones

Ketones are named by use of the characteristic suffix "-one."

EXAMPLES:

2-propane (acetone)	$\overset{1}{C}H_3\overset{2}{C}O\overset{3}{C}H_3$
1-hexen-1-one (butylketene)	$CH_3(CH_2)_3\overset{2}{C}H=\overset{1}{C}O$
4-cyclopentyl-2-butanone	diphenylmenthanone (benzophenone)	
See also **Ketones**.

Peroxides

Simple peroxides are named as follows:

EXAMPLES:

ethyl methyl peroxide	$C_2H_5OOCH_3$
benzoyl peroxide	
Halogenated Compounds

Hydrocarbons, esters, etc., which have one or more hydrogen atoms replaced by a halogen atom are named so that the substituents have the lowest possible numbers. When multiple functions are present, they are numbered according to precedences established by IUPAC or CAS nomenclature rules. Both trivial and systematic nomenclatures are used.

EXAMPLES:

chloromethane (methyl chloride)	CH_3Cl
2-iodobutane (*sec*- butyl iodide)	$\overset{1}{C}H_3\overset{2}{C}H(I)\overset{3}{C}H_2\overset{4}{C}H_3$
1-bromo-2-fluorobenzene	3-chloropentanoic acid (β-chlorovaleric acid)	$\overset{5}{C}H_3\overset{4}{C}H_2\overset{3}{C}H(Cl)\overset{2}{C}H_2\overset{1}{C}OOH$
chloroethane (vinyl chloride)	$CH_2{=}CHCl$
1,1-dichloroethene (vinylidene chloride)	$CH_2{=}CCl_2$
tetrabromomethane (carbon tetrabromide)	CBr_4

Acid halides are named as follows:

EXAMPLES:

acetyl chloride	CH_3COCl
6-heptenoyl chloride	$\overset{7}{C}H_2=\overset{6}{C}H(CH_2)_4\overset{1}{C}OCl$
cyclohexanecarbonyl bromide	benzoyl fluoride	
See also **Chlorinated Organics**.

Nonheterocyclic Nitrogen Compounds

Amines are named by adding the suffix "-amine" either to the name of the hydrocarbon or to the hydrocarbon radical. A second system names all amines as derivatives of primary amines.

EXAMPLES:

methanamine (methylamine)	CH_3NH_2
N, *N*-dipropyl-1-propanamine (tripropylamine)	$(CH_3CH_2CH_2)_3N$
benzenamine (aniline)	N-ethylcyclohexanamine (*N*-ethylcyclohexylamine)	
Imines are named from the hydrocarbon by the addition of the suffix "-imine."

EXAMPLES:

ethanimine	$\overset{2}{C}H_3\overset{1}{C}H=NH$
2,4-cyclopentadien-1-imine	
See also **Amines**.

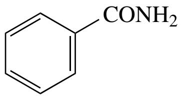
Names of amides are based on the corresponding acids. Thus, "-oic acid" becomes "-amide," and "-carboxylic acid" becomes "-carboxamide."

EXAMPLES:

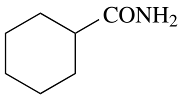
acetamide

2 1
CH_3CONH_2

benzamide



cyclohexanecarboxamide



N-methylpentadecanamide

15 1 N
$CH_3(CH_2)_{13}CONHCH_3$

N,*N*-dimethyl-2,4-pentadienamide

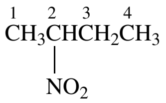
5 4 3 2 1 N
$CH_2{=}CHCH{=}CHCON(CH_3)_2$

See also **Amides**.

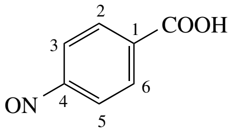
Nitro and nitroso compounds are named so that the substituents have the lowest possible numbers.

EXAMPLES:

2-nitrobutane



4-nitrosobenzoic acid



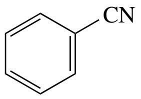
See also **Nitro- and Nitroso-Compounds**

Nitrile names are formed from common names of carboxylic acids.

EXAMPLES:

acetonitrile CH_3CN

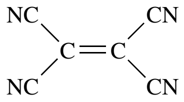
benzoinitrile (phenyl cyanide)



3-butenenitrile

4 3 2 1
$CH_2{=}CHCH_2CN$

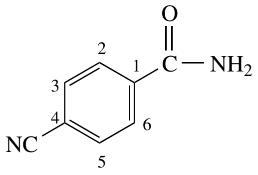
ethenetetracarbonitrile (tetracyanoethylene)



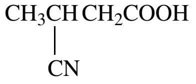
In the presence of more senior functional groups, the nitrile function is expressed by the prefix "cyano."

EXAMPLES:

4-cyanobenzamide



3-cyanobutanoic acid

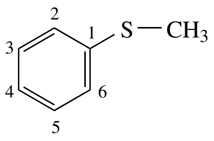


Nonheterocyclic Sulfur Compounds

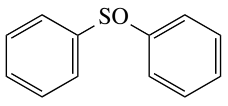
Sulfur compounds are named similarly to oxygen compounds.

EXAMPLES:

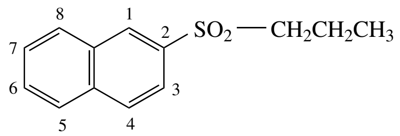
(methylthio)benzene (methyl phenyl sulfide)



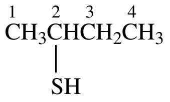
1,1′-sulfinylbis(benzene) (diphenyl sulfoxide)



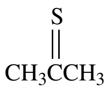
2-(propylsulfonyl)naphthalene (2-naphthyl propyl sulfone)



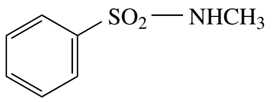
2-butanethiol (2-mercaptobutane)



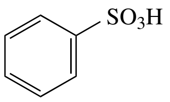
2-propanethione (thioacetone)



N-methylbenzenesulfonamide



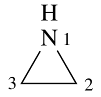
benzenesulfonic acid



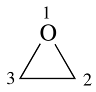
See also **Sulfonic Acids**.

Heterocyclic Compounds

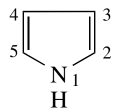
Some of the common heterocyclic nitrogen, oxygen, and sulfur compounds and their numbering systems are shown:



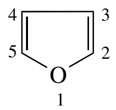
aziridine (ethylenimine)



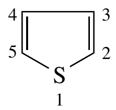
oxirane (ehylene oxide)



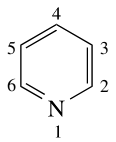
1*H*-pyrrole



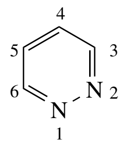
furan



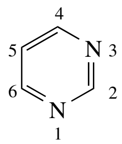
thiophene



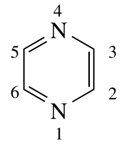
pyridine



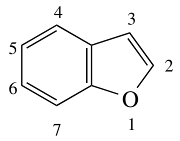
pyridazine



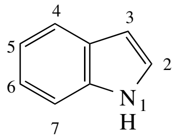
pyrimidine



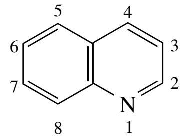
pyrazine



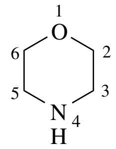
benzofuran



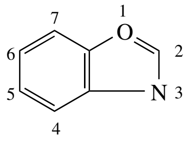
1*H*-indole



quinoline



morpholine



benzoxazole

Organic Reaction Mechanisms and Processes

Many reactions occur in which one organic compound is converted into another. The molecular details of the intermediate steps by which compounds are converted into new products are called reaction mechanisms. The four broad classes of reaction mechanisms are: cationic, anionic, free radical, and multicenter processes in which neither charged species nor odd electron species is involved. Examples of each type will be given, but many variations can exist within each type. Also, varying degrees of sophistication exist in our knowledge of the exact reaction pathways that organic compounds follow. The examples discussed show only the major steps involved.

Cationic and anionic mechanisms involve species that have either positive or negative charges, respectively (heterolytic reactions). An example of a reaction that proceeds via a cationic mechanism is the hydrolysis of *t*-butyl bromide (Scheme 2).

SCHEME 2

$$\underset{t\text{-Butyl bromide}}{(CH_3)_3CBr} + \underset{\text{Water}}{H_2O} \longrightarrow \underset{t\text{-Butyl alcohol}}{(CH_3)_3COH}$$

$$+ \underset{\text{Isobutylene}}{CH_3)_2\ C = CH_2} + \underset{\text{Hydrogen bromide}}{HBr}$$

Mechanism:

$$(CH_3)_3CBr \longrightarrow (CH_3)_3C^+ + Br^-$$

$$(CH_3)_3C^+ + H_2O \longrightarrow (CH_3)_3COH + H^+$$

$$(CH_3)_3C^+ \longrightarrow (CH_3)_2C{=}CH_2 + H^+$$

The addition of methanol to methyl acrylate in the presence of sodium methoxide is an example of a reaction that proceeds by an anionic mechanism (Scheme 3).

SCHEME 3

$$\underset{\text{Methyl acrylate}}{CH_2{=}CH\overset{O}{\overset{\|}{C}}OCH_3} + \underset{\text{Methanol}}{CH_3OH} \xrightarrow[\text{Sodium methoxide}]{CH_3O\text{–}Na^+} \underset{\text{Methyl }\beta\text{-methoxypropionate}}{CH_3OCH_2CH_2\overset{O}{\overset{\|}{C}}OCH_3}$$

$$CH_2{=}CH\overset{O}{\overset{\|}{C}}OCH_3 + CH_3O^- \longrightarrow CH_3OCH_2CH{=}\overset{O^-}{\overset{|}{C}}OCH_3$$

$$CH_3OCH_2CH{=}\overset{O^-}{\overset{|}{C}}OCH_3 + CH_3OH \longrightarrow CH_3OCH_2CH_2\overset{O}{\overset{\|}{C}}OCH_3 + CH_3O^-$$

Mechanism:

Free radical (homolytic) reactions involve species with an unpaired electron. The ultraviolet-light-initiated reaction of methane with chlorine is an example (Scheme 4).

SCHEME 4

$$\underset{\text{Methane}}{CH_4} + \underset{\text{Chlorine}}{Cl_2} \xrightarrow{hv} \underset{\text{Methyl chloride}}{CH_3Cl} + \underset{\text{Hydrogen Chloride}}{HCl}$$

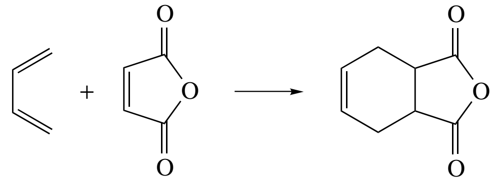
$$Cl_2 \xrightarrow{hv} 2Cl.$$

$$Cl\cdot + CH_4 \longrightarrow CH_3\cdot + HCl$$

$$CH_3\cdot + Cl_2 \longrightarrow CH_3Cl + Cl\cdot$$

A number of reactions do not seem to belong to any of the above mechanistic types. Such processes are referred to as multicenter reactions. The Diels-Alder cycloaddition reaction of 1,3-butadiene with maleic anhydride is an example (Scheme 5). No charged or odd electron intermediates seemingly are involved in this reaction.

SCHEME 5



1,3-Butadiene Maleic anhydride Cyclohex-4-ene-1,2-dicarboxylic anhydride

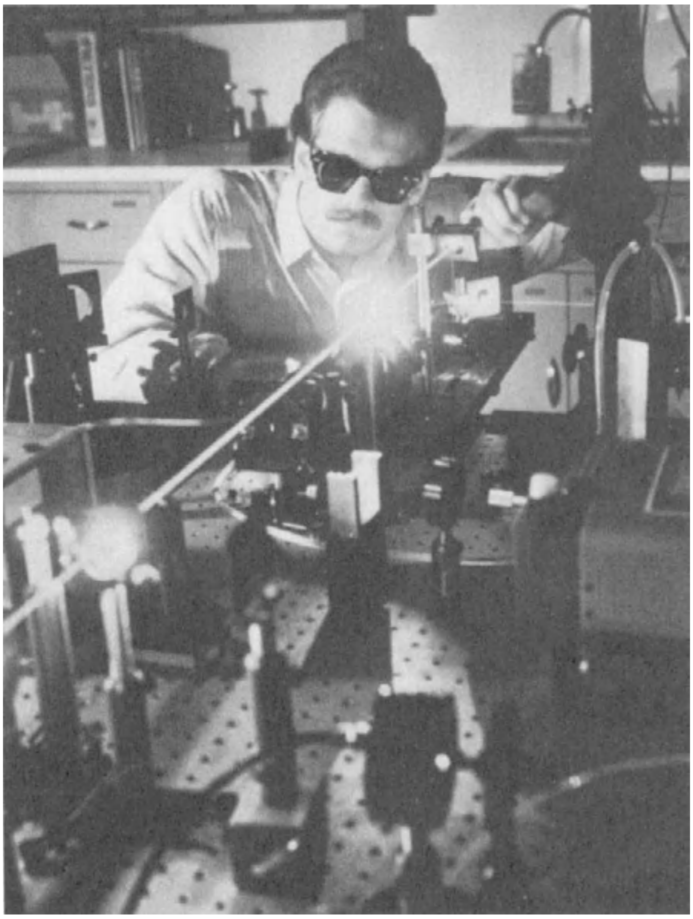


Fig. 2. Excited-state photochemical reaction being performed with a laser light source. (*The Dow Chemical Company*)

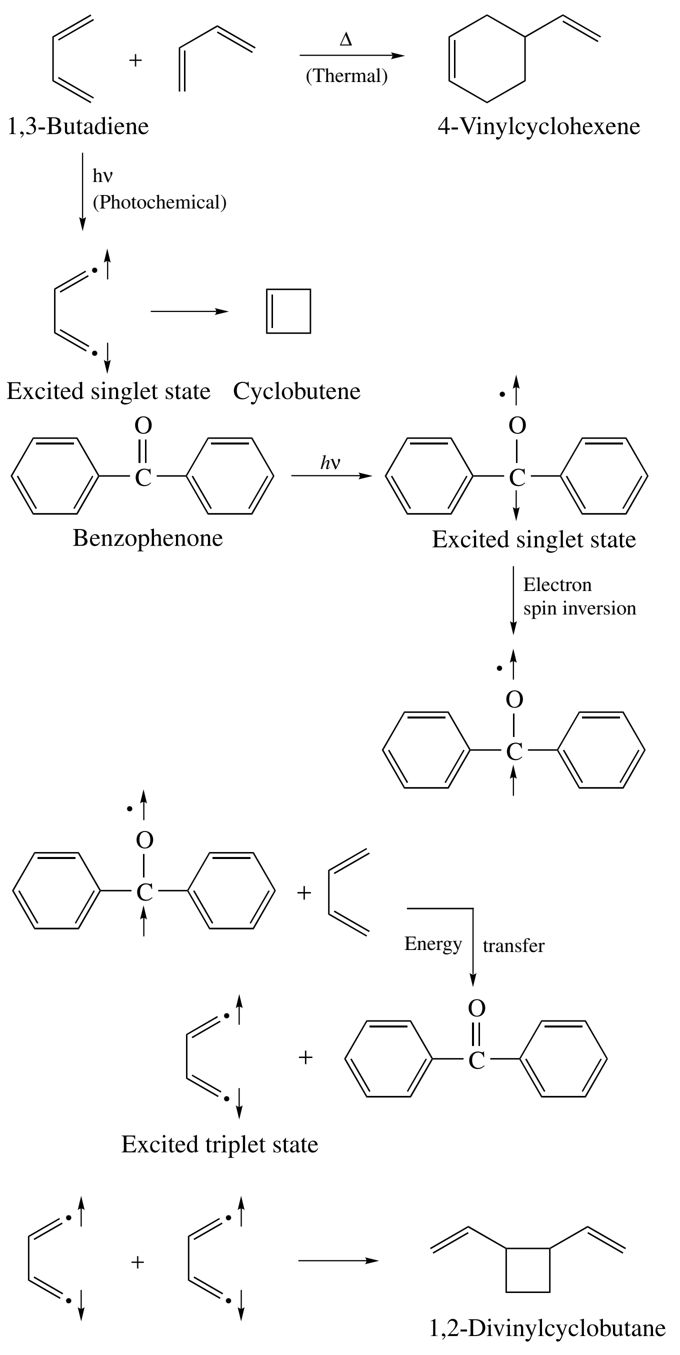
The reactions shown in Schemes 2–5, with the exception of the photodissociation of Cl_2 to Cl atoms (Scheme 4), occur in molecules that are in electronic ground states. Reactions also can occur in molecules existing in excited electronic states. Commonly, these excited states are produced by irradiating the reactants with ultraviolet or visible light, hence the term *photochemistry*. When a molecule is in an excited state, its reactions are often different from those it normally exhibits in its ground state. An organic compound often can exist in more than one excited state, as shown in Scheme 6.

SCHEME 6

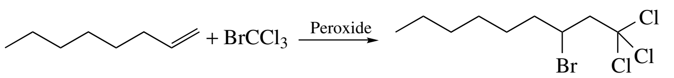


Excited state molecules usually differ from their ground state counterparts by having dissimilar electronic and geometric configurations, and shorter lifetimes, e.g., 10^{-2} to 10^{-10} second. See Fig. 2.

A few additional examples of organic reactions are shown in Scheme 7. Many novel and complex compounds can be prepared by these and similar reactions.

SCHEME 7. Examples of Organic Reactions.

Free Radical Addition



1-Octene Bromotrichloromethane 3-Bromo-1,1,1-trichlorononane

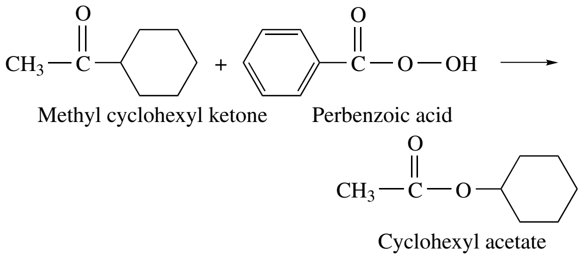
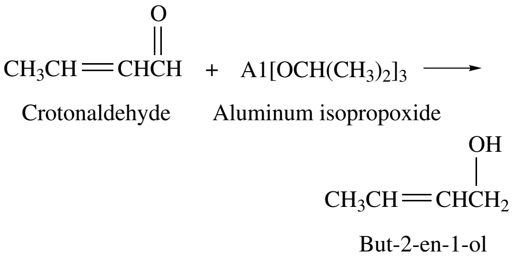
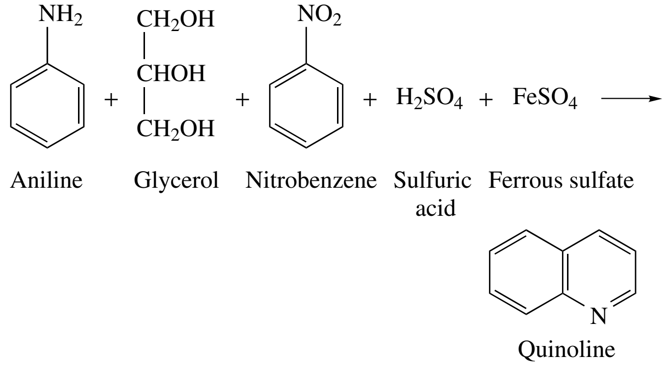
Baeyer-Villiger Oxidation



Meerwein-Ponndorf-Verley Reduction



Skraup Quinoline Synthesis



A very active area of organic chemistry is the synthesis of complex natural products. In these syntheses, numerous reactions, of which those in Schemes 7 and 8 are examples, are often employed serially to convert a starting compound into a final product that occurs in nature.

These syntheses are useful because they serve to verify structure that has been assigned, provide an alternate source of the compound if a larger supply is needed, or provide a route to derivatives or analogs of the natural material. The derivatives may possess enhanced properties, such as biological activity, that are not found in the natural product.

Some important industrial organic processes are shown in Scheme 9. Although most of these reactions involve mixtures of isomers or homologs as reactants and products, for simplicity only the major components are shown.

ORGANIC SYNTHESIS. See **Synthesis (Chemical)**.

ORGANOBORANE. A compound composed of an unsaturated organic group and a borane obtained by the hydroboration reaction. Such compounds are useful catalytic reagents in organic syntheses of some complexity, e.g., *cis*- or *trans*-olefins, optically pure alcohols, alkanes, and ketones. Prostaglandins and insect pheromones have been synthesized by this means. A particularly versatile example is triphenylboron $B(C_6H_5)_3$.

See also **Borane**; **Carborane**; and **Hydroboration**.

ORGANOCLAY (Organopolysilicate). A clay such as kaoliln or montmorillonite, to which organic structures have been chemically bonded; since the surfaces of the clay particles, which have a latticelike arrangement, are negatively charges, they are capable of binding organic radicals. When this type of structure is in turn reacted with a monomer such as styrene, a complex known as a polyorganosilicate graft polymer results.

ORGANOLEPTIC. A term widely used to describe consumer testing procedures for food products, perfumes, wines, and the like in which samples of various products, flavors, etc. are submitted to groups or panels. Such tests are a valuable aid in determining the acceptance of the products and thus may be viewed as a marketing technique. They also serve psychological purposes and are an important means of evaluating the subjective aspects of taste, odor, color, and related factors. The physical and chemical characteristics of foods are stimuli for the eye, ear, skin, nose, and mouth, whose receptors initiate impulses that travel to the brain, where perception occurs.

ORGANOMETALLIC COMPOUNDS. An organic compound composed of a metal attached directly to carbon (RM); such compounds have been prepared of practically all the metals, as well as with such nonmetals as silicon and phosphorus. Metallic salts (soaps) of organic acids are excluded. Examples are diethylzinc (the first known organometallic). Grignard compounds such as methy magnesium iodide (CH_3MgI), and metallic alkyls such as butyllithium (C_4H_9Li), tetraethyllead, triethyl aluminum, tetrabutyl titanate, sodium methylate, copper phthalocyanine, and metallocenes. Some are highly toxic or flammable; others are coordination compounds.

Reactive and moderately reactive organometallic compounds will react with all functional groups; two major types of reaction in which they are involved are oxidation and cleavage by acids. Probably the most important organometallic reactions are those involving addition to an

unsaturated linkage. Many of them are powerful catalysts and form useful coordination complexes.

See also **Catalysis**; **Coordination Compounds**; and **Metallocenes**.

ORGANOPHOSPHORUS COMPOUND. Any organic compound containing phosphorus as a constituent. These fall into several groups, chief of which are the following: (1) phospholipids, or phosphatides, which are widely distributed in nature in the form of lecithin, certain proteins, and nucleic acids; (2) plasticizers, insecticides, resin modifiers, and flame-retardants; (3) pyrophosphates, e.g., tetraethyl pyrophosphate, which are the basis for a broad group of cholinesterase inhibitors used as insecticides; (4) phosphoric esters of glycerol, glycol, sorbitol, etc., which are components of fertilizers. While many of these compounds play an important part in animal metabolism, those in group (3) are toxic and should be handled with extreme care. See also **Flame-Retarding Agents**.

ORGANOSILICON. An organic compound in which silicon is bonded to carbon (organosilane). Such compounds were first made by Friedel and Crafts in 1863. Silicon was found to have a remarkable chemical similarity to carbon, which it can replace in organic compounds. The silicon-carbon bond is about as strong as the carbon-carbon bond, and compounds containing them are similar in properties to all-carbon compounds. Organosilicon oxides (organosiloxanes or silicones) were discovered by F. S. Kipping in England in 1900; he found that Grignard reagents would react with silicon tetrachloride to form silicon-carbon-bonded polymers or both ring and chain types. See also **Grignard Reactions**. These were named silicones because of the similarity of their empirical formula (R_2SiO) to that of ketones (R_2CO).

An organosilicon compound (tetramesityldisilene) containing a silicon to silicon double bond has been synthesized. It is a crystalline solid, mp 176C, and has reactive properties similar to olefins. Compounds of the type are silylenes.

ORGANOSOL. Colloidal dispersion of any insoluble material in an organic liquid; specifically the finely divided or colloidal dispersion of a synthetic resin in plasticizer in which dispersion the volatile content exceeds 5% of the total.

See also **Plastisol**.

ORGANOTIN COMPOUNDS. A family of alkyl tin compounds widely used as stabilizers for plastics, especially rigid vinyl polymers used as piping, construction aids, and cellular structures. Some have catalytic properties. They include butyl tim trichloride, dibutyltin oxide, etc., and various methyltin compounds. They are both liquids and solids.

ORNITHINE. See **Amino Acids**.

ORNITHINE CYCLE. See **Urea**.

ORPIMENT. This mineral, like realgar, its frequent associate, is an arsenic sulfide. Oripment, however, is the trisulfide corresponding to the formula As_2S_3. It is monoclinic, usually in foliated, granular, or powdery aggregates; hardness, 1.502; specific gravity, 3.49; with a resinous to somewhat pearly luster; color, various shades of lemon yellow; translucent to nearly opaque. Oripment is found in association with realgar, although a somewhat rarer mineral. It is believed to be formed from the alteration of other arsenic-bearing minerals. It occurs in Czechoslovakia, Romania, Macedonia, Japan, and in the United States in Utah, Nevada, and Wyoming. The name oripment is derived from a corruption of the Latin *auripigmentum*, meaning golden paint, because of its color as well as the belief that it contained gold.

ORTHO COMPOUNDS. See **Organic Chemistry**.

ORTHO-STATE. 1. In diatomic molecules, such as hydrogen molecules, the ortho-state exists when the spin vectors of the two atomic nuclei are in the same direction (i.e., parallel), whereas the para-state is the one in which the nuclei are spinning in opposite directions.

2. In helium the ortho-state is characterized by a particular mode of coupling of the electron spins. See also **Helium**.

OSMIUM. [CAS: 7440-04-2]. Chemical element, symbol Os, at. no. 76, at. wt. 190.2, periodic table group 8, mp 3,015° to 3,075°C, bp 4,927° to 5,127°C, density 22.6g/cm^3 (solid), 22.8g/cm^3 (single crystal) (20°C). Elemental osmium has a close-packed hexagonal crystal structure. Compact osmium is a bluish-white metal and is not attacked by acids. Discovered by Tennant in 1804. The seven stable isotopes of osmium are ^{184}Os,^{186}Os through ^{190}Os, and ^{192}Os. Electronic configuration $1s^2 2s^2 2p^6 3s^2 3p^6 3d^{10} 4s^2 4p^6 4d^{10} 4f^{14} 5s^2 5p^6 5d^6 6s^2$. Ionic radius Os_4^+ 0.65 Å. Metallic radius 1.3377 Å. Oxidation potential $Os + 4H_2O \longrightarrow OsO_4 + 8H^+ + 8e^-$, −0.85 V.

Chemical Properties

Finely divided Os oxidizes in air, producing the poisonous and volatile tetroxide. The compact metal is not attacked by nonoxidizing acids. The finely divided metal dissolves in fuming HNO_3, aqua regia, and alkaline hypochlorite solutions. When fused with Na_2O_2 or KNO_3 and KOH, the metal is converted to the corresponding water-soluble osmate, K_2OsO_4. The brown or black insoluble osmium(IV) oxide, OsO_2, can be made by heating Os with a limited amount of O_2 or with osmium(VIII) oxide. This compound forms a brown to black-blue dihydrate that can be prepared by reducing a solution of the tetroxide or by hydrolyzing a solution of sodium hexachloroosmate, Na_2OsCl_6.

Osmium(VIII) oxide, the most important compound, is formed in one of the reactions unique to the platinum metals. Its ease of formation and volatility make it useful in a purification step for the refining or analysis of Os. The tetroxide is readily formed by heating the metal in air or distilling an osmium-containing solution from HNO_3. Although an aqueous solution of osmium(VIII) oxide is neutral to litmus, it is a weak acid with first dissociation constant of about 8×10^{-13}. Osmium(VIII) oxide is soluble in water, alcohol, and ether. The compound is widely used as a stain for tissues. When an alkaline solution of osmium(VIII) oxide is reduced with alcohol or KNO_2, an osmate(VI) is formed. Potassium osmate(VI) is formed by adding an excess of KOH to such a solution, resulting in the precipitation of violet crystals of $K_2OsO_4 \times 2H_2O$. The osmate(VI) ion is probably better written as $OsO_2(OH)_2$.

Osmium(II) chloride can be prepared by heating osmium(III) chloride in vacuum at 500°C. This dark-brown compound is insoluble in HCl or H_2SO_4. NHO_3 or aqua regia oxidizes it to the tetroxide. Osmium(III) chloride is best made by decomposing ammonium hexachloroosmate(IV), $(NH_4)_2OsCl_6$, in a Cl_2 stream at 350°C. The brown hygroscopic powder sublimes above 350°C, and at about 560°C it disproportionates into the tetrachloride and dichloride. Osmium(IV) chloride is formed from the elements at 650–700°C. The black compound slowly dissolves in water, eventually forming the dioxide. The free acid, H_2OsCl_6, is stable in solution and can be made by refluxing osmium(VIII) oxide with HCl and alcohol. The ammonium salt can be precipitated by adding NH_4Cl to such a solution. This salt is reduced to the metal when heated in H_2. The potassium salt is well known. Both are brownish-red solids yielding orange solutions in water.

Recent studies have established the reaction product of Os metal and F_2 at 300°C to be the hexafluoride, OsF_6. This yellow volatile solid had previously been described as an octafluoride. Osmium(VI) fluoride melts at 33.4°C and boils at 47.5°C. OsF_6 can be reduced to a pentafluoride and a tetrafluoride. The pentafluoride is a blue-gray crystalline solid that melts at 70°C to a green viscous liquid and boils at 226°C. The tetrafluoride distills at about 290°C. Potassium hexafluoroosmate(V), $KOsF_6$, can be made by reacting KBr, osmium(IV) bromide, and bromine trifluoride. The white powder dissolves in water to form a colorless solution that hydrolyzes to yield some osmium(VIII) oxide. On addition of 1 equiv of KOH to a fresh solution, an orange color develops, O_2 is evolved, and yellow crystals of potassium hexafluoroosmate(IV), K_2OsF_6, form.

Os forms many complexes with nitrite, oxalate, carbon monoxide, amines, and thio ureas. The latter are important analytically. Osmium forms the interesting aromatic “sandwich” compound, osmocene. A *metallocene* is described under **Ruthenium**. See also **Chemical Elements**; and **Platinum and Platinum Group**.

Proton nuclear magnetic resonance (NMR) is a widely used tool for researching biomolecules. Although much too detailed to report here, Zai-Wei Li and Henry Taube (Stanford University) reported in 1992 that they have had success in analyzing for certain molecules by using a dihydrogen osmium complex on a versatile 1H NMR recognition probe.

Osmium Isotopic Ratios in Paleogeology

As pointed out in 1983 by J.M. Luck and K.K. Turekian (Yale University), one of the most creative concepts regarding the cause of the many

paleontologic extinctions at the Cretaceous-Tertiary boundary is the one put forward by Alvarez et al. in 1980 involving the impact of a large asteroid or comet with the earth at that geologic time period. The Alvarez hypothesis stemmed from the finding of an exceptional chemical signature (high iridium concentration) at the Cretaceous-Tertiary boundary at Gubbio, Italy, a signature that was later found in other marine as well as continental sections which bracket the Cretaceous-Tertiary boundary. Because of the radioactive decay of rhenium-187 (4.6×10^{10} years), the osmium-187/osmium-186 ratio changes in planetary systems as a function of time and the rhenium-187/osmium-186 ratio. For a value of the $^{187}Re/^{186}Os$ ratio of about 3.2, typical of meteorites and the earth's mantle, the present $^{187}Os/^{186}Os$ ratio is about one. The earth's continental crust has an estimated $^{187}Re/^{186}Os$ ratio of about 400. Thus for a mean age of the continent of 2×10^9 years, a present $^{187}Os/^{186}Os$ ratio of about 10 is expected. Marine manganese nodules show values (6 to 8.4), which are compatible with this expectation if an allowance for a 25% mantle osmium supply to the oceans is made. The Cretaceous-Tertiary boundary iridium-rich layer in the marine section at Stevns Klint, Denmark, yields a $^{187}Os/^{186}Os$ ratio of 1.65 and the one in a continental section in the Raton Basin, Colorado, is 1.29. The investigators conclude that the simplest explanation is that these represent osmium imprints of predominantly meteoritic origin.

As reported in 1992 by M.F. Horan, J.W. Morgan and J.N. Grossman (U.S. Geological Survey), and R.J. Walker (University of Maryland), "Rhenium and osmium concentrations and the osmium isotopic compositions of iron meteorites were determined by negative thermal ionization mass spectrometry. Data for the IIA iron meteorites define an isochron with an uncertainty of approximately ±31 million years for meteorites ~4500 million years old. Although an absolute rhenium-osmium closure age for this iron group cannot be as precisely constrained because of uncertainty in the decay constant of ^{187}Re, an age of 4460 million years ago is the minimum permitted by combined uncertainties. These age constraints imply that the parent body of the IIAB magmatic irons melted and subsequently cooled within 100 million years after the formation of the oldest portions of chondrites. Other iron meteorites plot above the IIA isochron, indicating that the planetary bodies represented by these iron groups may have cooled significantly later than the parent body of the IIA irons."

OSMOSIS. Passage of a pure liquid (usually water) into a solution (e.g., of sugar and water) through a membrane that is permeable to the pure water but not to the sugar in the solution. This passage can also occur when the two phases consist of solutions of different concentration. The membrane is called semipermeable when the molecules of the solvent, but not those of the solute, can penetrate it. This pushing of water through a membrane into a solution results from the greater tendency of water molecules to escape from water than from a solution. The term *osmosis* us usually restricted to movement through a solid or liquid barrier that prevents the phases from mixing rapidly. In test apparatuses parchment or collodion membranes are used; in plants and animals the cell wall acts as a diffusion barrier. The pressure exerted by osmosis is substantial and accounts for the elevation of sap from root systems to the tops of trees. Osmosis is considered an essential characteristic of growth.

Reverse osmosis is used as a method of desalting seawater, recovering wastewater from paper mill operations, pollution control, industrial water treatment, chemical separations, and food processing. This method involves application of pressure to the surface of a saline solution, thus forcing pure water to pass from the solution through a membrane that is too dense to permit passage of sodium and chlorine ions. Hollow fibers of cellulose acetate or nylon are used as membranes, since their large surface area offers more efficient separation.

See also **Desalination**; **Diffusion**; and **Membrane Separations Technology**.

OSMOTIC COEFFICIENT. A factor introduced into equations for nonideal solutions to correct for their departure from ideal behavior, as in the equation:

$$\mu = \mu_x^0 + gRT \ln x_1$$

in which μ is the chemical potential, μ_x^0 is a constant, representing a standard value of the chemical potential, R is the gas constant, T the absolute temperature, x_1 is the mole fraction of solvent, and g is the osmotic coefficient.

OSMOTIC PRESSURE. Pressure that develops when a pure solvent is separated from a solution by a semipermeable membrane which allows only the solvent molecules to pass through it. The osmotic pressure of the solution is then the excess pressure which must be applied to the solution so as to prevent the passage into it of the solvent through the semipermeable membrane.

Because of the similarity in the relations for osmotic pressure in dilute solutions and the equation for an ideal gas, van't Hoff proposed his bombardment theory in which osmotic pressure is considered in terms of collisions of solute molecules on the semipermeable membrane. This theory has a number of objections and has now been discarded. Other theories have also been put forward involving solvent bombardment on the semipermeable membrane, and vapor pressure effects. For example, osmotic pressure has been considered as the negative pressure which must be applied to the solvent to reduce its vapor pressure to that of the solution. It is, however, more profitable to interpret osmotic pressures using thermodynamic relations, such as the entropy of dilution.

A number of methods have been developed for measurement of osmotic pressure.

In the Berkeley and Hartley method, a porous tube with a semipermeable membrane such as copper ferrocyanide deposited near the outer wall, and a capillary tube attached to one end contains the pure solvent. The solution surrounds the tube and is enclosed in a metal vessel to which a pressure may be applied which is just sufficient to prevent the flow of solvent into the solution. Berkeley and Hartley also developed a dynamic method for measuring osmotic pressure.

Simple osmometers have also been developed by Adair particularly for aqueous colloidal solutions. A thimble-type collodion membrane is attached to a capillary tube and contains the solution. When equilibrium is established the difference in level inside and outside the capillary is measured. Capillary corrections are made. For organic solvents a dynamic type osmometer may be used. A membrane of large surface area is clamped between two half cells and attached to each half cell is a fine capillary observation tube. With such an apparatus, equilibrium is rapidly established between solution and solvent contained in the half cells. The volume of the half cell may be small (about 20 cubic centimeters). The level of the solvent is usually arranged to be a little below the equilibrium position, and the height of the solvent in the capillary as a function of time is measured. This procedure is repeated with the level of the solvent just above the equilibrium position. A plot is then made of the half sum of these readings.

Since the osmotic pressure is related to the concentration of dissolved solute particles, it is related to the lowering of the freezing point and elevation of the boiling point.

The relation between osmotic pressure and lowering of the freezing point and the elevation of the boiling point may be expressed by the relation:

$$\Pi = \frac{LT}{\bar{v}T_0^2}\Delta T$$

where L is the molar heat of fusion or of vaporization of the solvent, T the temperature at which the osmotic pressure is measured, T_0 the freezing point or the boiling point of the solvent, $\overline{v}$, the partial molar volume of the solvent, and Π, the osmotic pressure.

Moreover, the relation to lowering of the vapor pressure is

$$\Pi = \frac{RT}{\overline{v}} \ln \frac{p_0}{p}$$

or

$$\Pi = -\frac{RT}{\overline{v}} \ln x_0 = -\frac{RT}{v} \ln(1-x)$$

For dilute solutions,

$$\Pi = cRT$$

where Π is the osmotic pressure, $\overline{v}$ *the partial molar volume of the solvent in the solution*, p_0 the vapor pressure of pure solvent, p the partial vapor pressure of the solvent in equilibrium with the solution, x_0 the mole fraction of the solvent, x the mole fraction of the solute, c the concentration of the solution in moles per liter, R, the gas constant, and T, the absolute temperature.

OSTWALD, WIHELM (1853–1932). A German chemist who won the Nobel prize for chemistry in 1909. He was considered to be a founder of modern physical chemistry. His work involved research in catalysis, the rates of chemical reactions, equilibrium, and conductivity of organic acids. He was an admirer of Mach and did not readily accept the atomic theory. He received honorary doctorates from several universities in Germany, Great Britain and the USA, and was made an honorary member of learned societies in Germany, Sweden, Norway, the Netherlands, Russia, Great Britain and the USA.

OUTGASSING. The removal of gas from a metal by heating at a temperature somewhat below melting, while maintaining a vacuum in the space around the metal.

OXALIC ACID. [CAS: 144-62-7]. Oxalic acid, HOOC–COOH, or ethanedioic acid, mol wt 90.04, is the simplest dicarboxylic acid. It is soluble in water, and acts as a strong acid. This acid does not exist in anhydrous form in nature and is available commercially as a solid dihydrate, $C_2H_2O_4 \cdot 2H_2O$, mol wt 126.07. The commercial product is packed in polyethylene-lined paper bags or flexible containers. Anhydrous oxalic acid can be efficiently prepared from the dihydrate by azeotropic distillation in a low boiling solvent that can form a water azeotrope, such as benzene and toluene.

Oxalic acid was synthesized for the first time in 1776 by Scheele through the oxidation of sugar with nitric acid. Then, Wöhler synthesized it by the hydrolysis of cyanogen in 1824.

The potassium or calcium salt form of oxalic acid is distributed widely in the plant kingdom. Oxalic acid is found in spinach, rhubarb, etc. Oxalic acid is a product of metabolism of fungi or bacteria and also occurs in human and animal urine; the calcium salt is a principal constituent of kidney stones.

Oxalic acid is used in various industrial areas, such as textile manufacture and processing, metal surface treatments leather tanning, cobalt production, and separation and recovery of rare-earth elements. Substantial quantities of oxalic acid are also consumed in the production of agrochemicals, pharmaceuticals, and other chemical derivatives.

Physical Properties

The physical and thermochemical constants of anhydrous oxalic acid and oxalic acid dihydrate are summarized in Table 1.

TABLE 1. PHYSICAL AND THERMOCHEMICAL PROPERTIES OF OXALIC ACID AND ITS DIHYDRATE

Property	Value
OXALIC ACID, ANHYDROUS, $C_2H_2O_4$	
melting point, °C	
α	189.5
β	182
density d_4^{17}, g/mL	
α	1.900
β	1.895
refractive index, β, n_4^{20}	1.540
vapor pressure (solid, 57–107°C), kPa[a]	$\log_{10} P = -(4726.95/T) + 11.3478$
specific heat (solid, −200 to 50°C), J/g	$C_p{}^b = 1.084 + 0.0318t$
heat of combustion, ΔE_c (at 25°C), kJ/mol[c]	−245.61
standard heat of formation, ΔH_f (at 25°C), kJ/mol[c]	−826.78
standard free energy of formation, ΔG_f (at 25°C), kJ/mol[c]	−697.91
heat of solution (in water), kJ/mol[c]	−9.58
heat of sublimation, kJ/mol[c]	90.58
heat of decomposition, kJ/mol[c]	826.78
specific entropy, S (at 25°C), J/(mol · K)[c]	120.08
logarithm of equilibrium constant, $\log_{10} K_f$	122.28
thermal conductivity (at 0°C), W/(m · K)[d]	0.9
ionization constant	
K_1	6.5×10^{-2}
K_2	6.0×10^{-5}
coefficient of expansion (at 25°C), nL/(g · K)	178.4
OXALIC ACID DIHYDRATE, $C_2H_2O_42H_2O$	
mp, °C	101.5
density d_4^{20}, g/mL	1.653
refractive index, n_4^{20}	1.475
standard heat of formation, ΔH_f (at 18°C), kJ/mol[c]	−1422
heat of solution (in water), kJ/mol[c]	−35.5
pH (0.1 M soln)	1.3

[a] To convert $\log_{10} P_{kPa}$ to $\log_{10} P_{mm\ Hg}$, add 0.875097 to the constant, $T = K$.
[b] To convert C_p, J/g, to C_p cal/g, divide both terms of the equation by 4.184.
[c] To convert J to cal, divide by 4.184.
[d] To convert W/(m · K) to (Btu · in.)/(h · ft^2 ·° F), divide by 0.1441.

Reactions

The reactions of oxalic acid, including the formation of normal and acid salts and esters, are typical of the dicarboxylic acids class. Oxalic acid, however, does not form an anhydride.

On rapid heating, oxalic acid decomposes to formic acid, carbon monoxide, carbon dioxide, and water (qv). In aqueous solution, it is decomposed by uv, x-ray, or γ-radiation with the liberation of carbon dioxide. Photodecomposition also occurs in the presence of uranyl salts.

Oxalic acid is a mild reducing agent, and is oxidized by potassium permanganate in acid solution to give carbon dioxide and water. Oxalic acid is catalytically reduced by hydrogen in the presence of ruthenium catalyst to ethylene glycol, and electronically reduced to glyoxylic acid.

Oxalic acid reacts with various metals to form metal salts, which are quite important as the derivatives of oxalic acid. It also reacts easily with alcohols to give esters.

Manufacture

Many industrial processes have been employed for the manufacture of oxalic acid since it was first synthesized. The following processes are in use worldwide: oxidation of carbohydrates, the ethylene glycol process, the propylene process, the dialkyl oxalate process, and the sodium formate process. Sodium formate process is no longer economical in the leading industrial countries, except for China.

Nitric acid oxidation is used where carbohydrates, ethylene glycol, and propylene are the starting materials. The dialkyl oxalate process is the newest, where dialkyl oxalate is synthesized from carbon monoxide and alcohol, then hydrolyzed to oxalic acid. This process has been developed by UBE Industries in Japan.

Many attempts have been made to synthesize oxalic acid by electrochemical reduction of carbon dioxide in either aqueous or nonaqueous electrolytes.

Health and Safety Factors

Oxalic acid is caustic and corrosive to humans. The severity of symptoms associated with oxalic acid poisoning is related to the concentration and quantity ingested. Oxalic acid removes calcium in the blood, forming calcium oxalate, and severe damage to the kidney may occur because of the insoluble calcium oxalate.

Uses

Because rare-earth oxalates have low solubility in acidic solutions, oxalic acid is used for the separation and recovery of rare-earth elements. The oxalic acid process for anodizing aluminum was developed in Japan. In addition to oxalic acid, inorganic oxalate salts are also used in coloring anodic coatings. Oxalic acid is a constituent of cleaners that are used for automotive radiators, boilers, and steel plates before phosphating. As a chelating agent, oxalic acid forms water-soluble complexes on metal surfaces during cleaning and rinsing.

In pulp bleaching, oxalic acid serves as a bleaching agent, but is often used together with other bleaching agents because of its relatively high cost. Oxalic acid is also used for the bleaching of cork, wood (particularly veneered wood), straw, cane, and natural waxes.

Oxalic acid has various uses in fabric cleaning, application of dyestuff, and modifying properties of cellulose fabrics. Oxalic acid is used as a pH modifier in leather tanning by tannin and basic chromium sulfate. It also functions as a bleaching agent for leather. It is used for marble polishing especially in Italy. It not only removes iron veins by forming water-soluble iron oxalate, but also serves as a polishing auxiliary. Starch powder is heated together with oxalic acid and hydrolyzed to produce millet jelly. Oxalic acid functions as a hydrolysis catalyst, and is removed from the product as calcium oxalate. This application is carried out in Japan. Oxalic acid is also used for the production of cobalt, as a raw material of various agrochemicals, and pharmaceuticals, for the manufacture of electronic materials, for the extraction of tungsten from ore, for the production of metal catalysts, as a polymerization initiator, and for the manufacture of zirconium and beryllium oxide.

Derivatives

Oxalic acid forms neutral and acid salts, as well as complex salts.

Ammonium Oxalate. Anhydrous ammonium oxalate is obtained when the monohydrate is dehydrated at 65°C. It is used for textiles, leather tanning, and precipitation of rare-earth elements.

Ammonium Iron(III) Oxalate. This mixed salt is produced as an emerald-green crystalline trihydrate. The compound is not stable to light. It was once used extensively in the manufacture of blueprinting papers.

Potassium Hydrogen Oxalate. Potassium acid oxalate, exists as a monohydrate. It is of historical interest because it is the salt of sorrel found in vegetation and the first oxalate isolated.

Potassium Oxalate. The monohydrate is produced as a colorless crystalline material or a white powder. The anhydrous salt is obtained when the monohydrate is dehydrated at 160°C. The monohydrate is preferred as a reagent in analytical chemistry and in miscellaneous uses principally because of its high solubility as compared with other simple neutral oxalates; the saturated solution, at 0°C, contains about 20 wt %, and at 20°C, about 25 wt % $K_2C_2O_4$.

Sodium Oxalate. This salt is obtained in such high purity and is so stable that it is used as a titrimetric standard.

Calcium Oxalate. The monohydrate is of importance principally as an intermediate in oxalic acid manufacture and in analytical chemistry; it is the form in which calcium is frequently quantitatively isolated.

Nickel Oxalate. This salt is produced as a greenish white crystalline dihydrate. Nickel oxalate is used for the production of nickel catalysts and magnetic materials.

Yttrium Oxalate. This compound exists as a trihydrate, nonahydrate, or heptadecahydrate. The compound is used for the production of a red fluorescent material for color television.

Dialkyl Oxalates. Oxalic acid gives various esters. Dialkyl esters ROOC−COOR, are industrially useful, but monoalkyl esters, ROOC−COOH, are not. The dialkyl esters are characterized by good solvent properties and serve as starting materials in the synthesis of many organic compounds, such as pharmaceuticals, agrochemicals, and fine chemicals (qv). Among the diesters, dimethyl, diethyl, and di-*n*-butyloxalates are industrially important.

Oxamide. This diamide is sparingly soluble in water and insoluble in various organic solvents. It melts at about 350°C, with accompanying decomposition. Because of the low solubility in water, the compound is granulated and used as a slow-release nitrogen fertilizer. Conventional nitrogen fertilizers such as ammonium sulfate, urea, ammonium nitrate, and ammonium phosphate, are soluble in water, and thus are easily lost as run-off when it rains. On the contrary, oxamide stays in the soil longer. Therefore, it is gradually decomposed by microorganisms in the soil and utilized by plants for longer periods.

Oxalyl Chloride. This diacid chloride is produced by the reaction of anhydrous oxalic acid and phosphorus pentachloride. The compound vigorously reacts with water, alcohols, and amines, and is employed for the synthesis of agrochemicals, pharmaceuticals, and fine chemicals.

Reduction Products. Glyoxylic acid is produced as aqueous solution by the electrolytic reduction of oxalic acid. It is used for the manufacture of vanillin.

Glycolic acid can be obtained by the electrolytic reduction of oxalic acid or the catalytic reduction of oxalic acid with hydrogen in the presence of a ruthenium catalyst. Because of its acidity it is used as a cleaning agent for metal surface treatments and for boiler cleaning. It also serves as an ingredient in cosmetics.

OXIDATION AND OXIDIZING AGENTS. Many years ago, the term *oxidation* signified a reaction in which oxygen combines chemically with another substance. The term now has a much broader meaning and includes any reactions in which electrons are transferred. Oxidation and reduction always occur simultaneously (redox reactions), and the substance which gains electrons is termed the *oxidizing agent*. For example, cupric ion is the oxidizing agent in the reaction: Fe (metal) $+ Cu^{++} \longrightarrow Fe^{++} + Cu$ (metal). Here, two electrons (negative charges) are transferred from the Fe atom to the Cu atom. Thus the Fe becomes positively charged (is oxidized) by loss of two electrons, while the Cu receives the two electrons and becomes neutral (is reduced). Electrons may also be displaced within the molecule without being completely transferred away from it. Such partial loss of electrons likewise constitutes oxidation in its broader sense and leads to the application of the term to a large number of processes which at first inspection might not be considered to be oxidations. Reactions of a hydrocarbon with a halogen, for example: $CH_4 + Cl_2 \longrightarrow CH_3Cl + HCl$, involves partial oxidation of the methane. Also, when a halogen addition to a double bond is made, this is regarded as an oxidation.

Dehydrogenation is also a form of oxidation, when two hydrogen atoms, each having one electron, are removed from a hydrogen-containing organic compound by a catalytic reaction with air or oxygen, as in oxidation of alcohols to aldehydes. See also **Dehydrogenation**.

Oxidizing agents are widely used throughout the chemical and petrochemical industries. It is also interesting to note that, while a primary thrust in food processing is to prevent oxidation (associated with rancidity and spoilage in foods), some powerful oxidizing agents are required by some processes to perform the function of bleaching. See also **Bleaching Agents**.

As one example, after a crude fat or oil is refined to remove its impurities, it must be further treated by bleaching to remove coloring materials that are typically present. Sulfuric and metaphosphoric acids and hydrogen peroxide have been used for this purpose. Calcium hypochlorite is used in bleaching sugar syrup prior to crystallization. Not all effective bleaching agents can be used because of their toxicity and inability to remove them completely. The aim is to remove all traces of the bleaching agent during subsequent processing so that they do not occur in the final product. Calcium peroxide, acetone peroxide, and benzoyl peroxides are other bleaching agents sometimes used in the food industry.

The use of oxidizers, such as potassium bromate, potassium iodate, and calcium peroxide as dough modifiers in the baking industry dates back many years. However, their mechanism has not been fully explained. Among authorities, there are at least two major viewpoints. It has been proposed that oxidizers inhibit proteolytic enzymes present in flour. It has also been proposed that the number of −S−S−bonds between protein chains is increased, forming a tenacious network of molecules. This action

leads to a tougher, drier, and more extensible dough. The need for oxidizers is less with well aged flours and in connection with supplemented flours that have been effectively *brominated* at the mills. When used properly, oxidizers contribute to improve appearance, brighter crumb, and better texture of breads. Oxidizers do not appear to interfere with the generation of gas by yeast or leavening chemicals. However, oxidizers used to excess can destroy the desirable properties of the dough and end-products.

OXIDATION NUMBER. In its original and restrictive sense, the number of electrons which must be added to a cation to neutralize the charge. The concept has been extended to anions by assignments of negative oxidation numbers. Moreover, it has been further extended, first to all atoms or radicals joined by electrovalent bonds, and then to covalent compounds in which the shared electrons are distributed equally. For the broadest use of the concept, the expression "oxidation state" is often used.

OXIDATION POTENTIAL. The potential drop involved in the oxidation (i.e., ionization) of a neutral atom to a cation, of an anion to a neutral atom, or of an ion to a more highly charged state (e.g., ferrous to ferric).

OXIDATION-REDUCTION. See **Phosphorylation (Oxidative)**; **Phosphorylation (Photosynthetic)**.

OXIDATION-REDUCTION EQUATIONS. See **Chemical Equation**.

OXIDATION-REDUCTION INDICATOR. A substance that has a color in the oxidized form different from that of the reduced form and can be reversibly oxidized and reduced. Thus, if diphenylamine is present in a ferrous sulfate solution to which potassium dichromate is being added, a violet color appears with the first drop of excess dichromate.

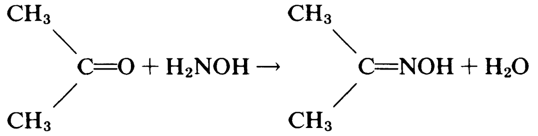
See also **Indicator (Chemical)**.

OXIDATIVE COUPLING. A polymerization technique for certain types of linear high polymers. Oxidation of 2,6-dimethylphenol with an amine complex of copper salt as catalyst forms a polyether, with splitting off of water. The product is soluble in aromatic and chlorinated hydrocarbons; insoluble in alcohols, ketones, and aliphatics. It is thermoplastic and unaffected by acids, bases, and detergents. It has a very broad useful temperature range (from −170 to +190°C). It is also dimensionally stable and has good electrical resistance. Oxidative coupling of diacetylenes and dithiols also yields promising polymers.

OXIDE. A mineral in which metallic atoms are bonded to oxygen atoms.

OXIDIZING MATERIAL. Any compound that spontaneously evolves oxygen either at room temperature or under slight heating. The term includes such chemicals as peroxides, chlorates, perchlorates, nitrates, and permanganates. These can react vigorously at ambient temperatures when stored near of in contact with reducing materials such as cellulosic and other organic compounds. Storage areas should be well ventilated and kept as cool as possible.

OXIMES. One of a number of compounds that result from the interaction of aldehydes, ketones, and other carbonyl-containing substances with hydroxylame, e.g., acetone yields acetoxime



OXIME TEST (Rheinboldt). An ethereal solution of an aldoxime gives a blue color with aqua regia.

OXONIUM COMPOUNDS. Coordination compounds, commonly of certain oxygen-containing organic substances, with mineral acids, of the general type $[R_2O]HCl$. These compounds bear a strong resemblance to the oxonium (hydronium) ion, which is a proton in combination with a water molecule, and is the form in which protons commonly exist in aqueous solutions.

OXO PROCESS. The oxo process, also known as hydroformylation, is the reaction of carbon monoxide and hydrogen with an olefinic substrate to form isometric aldehydes as shown in equation 1. The ratio of isomeric aldehydes depends on the olefin, the catalyst, and the reaction conditions.

$$RCH{=}CH_2 + CO + H_2 \xrightarrow{catalyst} RCH_2CH_2CHO + R(CH_3)CHCHO \quad (1)$$

If a double-bond shift occurs, the number of aldehyde isomers is increased.

Synthesis gas, a mixture of CO and H_2, also known as syngas, is produced for the oxo process by partial oxidation (eq. 2) or steam reforming (eq. 3) of a carbonaceous feedstock, typically methane or naphtha. The ratio of CO to H_2 may be adjusted by cofeeding carbon dioxide, CO_2, as illustrated in equation 4, the water gas shift reaction.

$$2CH_4 + O_2 \longrightarrow 2CO + 4H_2 \quad (2)$$

$$CH_4 + H_2O \longrightarrow CO + 3H_2 \quad (3)$$

$$CO_2 + H_2 \rightleftharpoons CO + H_2O \quad (4)$$

$$2CH_4 + CO_2 + O_2 \longrightarrow 3CO + 3H_2 + H_2O \quad (5)$$

The overall process for producing a 1:1 CO to H_2 ratio by partial methane oxidation and the water gas shift reaction is represented by equation 5.

The oxo reaction proceeds most frequently in the presence of a Group 8–10 (VIII) metal catalyst in the liquid phase, most particularly with members of Group 9, the Co-Rh-Ir triad. The earliest catalyst, hydrocobalt tetracarbonyl, $HCo(CO)_4$ was an outgrowth of Fischer-Tropsch investigations carried out prior to World War II on the effect of olefins on hydrocarbon synthesis. The hydroformylation reaction, as practiced in the early days using cobalt catalysis, presented formidable requirements of high pressure, containment of the hydrogen, containment of carbon monoxide, and handling of the toxic and unstable metal carbonyls.

The search for catalyst systems which could effect the oxo reaction under milder conditions and produce higher yields of the desired aldehyde resulted in processes utilizing rhodium. Oxo capacity built since the mid-1970s, both in the United States and elsewhere, has largely employed tertiary phosphine-modified rhodium catalysts.

Propylene is the predominant oxo process olefin feedstock. Ethylene as well as a wide variety of terminal, internal, and mixed olefin streams, are also hydroformylated commercially. Branched-chain olefins include octenes, nonenes, and dodecenes from fractionation of oligomers of C_3−C_4 olefins as well as octenes from dimerization and codimerization of isobutylene and 1- and 2-butenes.

Linear terminal olefins are the most reactive in conventional cobalt hydroformylation.

Oxo aldehyde products range from C_3 to C_{15}, ie, detergent range, and are employed principally as intermediates to alcohols, acids, polyols, and esters formed by the appropriate reduction, oxidation, or condensation chemistry.

The classic challenges in oxo technology are simultaneously to achieve high reaction rate, high selectivity to the desired aldehyde, and to utilize a highly stable catalyst.

Catalysts

Unmodified Cobalt. Typical sources of the soluble cobalt catalyst include cobalt alkanoates, cobalt soaps, and cobalt hydroxide (see **Cobalt**). These are converted *in situ* into the active catalyst, $HCo(CO)_4$, which is in equilibrium with dicobalt octacarbonyl.

Although largely supplanted by low pressure ligand-modified rhodium-catalyzed processes, the unmodified cobalt oxo process is still employed in some instances for propylene to give a low, e.g., ~3.3–3.5 : 1 isomer ratio product mix, and for low reactivity mixed and/or branched-olefin

feedstocks, e.g., propylene trimers from the polygas reaction, to produce isodecanol plasticizer alcohol.

Ligand-Modified Cobalt. The ligand-modified cobalt process, commercialized in the early 1960s by Shell, may employ a trialkylphosphine-substituted cobalt carbonyl catalyst, $HCo(CO)_3P(n\text{-}C_4H_9)_3$, to give a significantly improved selectivity to straight-chain product. There has been large industrial usage of the Shell process since the 1960s, particularly for the preparation of detergent range alcohols. 2-Ethyl-1-hexanol can be produced in a single step from propylene by conducting the hydroformylation in the presence of caustic.

Ligand-Modified Rhodium. The triphenylphosphine-modified rhodium oxo process, termed the LP Oxo process, is the industry standard for the hydroformylation of ethylene and propylene as of this writing (ca 1995). It employs a triphenylphosphine (TPP) modified rhodium catalyst. The process operates at low (0.7–3 MPa (100–450 psi)) pressures and low (80–120°C) temperatures. Suitable sources of rhodium are the alkanoate, 2,4-pentanedionate, or nitrate. A low (60–80 kPa (8.7–11.6 psi)) CO partial pressure and high (10–12%) TPP concentration are critical to obtaining a high (e.g., 10:1) normal-to-branched aldehyde ratio.

The first commercial LP Oxo process flow scheme (Fig. 1) used syngas and propylene feed.

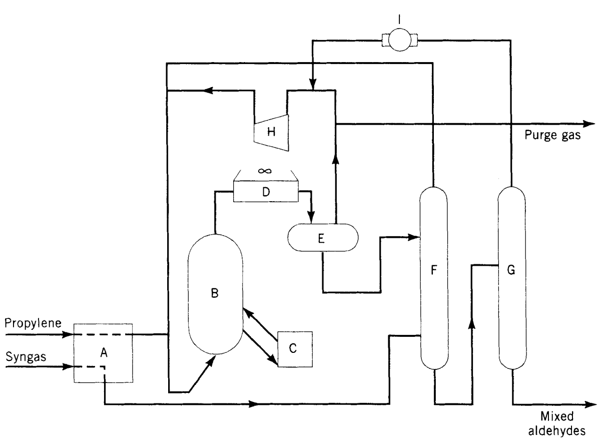


Fig. 1. LP Oxo gas recycle flow scheme: A, feedstock pretreatment; B, reactor; C, catalyst preparation and treatment systems; D, condenser; E, separator; F, stripper; G, stabilizer; H, cycle compressor; and I, stabilizer overhead gas compressor.

Rhodium Modified with Ionic Phosphine Ligands. In 1984, a rhodium catalyst process employing a water-soluble ligand, triphenylphosphine-*m*-trisulfonic acid trisodium salt (TPPTS) was commercialized. Product recovery is achieved by decantation from the aqueous phase containing rhodium and ligand. An isomer ratio of 20:1 is obtained with the TPPTS-modified rhodium catalyst, but the catalyst activity is significantly lower, so higher temperatures, higher rhodium concentrations, and higher propylene pressures are employed.

Other Rhodium Processes. Unmodified rhodium catalysts, e.g., $Rh_4(CO)_{12}$ have high hydroformylation activity but low selectivity to normal aldehydes.

Functional Olefin Hydroformylation. There are two commercially practiced oxo processes employing functionalized olefin feedstocks: allyl alcohol hydroformylation, and the production of 1,4-butanediol by successive hydroformylation of allyl alcohol aqueous extraction of the intermediate 2-hydroxytetrahydrofuran, and subsequent hydrogenation.

Hydroformylation Using Other Metals. Ruthenium, as a hydroformylation catalyst, has an activity significantly lower than that of rhodium and even cobalt.

Platinum catalysts that utilize both phosphine and tin(II) halide ligands give good rates and selectivities, in contrast to platinum alone, which has extremely low or nonexistent hydroformylation activity.

A further improvement in platinum catalysis is claimed from use of tin(II) halide and phosphine ligands which are rigid bidentates, e.g., 1,2-bis(diphenylphosphinomethyl)cyclobutane.

Future Trends. In addition to the commercialization of newer extraction/decantation product/catalyst separations technology, there have been advances in the development of high reactivity oxo catalysts for the conversion of low reactivity feedstocks such as internal and α-alkyl substituted α-olefins. These catalysts contain (as ligands) ortho-*t*-butyl or similarly substituted arylphosphites, which combine high reactivity, vastly improved hydrolytic stability, and resistance to degradation by product aldehyde, which were deficiencies of earlier, unsubstituted phosphites.

Uses

n-Propanol and *n*-propyl acetate account for about 70% of the U.S. propionaldehyde derivative market. These compounds are used principally in flexographic and gravure inks which require volatile solvents to prevent smearing and ink accumulation on the printing presses. Some propanol is also converted into *n*-propylamines which are important pesticide intermediates. *n*-Propanol is also employed as a precursor for glycol ethers.

The highest volume oxo chemical in the United States, *n*-butyraldehyde, is converted mainly into *n*-butanol, employed chiefly to produce butyl acrylate and methacrylate. In contrast, the principal *n*-butyraldehyde derivative in Europe and Japan is 2-ethylhexanol, the precursor to the poly(vinyl chloride) (PVC) plasticizer, DOP.

1,4-Butanediol (BDO) goes primarily into tetrahydrofuran (THF) for production of polytetramethylene ether glycol (PTMEG), used in the manufacture of polyurethane fibers.

The principal C_5 valeraldehyde derivatives, *n*-amyl and 2-methylbutyl alcohols, are used predominantly to make zinc diamyldithiophosphate lube oil additives.

C_7–C_9 oxo-derived acids are the principal derivatives of the C_7–C_9 oxo aldehydes, and in analogy to C_5 oxo aldehyde market applications, are used chiefly to make neopolyol esters which are employed almost entirely in aeromotive applications.

Several alcohols in the C_6–C_{13} range are produced by oxo reactions and are used in both plasticizer and detergent applications. Linear C_{12}–C_{15} alcohols are employed primarily in detergent applications.

Safety, Health, and Environmental Concerns

Oxo plants employ mixtures of highly toxic, flammable gases under pressure at high temperatures and require strict adherence to established operating safety codes and emergency reporting procedures to local, state, and federal authorities. In the United States, carbon monoxide is classified as both an acute, fire, and sudden release hazard.

The carbon monoxide component of the oxo reactant gases presents the most immediate human health hazard.

OXY. The radical –O– in organic compounds, performing in a manner similar to the oxo radical (O=) and the epoxy radical (–O–).

OXYACID. An acid that contains oxygen, such as chloric acid ($HClO_3$).

OXYAZO COMPOUNDS. Compounds of the type $RN{=}NC_6H_4OH$, containing both the azo group –N=N–, and a hydroxyl group –OH, both attached to carbon atoms in the same ring. These compounds are commonly produced by the action of diazo compounds upon phenols in alkaline solution. They constitute a class of dyes. See **Dyes**.

OXYCHLORINATION. See **Chlorinated Organics**.

OXYGEN. [CAS: 7782-44-7]. Chemical element, symbol O, at. no. 8, at. wt. 15.9994, periodic table group 16, mp –218.4°C, bp 182.96°C, critical temperature 118.8°C, critical pressure 49.7 atmospheres, density 1.568 g/cm^3 (solid), 1.429 g/L (0°C). Solid oxygen has a cubic crystal

structure. Oxygen at standard conditions is a colorless, odorless, tasteless gas. Oxygen is slightly soluble in H_2O (4.89 parts oxygen in 100 parts H_2O at 0°C), the solubility decreasing with increasing temperature (2.6 parts oxygen in 100 parts H_2O at 30°C; 1.7 parts oxygen in 100 parts H_2O at 100°C). Oxygen is slightly soluble in alcohol. Molten silver dissolves up to 10× its volume of oxygen, but easily gives up the gas upon cooling. There are three stable isotopes, ^{16}O through ^{18}O. Three radioactive isotopes have been identified, ^{14}O, ^{15}O, and ^{19}O, with short half-lives measured in seconds and minutes. In terms of abundance in igneous rocks in the earth's crust, oxygen ranks first, with an average composition by weight of 46.6%. In terms of abundance in seawater, oxygen also ranks first, with an estimated 4 billion tons of oxygen per cubic mile of seawater. In terms of cosmic abundance, oxygen ranks eighth. For comparisons, assigning a value of 10,000 to silicon, the figure for oxygen is 220,000 and that for hydrogen, estimated the most abundant, is 3.5×10^8. Of dry air in the earth's atmosphere, 23.15% is oxygen by weight; 20.98% by volume. In the atmosphere, the oxygen is mixed with nitrogen, argon, the rare gases, CO_2, and H_2O vapor. Oxygen first was identified by Priestly in 1774 when he was experimenting with mercuric oxide. In the same year, Scheele also identified the element. Oxygen is required for burning and combustion, although the conditions of combustion vary widely. For example, phosphorus burns in air at the low temperature of 34°C when ignited. The temperature if ignition for ether in air is 340°C, for ethyl alcohol in air, 560°C, kerosene in air, about 300°C, and hydrogen in air, about 600°C. The oxidation process may occur with the rapidity and violence of an explosion, or may be as slow as the rusting of iron. Nearly all known species of living things require oxygen in some form, either free or chemically bound. First ionization potential 13.614 eV; second, 34.93 eV; third, 54.87 eV. Oxidation potentials $H_2O_2 \longrightarrow O_2 + 2H^+ + 2e^-$, -0.68 V; $3H_2O \longrightarrow \frac{1}{2}O_2 + 2H_3O^+(10^{-7}M) + 2e^-$, -0.815 V; $3H_2O \longrightarrow \frac{1}{2}O_2 + 2H^+ + 2e^-$, 1.229 V; $4H_2O \longrightarrow H_2O_2 + 2H_3O^+ + 2e^-$, -1.77 V; $3H_2O \longrightarrow O(g) + 2H^+ + 2e^-$, -2.42 V; $HO_2^- + OH^- \longrightarrow O_2 + 2H_2O + 2e^-$, 0.075 V; $4OH^- \longrightarrow O_2 + 2H_2O + 4e^-$, -0.401 V; $3OH^- \longrightarrow HO_2^- + H_2O + 2e^-$, -0.87 V; $OH^- \longrightarrow OH + e^-$, -1.4 V. Other physical properties of oxygen are given under **Chemical Elements**.

Allotropic Forms

The three known allotropic forms of oxygen are (1) the ordinary oxygen in the air, with two atoms per molecule, O_2, (2) ozone, O_3, with three atoms per molecule, and (3) the rare, very unstable, nonmagnetic, pale-blue O_4. The latter breaks down readily into two molecules of O_2.

When oxygen is subjected to the silent electric discharge, activated atomic oxygen is produced. Atomic oxygen displays an afterglow upon cessation of the current, and the oxygen is notably active with hydrogen bromide, forming bromine; with H_2S, forming sulfur, SO_2, sulfur trioxide, and H_2SO_4; with CS_2, forming carbon monoxide, CO_2, and SO_2, and, strangely, reduced molybdenum trioxide to a white oxide not reducible with hydrogen. The concentration of atomic oxygen obtainable by the silent electric discharge through oxygen is estimated at 20%.

The normal electron distribution of the electrons of the oxygen atom is $1s^2 2s^2 2p_x{}^2 2p_y{}^1 2p_z{}^1$, with 2 unpaired electrons in the $2p$ orbitals. The covalent or partly covalent compounds of oxygen would be expected to have 90° bonding angles. But in many cases they have values significantly greater (ca. 104° for R_2O and 105° for H_2O). This suggests the promotion of a $2s$ electron to a $2p$ orbital (i.e., $2p_y$ orbital), still leaving two unpaired electrons (a $2s$ and a $2p_z$ electron), and permitting partial sp^3 hybridization (which is incomplete because sufficient energy is not available) but producing bond angles between 90° and 109° for the sp^3 tetrahedral structure, with covalent-polar bonds.

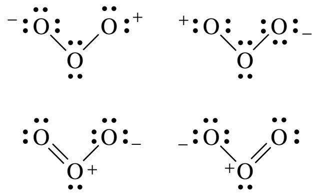
The oxygen molecule is paramagnetic with a moment in accord with two unpaired electrons. In molecular orbital terms, the configuration is written

$$O_2[KK(z\sigma)^2(y\sigma^*)^2(x\sigma)^2(w\pi^*)^4(v\pi^*)^2]$$

in which KK designates the complete $1s$ shells of the two atoms, which are nonbonding, the term $(z\sigma)^2$ denotes the bonding effect of one pair of $2s$ electrons, one from each of the O atoms, $(y\sigma^*)^2$ denotes the antibonding effect of the second pair, the $(x\sigma)^2$ term represents the s-bond formed by one pair of p-electrons, $(w\pi)^4$ represents the 2 π-bonds formed by the other two pairs of p-electrons, while the $(v\pi^*)^2$ term denotes the last pair of p-electrons, which go into the next π subshell (two orbitals) with unpaired spins, and are antibonding.

Ozone

[CAS: 10028-15-6]. **O_3**, obtained by electrical discharge through oxygen or high-current electrolysis of sulfuric acid, is considered on the basis of electron diffraction studies to have an O—O—O bond angle of 127 ± 3° and O—O bond length of 1.26 ± 0.02 Å. Its structure is considered to resonate among several forms, chiefly



Ozone is an unstable blue gas, of characteristic odor, liquefiable at −12°C, formed when ordinary oxygen is subjected to electrostatic discharge, density 1.5 times that of oxygen gas, mp −251.4°C, bp −111.5°C. It is explosive by percussion or under variations of pressure. Ozone reacts (1) with potassium iodide, to liberate iodine, (2) with colored organic materials, e.g., litmus, indigo, to destroy the color, (3) with mercury, to form a thin skin of mercurous oxide causing the mercury to cling to the containing vessel, (4) with silver film, to form silver peroxide, Ag_2O_2, black, produced most readily at about 250°C, (5) with tetramethyldiaminodiphenylmethane $(CH_3)_2N \cdot C_6H_4 \cdot CH_2 \cdot C_6H_4 \cdot N(CH_3)_2$, in alcohol solution with a trace of acetic acid to form violet color (hydrogen peroxide, colorless; chlorine or bromine, blue; nitrogen tetroxide, yellow). In contrast to hydrogen peroxide, ozone does not react with dichromate, permanganate, or titanic salt solutions. Ozone reacts with olefin compounds to form ozonide addition compounds. Ozonides are readily split at the olefinin-ozone position upon warming alone, or upon warming their solutions in glacial acetic acid, with the formation of aldehyde and acid compounds which can be readily identified, thus serving to locate the olefin position in oleic acid, $C_{17}H_{33} \cdot COOH$, as midway in the chain $(CH_3(CH_2)_7CH{:}CH(CH_2)_7COOH$. Ozone is used (1) as a bleaching agent, e.g., for fatty oils, (2) as a disinfectant for air and H_2O, (3) as an oxidizing agent. See also **Aerosols**; and **Ozone**.

The protective effects of an ozone layer in the stratosphere of the earth have been known for many years. Ozone prohibits full penetration of ultraviolet radiation from the sun to the surface of the earth. Much research has been conducted and is still underway to determine the extent to which certain chemical pollutants may be destroying the ozone layer gradually and, among other factors, causing marked warming of the earth.

Role of Oxygen in Water

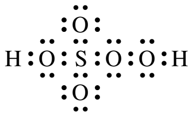
The solvent properties of H_2O are due in great part to the dipole moment of its molecules (1.8 debye units) and its high dielectric constant (ca. 78). Its hydrogen atoms form hydrogen bonds with electronegative atoms such as fluorine, nitrogen, or oxygen. In fact, the H_2O molecules associate in H_2O by this mechanism. Also, the oxygen atoms of H_2O because of their residual negative charges are electrically attracted by cations, so that the H_2O molecules arrange themselves around cations, facilitating solution and ionization. In the same way, H_2O molecules surround anions by attraction of the positive ends of the dipoles. By these two processes, as well as the dissociation of water into oxonium and hydroxide ions, it forms hydrates with many compounds. Moreover, H_2O readily reacts with large numbers of compounds because of these properties. Thus the hydrolysis of covalent halides that have at least one lone pair of electrons is initiated by the donation of a proton by the H_2O, followed by splitting off of hydrogen chloride.

Oxides

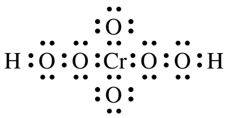
Oxygen forms oxides with all the elements except some inert gases. Oxides are said to be normal when they contain no oxygen atoms that are bonded to each other, as in the peroxides. The normal oxides may be divided into three groups, basic, acidic, and neutral. The basic oxides, which react with or dissolve in H_2O to produce alkaline solutions, are formed by the alkali and alkaline earth elements (except beryllium) by the lighter Lanthanides and actinium, by silver(I), thallium(I) and lead(II). The oxides of the nonmetals and of the transition metals in their higher oxidation states are in general acidic. The oxides lying in the positions between the two groups exhibit both basic and acidic properties (amphiprotic or amphoteric) such as those of aluminum, tin(II) and iron(III), Al_2O_3, SnO, and Fe_2O_3.

The known facts about the structure of hydrogen peroxide, H_2O_2, are that the O−H distances are 0.97Å, the O−O distances 1.47Å, the HOO angles 94°, and the dihedral angle between the planes of the two O−H radicals 97°. The O−O bond is essentially a single one. In the liquid, H_2O_2 is somewhat more self-ionized than water. In water $pK_A = 11.75$, $pK_B = 17$. Its reactions may be oxidizing or reducing. Thus, it oxidizes Fe(II) to Fe(III), Ti(III) to Ti(IV) and SO_3^{2-} to SO_4^{2-}; but it reduces MnO_4^- (acid solution) to Mn^{2+}. Peroxides are known for the alkali and alkaline earth metals, as well as zinc, cadmium, mercury, thorium, uranium, plutonium, etc. However, not all compounds of formula MO_2 (where M is a metal atom) are peroxides; some are merely dioxides, as MnO_2, PbO_2, etc., others are superoxides, such as NaO_2, KO_2, RbO_2, CsO_2, CaO_4, SrO_4, and BaO_4. These last compounds contain the group O_2^-, as evident from their paramagnetism and crystal structure. Perhydroxyl, the free acid corresponding to the superoxides, is unstable ($H_2O_2 \longrightarrow HO_2 + H^+ + e^-$, $E° = 1.5$ V; $HO_2 \longrightarrow O_2 + H^+ + e^-$, $E° = +0.13$ V). It is a moderately strong acid, $pK_A = 2.2$.

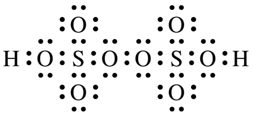
The peroxyacids containing −O−OH groups, are formed with all the transition elements in groups 4, 5, 6 of the periodic table, with main group elements 4 and 5 as well as elements of atomic numbers from boron to sulfur, inclusive. Representative peroxyacids are peroxymonosulfuric acid,



and peroxychromic acid,



The only peroxydiacids are formed by sulfur, phosphorus, carbon and boron, of which the most important is peroxy disulfuric acid



although peroxy bridge compounds are also formed by certain transition element complexes, e.g., $[Co(NH_3)_5OOCo(NH_3)_5]^{4+}$ and $[Co(NH_3)_5OOCo(NH_3)_5]^{5+}$.

Industrial Oxygen

As with hydrogen, the electrolysis of water offers one approach to the production of pure oxygen. However, the economics are as unfavorable for oxygen production in this manner as for hydrogen. See also **Hydrogen**. For industrial oxygen production, air is the raw material. Using air, processes are of two major types: (1) liquid-oxygen processes wherein the oxygen is fractionally distilled from liquid air, and (2) gaseous-oxygen processes. See also **Cryogenics**.

Because of the relatively high energy costs of compressing and refrigerating involved in oxygen production, many processes have been developed and tested over the years, a high percentage of these later abandoned. An idea of the alternatives which face the process designer can be gathered from scanning the methods available specifically in the area of producing refrigeration for these processes: (1) Joule-Thomson effect only; (2) Joule-Thomson effect plus auxiliary refrigeration with an ordinary liquid-vapor cycle at moderate- or high-temperature levels, i.e., relative to liquid-air temperature; (3) Joule-Thomson effect plus approximately reversible expansion of the air or products in an expander; (4) refrigeration essentially due only to approximately reversible expansions of auxiliary fluid or fluids operating in liquid-vapor cycles, i.e., the cascade process; and (5) processes using an auxiliary nitrogen-liquefaction cycle.

Designers also face the choice of capacity of an oxygen plant. Costs per unit weight of oxygen made are lowered as the capacity of the plant goes up. For example, a plant with a capacity of 2000 tons (1800 metric tons) per day will produce oxygen at approximately 50% of the cost per unit weight as a plant with a 200-ton (180-metric ton) capacity per day.

The demand for industrial oxygen has created the need for several new plants during the past 20 years. Capacities for most recent plants range from about 1100 tons (990 metric tons) per day to 2500 tons (2250 metric tons) per day.

An oxygen pipeline system was established in western Europe in the late-1970s that is 592 miles (956 kilometers) long. The Eastern Network of this system serves 30 consumers in France, Luxembourg, and West Germany; the Northern Network serves some 40 additional users in France, Belgium, and the Netherlands.

Uses

In addition to the requirements by the chemical industry for oxygen as a reactant, either directly from the air or in purer, more concentrated form as from a separation plant, significant quantities of purified oxygen are used for welding and cutting metals. Oxygen of a purity of 99.5% is required for oxyacetylene and oxyhydrogen torches. When combined in proper proportions, acetylene and oxygen yield a flame with a temperature of about 3,480°C. Oxyhydrogen flames are somewhat lower in temperature, but they are particularly useful for welding light-gage aluminum and magnesium allows and for underwater cutting. In welding applications, a reduction in purity of oxygen used from 99.5% to 99.0% will cut welding efficiency by over 10%. During the past several years, basic oxygen steelmaking has increased requirements for pure oxygen. In this process, nearly pure oxygen is introduced by means of a lance into molten iron and scrap. The oxygen combines with carbon and other unwanted elements and refines raw steel in much less time than the older open-hearth furnaces. The basic oxygen process exceeded the open-hearth process in terms of output to the United States in 1970 for the first time. On the total scale of consumption, relatively limited amounts of oxygen go into medical and life-support applications, as required for emergency situations in aircraft at high altitudes.

Role of Oxygen in Corrosion

Oxygen and oxidizing agents exert both a positive and negative influence on corrosion of metals. On the one hand, an oxidizing agent may form a protective oxide film on the surface of certain metals, aluminum being an excellent example, which essentially arrests corrosion by many external agents. On the other hand, the presence of oxidants may increase the rate of corrosion by supporting cathode reactions. As an example, Monel metal fully resists attack by oxygen-free 5% H_2SO_4 at room temperature. The corrosion rate rises, however, in almost direct proportion to oxygen content. A 20% oxygen content will cause a corrosion rate of about 150 mdd (milligrams of metal corroded per square decimeter per day). A concentration of 40% will increase the rate to about 250 mdd; a concentration of 80% to about 450 mdd. The oxygen need not be present in all of the acid contained in the metal vessel, but simply present in that concentration at the interface of metal, acid, and surrounding atmosphere. The effect of oxidizing salts on corrosion can be dramatic. Several factors, in addition to oxygen, affect corrosion, including the presence of other metals (electromotive-force displacements of one metal by another), temperature, acidity, and velocity. These factors are discussed further under **Corrosion**.

Oxygen Toxicity of Plants

As early as 1801, Huber and Senebier observed that grains develop more satisfactorily in an atmosphere containing a mixture of 3 parts nitrogen and 1 part oxygen than in an atmosphere containing 3 parts of oxygen and 1 part nitrogen. Considerably later, in 1878, Bert noted that the earlier observations also apply to the development of many plant species and are not peculiar to grains. Bert further suggested that excessive oxygen may slow down various reactions involving fermentation. It was not until much later, in the mid-1940s, that scientists (Dickens, Haugaard, and Stadie) further confirmed that enzymes are inactivated by oxygen excesses. They particularly stressed this fact in connection with enzymes that contain a sulfhydryl group in the active site. Machaelis (1946), Barron (1946), and Gilbert (1963) later pointed out that molecular oxygen alone acts in a rather sluggish manner in this regard and that, therefore, a special process or phenomenon must be involved. Molecular oxygen can be reduced only by accepting one electron at a time.

A number of scientists in the late 1960s through the mid-1970s pointed out that many sources in biological systems produce oxygen *free radicals*. For example, some oxidative enzymes which contain flavin as a prosthetic group proceed by a radical mechanism. When illuminated,

chloroplasts produce superoxide ions and singlet oxygen. Because of its singlet configuration, the latter is not hindered in its interactions with biological materials. As pointed out by Griffiths and Hawkins, singlet oxygen can be formed from the ground state when energy, usually in the form of light, is supplied n the presence of a photosensitizer. The compounds that are photosensitized include many dyes and pigments, such as chlorophyll, flavins, and hematoporphyrins. The interaction between the sensitizer and oxygen results in the transfer of electrons, with the formation of superoxide ion. McCord and Fridovich (1969) discovered the enzyme superoxide dismutase. Their later findings show that aerobic organisms contain it, giving further credence to the proposal that all oxygen-metabolizing organisms from superoxide free radicals as a result of a univalent reduction of oxygen. As pointed out by Kon (1978), those free radicals that are toxic to the organism, by themselves or through interaction with other active forms of oxygen, are dismutated by the action of this enzyme.

There is a close relationship between oxygen toxicity and radiation on enzymes, DNA, and fats. Gerschman et al. (1954) showed that the same substances that afford protection against oxygen poisoning also increase resistance to radiation. Their results were further strengthened by experiments that demonstrated that additive nature of the two effects. Work on the effects that free radicals have on some of the polysaccharides used in food processing was commenced by Kon and Schwimmer and reported in 1977.

Environmental Aspects of Oxygen

Gaseous oxides, notably those of carbon, nitrogen, and sulfur which result from the combustion of fossil fuels and numerous industrial processes, comprise a large portion of the air pollution problem. These compounds are discussed under the specific elements and, in particular, are described under **Pollution (Air)**. In connection with the pollution of water in streams, lakes, ponds, rivers, etc., the content of dissolved oxygen in water is of prime concern. Dissolved oxygen must be available to support fish and other desirable living species in natural waters, and sufficient additional oxygen must be available in the water to effect biological degradation of both natural and manufactured materials which reach the water. The overuse of streams for disposal purposes in many instances has almost fully depleted the dissolved oxygen available for life support and hence has given rise to the term "dead" lakes or streams. Two terms are widely used: (1) BOD (biological oxygen demand) which is the requirement for dissolved oxygen in water to degrade or decompose organic matter within a measured time period at a given temperature, and (2) COD (chemical oxygen demand) which is the requirement for dissolved oxygen in water to combine with chemicals, essentially of an inorganic nature, which are introduced into a stream as the result of disposal operations. These aspects of oxygen are discussed under **Water Pollution**.

Earth's Oxygen Supply

The manner in which the earth's present oxygen system and reserves were formed has been the subject of much postulation for many years. Many of the details remain unclear and unconfirmed. In a theory proposed by Berkner-Marshall (1964, 1965), as the earth's atmosphere evolved, there was a slow buildup of the concentration of oxygen—proceeding from a trace to the present content of 23.15% (weight). This theory also proposes that the oxygen content of the atmosphere fluctuated from time to time in a major and relatively rapid manner. There is speculation that these major alterations may have accounted for the extinctions of animal and life forms that took place at the ends of the Paleozoic and Mesozoic eras. For example, there was a great reduction in life in the latter part of the Permian period (Paleozoic era) when many kinds of strange reptiles and trilobites disappeared and seem to have left no descendents. Plant life declined greatly too during the late Paleozoic. From thousands of species in the Pennsylvanian period, there remained only a few hundred during the late Permian. Numerous explanations, particularly of a climatic nature, have been offered for these periods of reduction in life.

As pointed out by Van Valen (1971), photosynthesis does not produce a net change in oxidation. Except in bacterial photosynthesis, oxygen production is accompanied by a stoichiometrically equal quantity of reduced carbon. Thus, almost all of the oxygen is eventually used to oxidize reduced carbon. Predominantly, this oxidation occurs as the result of respiration in animals and plants. Further oxidation occurs as the result of forest fires. As observed by Borchert (1951), the only net gain in oxygen equals the amount of reduced carbon buried, as in the form of peat, black mud, and similar sediments. It has been estimated that most individual molecules of carbon remain reduced only for relatively short periods (months or years) because animals and plants have geologically very short lives. Plants respire and so oxidize some reduced carbon almost immediately. Other net sources of oxygen include nitrogen fixation and the photolysis of water in the upper atmosphere. Some investigators have considered these sources quantitatively unimportant, although Brinkmann (1969) suggests that this process would produce, over the earth's history (4.5×10^9 years), about seven times the present mass of oxygen in the atmosphere.

Numerous ways have been proposed to explain a net loss of molecular oxygen. Oxidation of volcanic gases, ferrous iron, sulfur, sulfide, and manganese, and the accretion of hydrogen from the solar wind are among these. Such processes are sometimes referred to as *oxygen sinks*. Estimates by Holland (1962) indicate that the net gain and net loss over geologic time are essentially in balance.

Van Valen has posed the question, "What can happen if photosynthesis is suddenly and drastically reduced?" Under such conditions, at a new steady state, production of oxygen and its consumption in the oxidation of carbon would be equal. But, before the new steady state occurs, would animals and decomposers use up much of the previously stored carbon in plants, thus creating a new loss of oxygen? Several investigators have observed that even if all the carbon in all organisms now alive were oxidized, this would decrease the atmospheric concentration of oxygen by less than 0.1% of its present value. And, further, still less than 1% of the present oxygen concentration would be used if all the reduced carbon available in soils and the like were reduced.

Much more detailed explanation of the stability of atmospheric oxygen is contained in the excellent review by Van Valen (1971).

As pointed out by Broecker (1970), the earth's oxygen supply is frequently included in lists of concerns over alterations in the environment, particularly as brought about by anthropogenic activities. Several investigators have made a number of observations which tend to invalidate any claims that oxygen is in danger of serious depletion. Broecker observes that each square meter of the earth's surface is covered by 60,000 moles of oxygen gas. Further, plants living in the ocean and on land produce about 8 moles of oxygen per square meter of surface each year. It is also observed that animals and bacteria destroy nearly all of the products of this photosynthetic activity—thus they use an amount of oxygen nearly equal to that generated by plants. Using the rate at which organic carbon enters the sediments of the ocean as a measure of the amount of photosynthetic product preserved each year, Broecker estimates this to be about 3×10^{-3} mole of carbon per square meter per year. This corresponds to approximately 1 part in 15 million of the oxygen present in the atmosphere. It is estimated, however, that this small amount of oxygen is probably being destroyed by a number of processes, including oxidation of reduced carbon, iron, and sulfur (weathering mechanisms). Broecker points out that the oxygen content of the atmosphere is thus well buffered, particularly in terms of relatively short time spans (100 to 1000 years).

Over a period of time, people have recovered about 10^{16} moles of fossil carbon and the fuels containing this carbon have been oxidized as sources of energy. Byproduct carbon dioxide from this combustion represent about 18% of the carbon dioxide content of the atmosphere. Two moles of atmospheric oxygen are used to liberate each mole of carbon dioxide from fossil fuel sources. Broecker points out that this process uses up only 7 out of every 10,000 available oxygen molecules. It is estimated that if these fuels are burned at an accelerating rate (5% per year), by the end of this century, only about 0.2% of available oxygen (20 molecules in every 10,000) will be used. It is estimated that if all known fossil fuels were ultimately burned, only 3% of available oxygen would be consumed. In terms of urban oxygen needs, particularly for automotive combustion needs, it is estimated that carbon monoxide levels in the atmosphere (in terms of physiological damage) would reach intolerable levels before the oxygen content of the atmosphere would have decreased by 2%.

The case of anthropogenic alterations of photosynthetic rates and its possible effects on oxygen supply has been covered previously by the observation that stoppage of all photosynthetic activity would require less than 1% of the present oxygen concentration.

Sverdrup et al. (1942) estimated that the oxygen content of deep sea water averages about 2.5 cubic centimeters at standard temperature and pressure per liter (0.1 mole per cubic meter). Thus, there are about 250

moles of oxygen gas in the deep sea for each square meter of earth surface. The oxygen content of the deep-sea waters is renewed about every 1000 years. The magnitude of this oxygen reservoir is tremendous. Broeker emphasizes this by observing that if the entire terrestrial photosynthetic product were dumped each year into the deep sea, the supply of deep-sea oxygen would last 50 years. But, if the waste products of 1 billion people were limited to 100 kilograms of dry organic waste per year, this would consume 0.01 mole of oxygen per square meter of earth surface and the deep-sea oxygen supply would last some 25,000 years.

In the summary of this report, Van Valen (1971) states, "There are three processes weakly concentration-dependent that keep changes in concentration of atmospheric pressure from being a random walk—inhibition of net photosynthesis by oxygen, the passage of hydrogen through the oxidizing part of the atmosphere before it escapes from the earth, and burial of reduced carbon in anaerobic water. A stronger regulator seems desirable but remains to be found. The cause of the initial rise in oxygen concentration presents a serious and unresolved quantitative problem."

And, in summary of his report, Broeker (1970) states, in part, "It can be stated with some confidence that the molecular oxygen supply in the atmosphere and in the broad expanse of open ocean are not threatened by human activities in the foreseeable future. Molecular oxygen is one resource that is virtually unlimited."

OXYGEN BALANCE. Oxygen content relative to the total oxygen required for oxidation of all carbon, hydrogen, and other easily oxidizable elements to carbon dioxide, water, etc.

OXYGEN CELL. An electrolytic cell whose emf is due to a difference in oxygen concentration at one electrode compared with that at another electrode of the same material.

OXYGEN CONSUMED (OC; COD; DOC). A measure of the quantity of oxidizable components present in water. Since the carbon and hydrogen, but not the nitrogen, in organic matter are oxidized by chemical oxidants, the oxygen consumed is a measure only of the chemically oxidizable components and is dependent on the oxidant, structure of the organic compound, and manipulative procedure. Since this value does not differentiate stable from unstable organic matter, it does not necessarily correlate with the biochemical oxygen demand value. It is also known as chemical oxygen demand (COD) and dichromate oxygen consumed (DOC).

See also **Biochemical Oxygen Demand (Bod)**; and **Disolved Oxygen (DO)**.

OXYGEN DEBT. A term used to refer to the buildup of a need for oxygen through anaerobic respiration of muscle cells in a higher vertebrate animal during violent exercise. When the energy demands are too great to be satisfied by the aerobic respiration, the cells turn to anaerobic respiration. Lactic acid is an end product of such respiration; this acid tends to accumulate in the muscles and some of it diffuses out into the blood and accumulates in the liver. When the activity ceases, deep breathing continues and the extra oxygen is used to reconvert the lactic acid back to pyruvic acid and to carry the pyruvic acid on through the tricarbocyclic acid cycle. It may also be reconverted back to glucose and glycogen. We say that the muscles have built up an oxygen debt during the very active exercise and this is repaid in the continued deep breathing during rest following the exercise.

OXYGEN GROUP (The). The elements of group 16 of the periodic classification sometimes are referred to as the Oxygen Group. In order of increasing atomic number, they are oxygen, sulfur, selenium, tellurium, and polonium. The elements of this group are characterized by the presence of six electrons in an outer shell. The similarities of chemical behavior among the elements of this group are less striking than hold for some of the other groups, e.g., the close parallels of the alkali metals or alkaline earths. With exception of oxygen, all elements of the group have a valence of 4+, in addition to other valences. All of the elements with the exception of polonium also have a valence of 2−. Unlike the alkali metals or alkaline earths, for example, the elements of the oxygen group are not so similar chemically that they comprise a separate group in classical qualitative chemical analysis separations. Tellurium and selenium do appear together among the rarer metals of the second group in terms of qualitative chemical analysis.

OXYGEN SINK. A reservoir consisting of a chemical element or compound that combines readily with oxygen and thus removes it from the atmosphere. During the early part of Precambrian time, sulfur iron, and other elements and compounds served as important oxygen sinks, preventing oxygen from accumulating in the atmosphere.

OXYL PROCESS. A method for directly producing higher alcohols by catalytically reducing carbon monoxide with hydrogen.

OXYTOCIC HORMONE. See **Hormones**.

OXYTOCIN. A polypeptide hormone which is secreted by the posterior lobe of the pituitary gland of mammals and other vertebrates. Oxytocin exerts a stimulating effect upon the muscles of the breast (milk-ejection) and those of the uterus of mammals. It is sometimes used medically to stimulate labor in cases of difficult childbirth and to time the onset of labor.

OZOCERITE. Sometimes spelled ozokerite, this is a natural, brown to jet black mineral (paraffin) wax comprised mainly of hydrocarbons. The melting point is variable. The material is soluble in chloroform. When heated with sulfuric acid (20–30%) from 120–200°C, ozocerite yields ceresine. Sometimes called earth wax, fossil wax, mineral wax, and native paraffin.

OZONE. [CAS: 10028-15-6]. Ozone, O_3, is an allotropic form of oxygen first recognized as a unique substance in 1840. Its pungent odor is detectable at ~0.01 ppm. It is thermally unstable and explosive in the gas, liquid, and solid phases. In addition to being an excellent disinfectant, ozone is a powerful oxidant not only thermodynamically, but also kinetically, and has many useful synthetic applications in research and industry. Its strong oxidizing and disinfecting properties and its innocuous

by-product, oxygen, make it ideal for the treatment of water. Indeed, the most important application of ozone is in the treatment of drinking water, which began in Europe. The treatment of swimming pool water was also developed in Europe. Another important ozone application is for odor control in industrial processes and municipal wastewater-treatment plants. Ozone also is used on a large scale for the treatment of municipal secondary effluents. Industrial high quality water supplies are also treated with ozone. In addition, ozone has applications in the treatment of cooling-tower water and in pulp bleaching. Advanced oxidation processes employing ozone in combination with uv, H_2O_2, and/or solid catalysts such as TiO_2 greatly improve the reactivity of ozone toward organic contaminants.

Ozone, which occurs in the stratosphere (15–50 km) in concentrations of 1–10 ppm, is formed by the action of solar radiation on molecular oxygen. It absorbs biologically damaging ultraviolet radiation (200–300 nm), prevents the radiation from reaching the surface of the earth, and contributes to thermal equilibrium on earth.

Properties

At ordinary temperatures, pure ozone is a pale blue gas ($d = 2.1415$ g/L at 0°C and 101.3 kPa (1 atm)) that can be condensed to an indigo blue liquid, which freezes to a deep blue-violet solid. The solubility of gaseous ozone at atmospheric pressure and 0°C is 1.1 g/L H_2O. Gaseous ozone can be adsorbed by porous solid substrates such as silica gel and is often used in this form in organic synthesis.

Ozone is endothermic, thus it can burn or detonate by itself and represents the simplest combustible and explosive system. The concentration threshold for spark-initiated explosion of liquid ozone in oxygen at −183°C is 18.6 mol % O_3; the concentration limit for shock wave-initiated detonation of gaseous ozone-oxygen at 25°C is 9.2 mol % O_3. Gaseous ozone exhibits three principal absorptions in the infrared at 710, 1043, and 2105 cm^{-1}.

Ozone is a triangular molecule; its bond angle (116.8°) was established by microwave spectroscopy. The bond length of the ozone molecule (0.1278 nm) is intermediate to that of a single and double oxygen bond, corresponding to a bond order of 1.7. Ozone is diamagnetic with C_{2v} symmetry and has a low dipole moment of 1.77×10^{-30} C · m (0.53 D). Based on Pauling resonance concepts, the structure of ozone is a hybrid, principally of form (1), with a small contribution from (2).

Thermal Decomposition

Gas Phase. The decomposition of gaseous ozone is sensitive not only to homogeneous catalysis by light, trace organic matter, nitrogen oxides, mercury vapor, and peroxides, but also to heterogeneous catalysis by metals and metal oxides.

The calculated half-life of 1 mol % (1.5 wt %) of pure gaseous ozone diluted with oxygen at 25, 100, and 250°C is 19.3 yr, 5.2 h, and 0.1 s, respectively. Although pure ozone-oxygen mixtures are stable at ordinary temperatures in the absence of catalysts and light, ozone produced on an industrial scale by silent discharge is less stable due to the presence of impurities; however, ozone produced from oxygen is more stable than that from air. At 20°C, 1 mol % ozone produced from air is ∼30% decomposed in 12 h.

Aqueous Phase. In pure water, the decomposition of ozone at 20°C involves a complex radical chain mechanism, initiated by OH^- and propagated by O_2^- radical ions and HO radicals.

Hydrogen peroxide greatly accelerates the decomposition of ozone in alkaline solutions because of formation of HO_2^-, which reacts rapidly with ozone to form the radical ion O_2^-.

Photochemical Decomposition

Gas Phase. Gaseous ozone is decomposed to oxygen atoms and molecules by absorbing radiation in the visible and uv spectrum: $O_3 + h\nu \longrightarrow O_2 + O$.

Aqueous Phase. In contrast to photolysis of ozone in moist air, photolysis in the aqueous phase can produce hydrogen peroxide initially because the hydroxyl radicals do not escape the solvent cage in which they are formed. Hydrogen peroxide is photolyzed slowly to hydroxyl radicals, which decompose ozone.

Chemistry of Ozone

The inorganic chemistry of ozone is extensive, encompassing virtually every element except most noble metals, fluorine, and the inert gases.

Ozone reacts rapidly with various free radicals and radical ions such as O, O_2^-, H, HO, N, NO, Cl, and Br. Some of these radicals (HO, NO, Cl, and Br) can initiate the catalytic decomposition of ozone.

The strong electrophilicity of ozone is manifested in its reaction with a wide variety of organic and organometallic functional groups, e.g., olefins, acetylenes, aromatics (carbocyclic and heterocyclic), activated C−H bonds (acetals, alcohols, aldehydes, ethers, and glycosides), unactivated C−H bonds (alkanes, cycloalkanes, and alkyl aromatics), deactivated C−H bonds (carboxylic acids and ketones), C=N and N=N bonds, Si−H and Si−C bonds, organometallic bonds (e.g., Grignard reagents), and nucleophiles (e.g., ammonia, amines, amino acids, arsines, disulfides, hydroxylamines, nitriles, phosphites, selenides, sulfides, and thioethers). Ozone also acts as a nucleophile, e.g., in its reaction with carbocations.

Atmospheric Ozone

Stratosphere. Ozone is formed rapidly in the stratosphere (15–50 km) by the action of short-wave ultraviolet solar radiation (<240 nm) on molecular oxygen, $O_2 + h\nu \longrightarrow 2O$. At wavelengths above 175 nm, only ground-state (^3P) atoms are formed; whereas at wavelengths below 175 nm, one ground-state and one excited (^1D) atom are formed. Ground-state atoms also can be formed by the pre-dissociation of electronically excited O_2. The oxygen atoms can react with molecular oxygen to yield ozone: $O + O_2 + M \longrightarrow O_3 + M$. Ozone can be destroyed photochemically: $O_3 + h\nu \longrightarrow O + O_2$; at 226 nm, however, this reaction also can produce vibrationally excited O_2 capable of forming ozone. In addition, ozone can be destroyed by reaction with oxygen atoms, as well as with excited O_2 molecules and other free radicals. Since the early 1960s, it has been recognized that radicals such as NO, OH, Cl, and Br affect the abundance and distribution of ozone in the stratosphere. Earlier studies simulating stratospheric chemistry concluded that ozone formation is significantly less than its destruction, hence the ozone deficit problem. However, studies indicate that this may not be the case.

Most ozone is formed near the equator, where solar radiation is greatest, and transported toward the poles by normal circulation patterns in the stratosphere. Consequently, the concentration is minimum at the equator and maximum for most of the year at the north pole and about 60°S latitude. The equilibrium ozone concentration also varies with altitude; the maximum occurs at about 25 km at the equator and 15–20 km at or near the poles. It also varies seasonally, daily, as well as interannually. Absorption of solar radiation (200–300 nm) by ozone and heat liberated in ozone formation and destruction together create a warm layer in the upper atmosphere at 40–50 km, which helps to maintain thermal equilibrium on earth.

Troposphere. Ozone and nitric oxide are transported from the stratosphere to the troposphere, the region of the atmosphere below 15 km. Though only about 10% of the atmospheric ozone is present in the troposphere, this small fraction plays a fundamental role in atmospheric chemistry because it leads to the formation of hydroxyl radicals. Hydroxyl radicals initiate the oxidation and prevent the buildup of many organic and inorganic pollutants in the atmosphere. The radical-dominated chemistry of the troposphere is complex, involving intertwining cycles of gas-phase, condensed-phase, and multiple-phase reactions. In unpolluted atmosphere, HO radicals react with naturally occurring CO and methane, resulting in a net increase in ozone concentration.

Although the naturally occurring concentration of ozone at the earth's surface is very low, this distribution has been altered by the emission of anthropogenic pollutants which increase the production of ozone via the above mechanism. Photochemical smog, an aerosol irritant gas mixture, occurs in urban industrialized areas where heavy motor vehicle traffic is common, especially those areas where temperature inversions are common. It forms at low altitudes by photolytic reactions involving nonmethane hydrocarbons, NO, and CO, resulting in low but potentially harmful concentrations of ozone and other irritating substances, such as aldehydes, ketones, acids, H_2O_2, organic peroxides, and peroxyacetyl nitrate.

Although the background concentration of ozone in surface air is ∼0.01–0.03 ppm, during severe smog days in the Los Angeles area, for example, it has often reached 0.5 ppm, and a maximum of 1 ppm in 1957. In the early morning hours, NO is removed slowly by the oxygen atom chain, which is initiated by the photolysis of NO_2 and subsequently by the photolysis of ozone. Later in the day when the light intensity is higher, the hydroxyl chain causes the NO conversion to accelerate.

Ozone can react rapidly with NO to produce NO_2, which re-enters the ozone formation cycle: $O_3 + NO \longrightarrow O_2 + NO_2$. This is the main

ozone-depleting reaction in the absence of sunlight. Ozone also reacts with NO_2 (to form NO_3, which in turn reacts with NO_2 to form N_2O_5), C_2H_4, as well as HO and HO_2 radicals. Nitric acid formed by the reaction $HO + NO_2 \longrightarrow HNO_3$ is removed from the atmosphere by rain-out.

Ozone Generation

Ozone can be generated by a variety of methods, the most common of which involves the dissociation of molecular oxygen electrically (silent discharge) or photochemically (uv). The short-lived oxygen atoms (lifetime $\sim 10^{-5}$ s) react rapidly with oxygen molecules to form ozone. The widely employed technique of electric discharge produces much higher concentrations than the ultraviolet technique and is more practical and efficient for production of large quantities. A less common method of ozone formation is electrochemical generation.

Silent Electric Discharge. Commercial production and utilization of ozone by silent electric discharge consists of five basic unit operations: gas preparation, electrical power supply, ozone generation, contacting (i.e., ozone dissolution in water), and destruction of ozone in contactor off-gases.

Ultraviolet Light. The mechanism of the practical photochemical production of ozone is similar to that in the stratosphere; that is, oxygen atoms, formed by the photodissociation of oxygen by short-wavelength uv radiation ($\leq$240 nm), react with oxygen molecules to form ozone. In practice, ozone concentrations obtained by commercial uv devices are low. This is because the low intensity, low pressure mercury lamps employed produce not only the 185-nm radiation responsible for ozone formation, but also the 254-nm radiation that destroys ozone, resulting in a quantum yield of $\sim$0.5 compared to the theoretical yield of 2.0. The low concentrations of ozone available from uv generators preclude their use for water treatment because the transfer efficiencies of ozone from air into water is low and large volumes of carrier gas must be handled.

Uses

Ozone is used in the treatment of drinking water and in industries where high purity water is required (e.g., breweries, pharmaceuticals, and electronics). Ozone is also used in industrial wastewater pollution control, wastewater disinfection, and odor control; in the treatment of process water, such as cooling tower water; in the treatment of swimming pools and spas; in pulp bleaching; and in organic synthesis, as a selective oxidant.

Among other uses, ozone therapy, employing O_3–O_2, is increasingly being employed and studied in dentistry, veterinary and sports medicine, and proctology. Ozone is used as an aquatic oxidant and disinfectant in zoos, large aquariums, as well as fish and shrimp hatcheries. Ozone also is used for food preservation, in cold storage rooms, brewery cellars, hotel and hospital air ducts, and air conditioning systems. Ozone has also been used in textile bleaching and in the bleaching of esters, oils, fats, waxes (qv), starch, flour, ivory, etc. Oxidation of Ag^+ by ozone is employed commercially to produce high purity AgO. The use of ozone as a chemical agent decontaminant has been patented.

Health and Safety

As a constituent of the atmosphere, ozone forms a protective screen by absorbing radiation of wavelengths between 200 and 300 nm, which can damage DNA and be harmful to life. Consequently, a decrease in the stratospheric ozone concentration results in an increase in the uv radiation reaching the earth's surfaces, thus adversely affecting the climate as well as plant and animal life. For example, the incidence of skin cancer is related to the amount of exposure to uv radiation. Ozone can be toxic to plants, animals, and fish.

The toxicity of ozone to humans is largely related to its powerful oxidizing properties. The odor threshold of ozone varies among individuals but most people can detect 0.01 ppm in air, which is well below the limit for general comfort. The symptoms experienced on exposure to 0.1–1 ppm ozone are headache, throat dryness, irritation of the respiratory passages, and burning of the eyes caused by the formation of aldehydes and peroxyacyl nitrates. Exposure to 1–100 ppm ozone can cause asthma-like symptoms such as tiredness and lack of appetite. Short-term exposure to higher concentrations can cause throat irritations, hemorrhaging, and pulmonary edema.

Ozonation of drinking water produces various by-products such as aldehydes, ketones, carboxylic acids, organic peroxides, epoxides, nitrosamines, N-oxy compounds, quinones, hydroxylated aromatic compounds, brominated organics, and bromate ion. Although some of these compounds are potentially toxic or carcinogenic, most bioassay-screening studies have shown that ozonated water induces substantially less mutagenicity than chlorinated water.

PAINT AND FINISH REMOVERS. The term finish denotes the final process of manufacturing. Finishing operations include such processes as clear coating (varnishes and lacquers), painting, plating, anodizing, phosphatizing, galvanizing, and blueing, all of which take place at the terminal point of manufacturing. Finishing is defined as the process of coating or treating a surface for the purpose of protecting and/or decorating the product. The useful life of most usable objects is greater than the finish. This results in a periodic need to remove and replace the finish.

The physical properties of finish removers vary considerably due to the diverse uses and requirements of the removers. Finish removers can be grouped by the principal ingredient of the formula, method of application, method of removal, chemical base, viscosity, or hazardous classification. Except for method of application, a paint remover formulation usually has one aspect of each group, by which it can be used for one or more applications.

Finish removers are applied by brushing, spraying, troweling, flowing, or soaking. Removal is by water rinse, wipe and let dry, or solvent rinse. Removers may be neutral, basic, or acidic. The viscosity can vary from water thin, to a thick spray-on, to a paste trowel-on remover. The hazard classification, such as flammable or corrosive, is assigned by the U.S. Department of Transportation (DOT) for the hazardous materials contained in the remover.

Organic Finish Removers

Methylene Chloride Finish Removers. Methylene chloride formulas are the most common organic chemical removers. The low molar volume of methylene chloride allows it to rapidly penetrate the finish by entering the microvoids of the finish. When the solvent reaches the substrate, the remover releases the adhesive bond between the finish and the substrate and causes the finish to swell. The result is a blistering effect and an efficient rapid lifting action. Larger molecule solvents generally cannot cause this lifting action and must dissolve the finish. When methylene chloride is used in amounts of 78% or more, even with flammable cosolvents, the mixture is nonflammable. A typical methylene chloride base remover includes cosolvents, activators, evaporation retarders, corrosion inhibitors, thickeners, and wetting agents.

Typical cosolvents include methanol, ethanol, isopropyl alcohol, or toluene. The selection of cosolvents depends on the requirement of the formula and their interaction with other ingredients. Methanol is a common cosolvent in methylene chloride formulas since it has good solvency and is needed to swell cellulose-type thickening agents. A typical methylene chloride formula used to strip wood is as follows: methylene chloride 81.1%; 1toluene 2.1%; paraffin wax (ASTM 50–53°C mp), 1.6%; methycellulose,1.2%; methanol, 7.8%; and mineral spirits 6.2%.

The rate of stripping or the stripability on catalyzed urethane and epoxy resin finishes can be increased by adding formic acid, acetic acid, and phenol. Sodium hydroxide, potassium hydroxide, and trisodium phosphate may be added to the formula to increase the stripability on enamel and latex paints. Other activators include oleic acid, trichloroacetic acid, ammonia, triethanolamine, and monoethylamine. Methylene chloride-type removers are unique in their ability to accept cosolvents and activators that allow the solution to be neutral, alkaline, or acidic. This ability greatly expands the number of coatings that can be removed with methylene chloride removers.

Paraffin wax vapor barriers are used in water rinse removers that can disperse the wax without coating the substrate. In soak tank applications, water is sometimes floated on top of an all-solvent, neutral pH, nonwater rinse remover to prevent evaporation. Flotation devices that cover the exposed surface area may be used with other formulas.

Health and Safety. Remover formulas that are nonflammable may be used in any area that provides adequate ventilation. Most manufacturers recommend a use environment of 50–100 parts per million (ppm) time weighted average (TWA). The environment can be monitored with passive detection badges or by active air sampling and charcoal absorption tube analysis. The vapor of methylene chloride produces hydrogen chloride and phosgene gas when burned. Methylene chloride-type removers should not be used in the presence of an open flame or other heat sources such as kerosene heaters

Persons exposed to methylene chloride removers should wear protective clothing and eye protection.

Environmental Impact. Methylene chloride is nonphotochemically reactive and is not listed as an ozone (qv) depleter. Methylene chloride removers can easily be recovered from paint chips and other residue sedimentation, thus allowing recovery of remover and its continued use. This greatly increases the useful life of the remover and, when mixed with fresh remover, eliminates the need for disposing of the used remover. This process requires no special recovery equipment. The high volatility of methylene chloride allows the waste residue from the stripping process to be easily dried. The resulting waste is normally considered hazardous because of the amounts of heavy metals from old finishes.

Petroleum and Oxygenate Finish Removers. Many older finishes can be removed with single solvents or blends of petroleum solvents and oxygenates. Varnish can be removed with mineral spirits, shellac can be stripped with alcohols, and lacquers can be removed with blends of acetates and alcohols (lacquer thinners). The removal mechanism is one of dissolving the coating, then washing the surface or wiping away the finish. This method is often used to reamalgamate or liquefy old finishes on antique items of furniture.

In petroleum and oxygenate finish removers, the major ingredient is normally acetone, methyl ethyl ketone, or toluene. Cosolvents include methanol, n-butanol, sec-butyl alcohol, or xylene. Sodium hydroxide or amines are used to activate the remover. Paraffin wax is used as an evaporation retarder though its effectiveness is limited because it is highly soluble in the petroleum solvents. Cellulose thickeners are sometimes added to liquid formulas to assist in pulling the paraffin wax from the liquid to form a vapor barrier or to make a thick formula. Corrosion inhibitors are added to stabilize the formula for packaging (qv).

Wetting agents are used to make a water rinse remover. Water rinse removers are normally used for removing paint, where the surfactants help remove paint and remover from the substrate. Solvent rinse removers or wipe and dry formulas may be used for stripping clear finishes. A typical petroleum and oxygenate formula is as follows: toluene 21%; acetone19%; alkyl acetate 31%; methyl ethyl ketone19%, and butyl alcohol10%.

This is a liquid scrape-off remover for brush or soak applications. Clean up is with a solvent that is compatible with finish to be used, or wipe and dry.

Health and Safety. Petroleum and oxygenate formulas are either flammable or combustible. Flammables must be used in facilities that meet requirements for hazardous locations.

Adequate ventilation that meets the exposure level for the major ingredient must be attained. Extreme caution must be taken to prevent the possibility of fire when using flammable removers.

Environmental Impact. Most petroleum and oxygenate removers are photochemically reactive and classed as volatile organic compounds (VOCs). Disposal of this type of remover is difficult because the dissolved finish cannot be separated from the spent remover and the whole mixture must be disposed as a liquid hazardous waste. Distillation to recover

the solvents is dangerous because the nitrocellulose from lacquer finish may cause autoignition in the still. Several states restrict the use of these products.

Other Organic Removers. Concerns over the reported toxicity and carcinogenicity of methylene chloride have stimulated research for alternative solvents in remover formulas. N-Methylpyrrolidinone and dibasic esters (dimethyl glutarate or dimethyl adipate) have been used in removers. They remove single-component finishes but work much more slowly than methylene chloride, petroleum, and oxygenate group removers. They have little success on epoxy and catalyzed finishes.

Health and Safety. Both N-methylpyrrolidinone and dibasic esters have very low vapor pressure which limits worker exposure to vapors. Manufacturers recommend that the same safety precautions be taken as with other organic solvents. Hazardous location requirements must be considered if the formula is flammable. Ventilation that reduces vapors to manufacturer's recommended exposure levels should be used. Protective clothing must be worn during use.

Environmental Impact. The volume of waste remover from these products is remarkably increased when compared to methylene chloride, petroleum, and oxygenate removers, since both N-methylpyrrolidinone and dibasic esters have low vapor pressures. Recovery of the remover after use is difficult because the finish is resolubilized by the remover.

Inorganic Finish Removers

Liquid Alkaline Removers. This group consists of alkaline materials that are dissolved in water then heated to an appropriate temperature to remove finishes. In a typical application, a hot water bath large enough to submerge an item is used. Various alkaline materials may be used to provide the desired alkalinity. Of these, sodium compounds are preferred, such as sodium hydroxide, sodium carbonate, sodium silicates, mono-, di-, and trisodium phosphates, tetrasodium pyrophosphate, and sodium tripolyphosphate. Compounds of other metals, such as potassium or lithium, may be used.

This aqueous alkaline remover is used for stripping the finish from wood or ferrous metals at a mix ratio of 30–600 g/L (0.25–5 lbs/gal).

Paste-Type Alkaline Removers. Sodium hydroxide, potassium hydroxide, or other caustic compounds are blended to make these types of removers. Polymer-type thickeners are added to increase the viscosity that allows the remover to be applied with a brush, trowel, or spray. Some of these products use a paper or fabric covering to allow the remover finish mixture to be peeled away. The most common application for this group of removers is the removal of architectural finishes from the interior and exterior of buildings. The long dwell time allows for many layers of finish to be removed with one thick application of remover.

Sodium hydroxide and salt can be heated to a fused state in baths to allow the removal of finishes from ferrous metals. The most common use of this method is the removal of heavy concentrations of paint on conveyer parts and hangers used in production spray systems.

Health and Safety. Protective clothing that is compatible with the remover formula must be worn. Caustic soda baths should be ventilated to remove vapors from the work area. Most caustic removers are corrosive and cause severe burns with minimal contact to the skin.

The liquid from spent caustic soda baths must be disposed of or treated as a hazardous waste. The finish residue may contain heavy metals as well as caustic thus requiring treatment as a hazardous waste.

Manufacturing and Processing

Finish removers are manufactured in open or closed kettles. Closed kettles are preferred because they prevent solvent loss and exposure to personnel. To reduce air emissions from the solvents, condensers are employed on vent stacks.

Standard 0.25 or 0.50 lb (227 g) tin coated cans are used for packaging liquid with neutral and mildly alkaline base formulas; polypropylene is used for acid–base removers. Steel and polypropylene drums are used for industrial removers. Viscous removers are packaged in removable top containers. Dry caustic removers are packaged in bag-lined boxes or fiber drums.

The DOT has established standards for the packaging and labeling of hazardous materials offered for shipment by public transportation. The Consumer Product Safety Commission (CPSC) has set standards for retail labeling and packaging. OSHA and the U.S. EPA have labeling requirements.

PAINTS AND COATINGS. Traditionally, paints and other coatings have been considered in terms of protecting and decorating buildings, houses, furniture, automobiles, toys, boats, machines, and the like. These products represent a large industry estimated at about $15 billion per year worldwide. Nevertheless, these kinds of coatings account for only 10–15% of the total coatings industry.

One researcher[1] has classified coatings in two technically defined categories.

Type I—Products manufactured and sold with several coating layers. Examples are the aforementioned applications, but also include color photographic film, graphic arts films for printing, coated papers for printing, coated containers for food packaging, magnetic storage media for computers and audio/visual equipment, optical disks for digital data storage, adhesive tapes, wallpaper, and metallized films.

Type II—Coatings that become an integral part or a key intermediary for a device or piece of equipment. Sometimes, the term *core technology* is used for such applications. There is a wide variety of coating products in this classification. They would include photoresists for circuit board manufacture, thick- and thin-film coatings on integrated circuits, adhesives for bonding metals, phosphor coatings on electronic display screens, stain repellents on fibers, dyes on fibers, ceramic glazes, encapsulated time-release drugs, and thin-film photovoltaic cells.

The foregoing categories of coatings immediately dramatize the versatility and specialization of a huge industry that has developed essentially during the past three decades. With the continuing interest in materials composites, continued rapid growth is expected. Coating technology is a complex undertaking fraught with numerous design and manufacturing problems. These are particularly difficult in scaling up laboratory procedures to high production rates on the factory floor. Consequently, a number of successful processes remain proprietary. The technology has demanded much of chemists and chemical and mechanical engineers, with particular emphasis on an understanding of fluid dynamics.

Although the two foregoing classifications may serve a very useful purpose at the scientific level, for the purposes of this article, the first part is devoted to traditional surface coating products that serve protective and decorative purposes. The second part, in less depth, addresses coatings that are used for special purposes as represented, (e.g., by uses in electronic devices).

PROTECTIVE AND DECORATIVE COATINGS[2]

Paint, coating, and finish are terms used to describe a wide variety of materials designed to adhere to a substrate and act as a thin, plastic-like layer. Paints are available for decorative, protective, and other purposes. They can be decorative by covering defects (being opaque), by changing color, or by providing a desired gloss or sheen. Protective uses include shielding metals from corrosion, protecting plastic from degradation caused

[1] E.D. Cohen, E.I. Du Pont De Nemours & Co., Parlin, New Jersey.

[2] Some of this information was provided by The Sherwin-Williams Company, Cleveland, Ohio.

by ultraviolet light, acting as a moisture barrier and providing mar and scratch resistance for wood or plastic surfaces. A paint can also be used for its special spectral properties (e.g., light absorbing for heating swimming pools; radar absorbing for military vehicles; etc.), or unusual physical properties (e.g., strippable coatings for the interior of paint spray booths, insulating coatings for electrical parts, etc.).

Paints are generally liquids before they are applied to a surface. When applied, they should completely replace the substrate/air interface with a substrate/paint interface (called wetting). The forces of attraction created by this wetting process are responsible for the paint's adhesion. The paint then dries and/or cures to form a hard film. Drying is the physical action of solvent leaving the film, while curing refers to a chemical reaction which connects polymer chains of the paint together.

Composition

Thousands of raw materials are used to manufacture coatings, but they can generally be classified into four categories: (1) binders or resins, (2) pigments, (3) solvents, and (4) additives. Binders and resins are generally organic compounds, usually polymeric or oligomeric in nature, which provide a continuous matrix in the final film and have a major influence on the toughness, flexibility, gloss, chemical resistance and cure/dry properties of the coating.

Pigments. These are finely divided powders (particles between 0.1 and 50 micrometers in diameter) which are dispersed throughout the binder. In addition to reinforcing the final film, much as they do in composite plastics, they influence a coating's resistance to abrasion and corrosion, and they also are the major factor in the gloss, color, and opacity of a coating.

Solvents or Thinners. These substances have a major effect on a paint's application viscosity and also affect a coating's cure dry properties, and often its toxicity. Most solvents evaporate and leave the film during the drying process, although certain "reactive dilutents" are designed to react with the resin and become part of the binder system. Water is a popular solvent because of its low cost, low toxicity, and nonpolluting nature. Almost half of the coatings currently produced use water as a major solvent. Disadvantages of using water include the effect of humidity on the drying characteristics of the paint and the difficulty of making a water-resistant film from materials suspended in water. Major organic solvents include mineral spirits, ketones, acetates, alcohols, and xylene.

Additives. Among the more important classes of additives used in coatings are: (1) *surfactants*, which are used to suspend pigment and binder particles; (2) *thickeners* to obtain proper rheology (especially in latex paints); (3) *plasticizers*, which lower the glass transition temperature of the binder and increase the flexibility of the coating; (4) *antifoam agents* to prevent bubbles in aqueous paints; (5) *antiskin agents*, which prevent the formation of a dry layer on top of the paint while it is still in the can; (6) *preservatives*, such as biocides and mildewcides to protect the binder from microscopic organisms both before and after application; (7) *ultraviolet light absorbers* to protect the binder and/or substrate from degradation due to sunlight; and (8) a variety of surface *conditioners* and *lubricants*, which help the film adhere to the substrate or protect the film by giving it a lubricated surface. Additives will often interact and coating formulators must be careful to watch for synergistic and antagonistic effects.

Ratio of Components. The ratio of the four aforementioned components (binders, pigments, solvents, and additives) greatly influences the properties of a coating. The volume fraction of the solid film (which is pigment) is referred to as the *pigment volume concentration*. The concentration where there is barely sufficient binder to fill in the voids between the pigment particles is referred to as the *critical pigment volume concentration* (or *CPVC*). When the composition of a coating is changed from below its CPVC to above it, the properties of the coating begin to dramatically degrade (except for opacity, which increases). The performance changes are primarily due to the pockets of air which form in the final film because of the shortage of binder. With the exception of flat architectural (house) paints, fillers, and certain primers, almost all coatings have a pigment volume concentration less than the CPVC. The CPVC is a function of a pigment combination's oil adsorption and particle size distribution.

The ratio of solvent to nonvolatiles is important since the volatile organic compound (VOC) composition of coatings is increasingly a target of government regulations. Usually the VOC of a coating is expressed in units of *mass per volume* and is calculated by multiplying the density of the coating by that fraction of the coating that is volatile. For coatings using water (or certain chloroalkanes) as a solvent, the effect of these "exempt" solvents is subtracted out before the calculation is made. Current VOC limits in the United States range from 250 grams per liter for some California architectural alkyds to 450 grams per liter for some furniture finishes.

Binder Classifications

Paints are often classified by the type of binder they include. The most common classifications (with percent of total coatings used in 1985) are: Latexes (31%); waterborne (10%); non-aqueous dispersions (2%); solvent-borne (55%); and one hundred percent solids coatings (2%). A small volume of paint is made with silane binders.

Latexes. These are dispersions of high-molecular-weight polymer particles in an aqueous medium. Since the polymer is in a suspended form, the viscosity of the mixture is almost exclusively a function of the viscosity of the continuous phase (i.e., water) and is not affected by the molecular weight of the polymer. This permits the use of higher-molecular-weight material than can be used with a solution-type approach. The film forms (i.e., the paint dries) when the water evaporates and the spherical latex particles are forced together, overcoming the steric and ionic forces which had been stabilizing them. Once the particles touch, the surface tension of the latex causes the individual particles to coalesce (i.e., the polymers in adjoining particles entangle), aided by the capillary forces created by the evaporating water. Latex particles are generally 0.1 to 0.5 micrometer in diameter, although particle sizes as much as an order of magnitude on either side of these values is used for specialized purposes.

The two most commonly used latex systems are acrylic systems (40% of usage), which perform very well, but are relatively expensive, and the vinyl-acrylic copolymer systems (57% of usage and growing), which do not perform as well, but are less expensive.

Latexes are usually considered separate from other waterborne binders because the method employed for synthesizing and suspending them is very different. For latexes, emulsion polymerization is used and no organic solvent is required to obtain or stabilize the emulsion. In contrast, most waterborne binders are synthesized in organic solvent solutions and then "let down" with water. Often, some quantity of organic solvent must remain or the resulting aqueous mixture will not be stable. Most waterborne resins need to be cured. Reactions commonly used include the oxidative polymerization of unsaturated aliphatic chains, the reaction with aminoplast resins, and the reaction of epoxies to form ether or ester bonds. Waterborne resin compositions include acrylics, polyesters (including alkyds), urethanes, phenolics, and epoxies, among others.

Non-Aqueous Dispersions (NADs). These are the solvent-borne analogues of latexes. They were used as automotive finishes in the 1970s, but their use is now declining. The use of NADs as an auxiliary binder, however, is increasing as it has been found that the addition of a small amount of NAD can improve a coating's drying characteristics and rheology.

Solvent-Borne Coatings. These cover a wide variety of resins including alkyds. Alkyds are polyesters made from soya, linseed, or other oils and are a major factor in architectural, automotive, and industrial maintenance usages, among other applications. Acrylics are known for their exterior durability and are the major binder in automotive coatings. Epoxies are used mostly in automotive, industrial maintenance, metal container, and coil coatings. Polyurethanes are isocyanate-based binders and are used where excellent properties are required, such as in the magnetic media, magnet wire, industrial maintenance, and deck coatings fields. Polyesters, other than alkyds, are used in coil, metal furniture, metal container, appliance, and automotive coatings. Amino crosslinkers primarily are modified melamines and are important in metal container, automotive, coil, and metal furniture applications, among others.

In addition to drying, most solvent-borne coatings undergo some type of cure. Chemical reactions used for the cure of solvent-borne coatings include the oxidative crosslinking of unsaturated carbon bonds (alkyds and polyesters), the reaction of melamine derivatives to form ureas (polyesters, alkyds, acrylics, and amino resins), ether and ester formation by epoxies (epoxies, polyesters and acrylics), and urethan formation by isocyanates. Curing is especially important in low VOC coatings because the viscosity of a resin is a function of the molecular weight of the material. The demand for lower VOC (i.e., higher solids) coatings has resulted in a move toward lower-molecular weight and more reactive solvent-borne coatings. About

one-quarter of the solvent-borne coatings currently used are considered "high solids" (i.e., they have a VOC of 350 grams/liter or less).

The thrust for higher solids also has been a factor in the growth of *100% solids* coating technologies. These technologies include polymerization initiated by ultraviolet radiation or an electron beam; the use of powdered coatings which coalesce when sufficient heat is applied; and vapor cure technology, where a reactive resin is crosslinked by exposure to a reactive vapor. While the capital investment required by these technologies is high, their use is expected to continue to grow because of their efficient use of material and the superior properties that can be obtained. Another means of using a *solventless system is hot melt coatings*. These are applied at high temperatures without solvent and dry by cooling them to room temperature.

Silanes. Silanes and silane derivatives dominate the small market for inorganic binders. These materials are used both in combination with organic binders and by themselves. As co-binders, they increase the chemical and moisture resistance of a film. When used by themselves, they form brittle, very chemical-resistant films. Silane coatings are usually more expensive than their organic counterparts and must be kept dry before application.

Pigment Classifications

Pigments used in the paint industry are commonly classified by function: (1) *Hiding* (or *prime*) pigments scatter light and are used to obtain opacity; (2) *extender* (or "inert") pigments are used to reinforce the binder, increase the pigment volume concentration, lower gloss, and lower the cost of a paint; (3) *colored* pigments which are used to tint a paint can be either inorganic or organic; (4) *metallic* pigments are used for corrosion prevention and appearance reasons; and (5) *protective* and other *functional pigments* can be used to add special features to a coating.

Hiding Pigment. The refractive index of hiding pigments must be sufficiently different from the refractive index of the binder (usually about 1.5) if light is to be effectively scattered. Two crystal structures of titanium dioxide (commonly referred to as titanium) are the most widely used hiding pigments in the paint industry with the rutile version being more popular than anatase because the refractive index of rutile (2.76) is higher than that of anatase (2.55). Rutile is also more thermally stable and photostable, although the chalking property of the anatase pigment has been used to advantage in making "self-cleaning" paints. Like most inorganic pigments, titanium dioxide is a naturally occurring compound that must be mined, crushed and processed before it is a suitable raw material for paint. The optimum diameter for light scattering is about 0.2 micrometer.

Other naturally occurring hiding pigments include zinc oxide (refractive index = 2.01) and zinc sulfide (refractive index = 2.37). At one time, lead carbonate (refractive index = 2.0) was a leading hiding pigment. In addition to hiding, zinc oxide is a fungistat (i.e., it inhibits the growth of fungi).

Pockets of air (refractive index = 1.0) encapsulated in plastic are also used as light-scattering pigments. The size of these synthetic pigments range from 0.6 to 20 micrometers, depending upon the number of 0.5-micrometer bubbles per particle.

Extender Pigment. The major classes of extender pigments are as follows:

Calcium carbonate (also called *whiting*). *Calcium carbonate* is inexpensive, has a low binder demand, and is not colored, but is acid sensitive.

Clay (or *kaolin*) covers a wide variety of materials which are inert and inexpensive, but it is more yellow than calcium carbonate.

Talcs are very inexpensive and easily suspended pigments.

Silicas (mostly silicon dioxides) are low cost, inert, and very hard.

Other extender pigments include barium sulfate, feldspar, diatomite, and mica.

Color Pigments. Chrome yellow is the leading inorganic color pigment. It is used primarily in traffic-marking paint for roads and highways. The yellow, red, and brown versions of iron oxide also are important and are used in a variety of industrial and architectural coatings.

There are hundreds of organic color pigments used in the paint industry, the vast majority of which are synthetic. Since many of these are vulnerable to ultraviolet light or chemical degradation, great care must be taken in choosing pigments that are suitable for a given paint and its intended usage.

The most commonly used black pigments are carbon blacks. In addition to being efficient light absorbers, some varieties of these small-particle-size materials impart electrical conductivity and thixotropy to paints. The leading inorganic black pigment is black iron oxide. This material is used primarily because it is easier to disperse than the carbon blacks. See also **Carbon Black**.

Metallic Pigments. The leading metallic pigment is zinc dust, which is used mostly in zinc-rich primers, where it acts as a *passivating agent*. Aluminum flake is used for the silvery metallic appearance that it imparts.

Anticorrosive Pigments. Several pigments are used primarily because of their anticorrosive properties. Chromates (zinc, strontium, and lead, if permitted) are the most effective anticorrosive pigments, but the chronic toxicity danger associated with them is a matter of serious concern. Barium metaborate, red lead, and borosilicates have been the principal nonchromate materials used. Other pigments used for special purposes include iron oxide for magnetic media and copper oxide in marine coatings to prevent barnacle and algae growth.

Tributyltin acetate CAS: 56-36-0, $(C_4H_9)_3SnOOCCH_3$, gained widespread usage in marine paints. The loss of ship performance and efficiency resulting from the growth of barnacles, seaweeds, tubeworms, and other organisms on boat bottoms has been known since the time of the Phoenicians, when copper strips were fastened to hulls to prevent fouling. Various navies and ocean shippers worldwide have found tributyltin acetate (TBT) effective, particularly in tropical waters. Unfortunately, the ingredient in paint has been found to be toxic. One authority in ocean chemistry has observed that TBT is the most toxic compound man has introduced into the marine environment. In recent years, numerous studies and evaluations of TBT-based paints have been made. Some countries have regulations against its use. Details on the adverse growth of oysters, for example, have been reported. Some of these observations are covered in the Champ reference listed.

Coating Manufacturing Process

There are usually two steps in the paint-making process: (1) dispersing the pigment (called *grinding*) and (2) mixing in the raw materials not used in grinding (called *letting down*). Except for NADs, solvent-borne coatings are made by grinding the pigment into a binder/solvent solution. The polymer serves a dual purpose in the step: (1) It thickens the mixture, increasing the dispersing efficiency of energy put into the system, and (2) it adsorbs onto the surface of the pigment particles, stabilizing them in suspension. Once stabilized, the suspension is let down by stirring in the remaining raw materials. For most waterborne paints (including all latexes), the grinding step consists of dispersing the pigment in water. The binder is not included since it is not stable enough to withstand the grinding process. Instead, surfactants are used to help wet and stabilize the pigment. Paints prepared in this manner add the binder in the letdown.

Mills. Several types of machines (called *mills*) are used for grinding pigment. *Media mills* have a chamber where the pigment, binder and a solid media are all ground together. The grinding action of the media particles on one another provides the shear needed to breakdown the pigment agglomerates. Some media mills have chambers that hold an entire batch at one time, while others have smaller chambers through which a batch is passed in a continuous flow. Batch mills (those falling into the former category) include those using pebbles, ceramic beads, or steel shot as media. Continuous mills (where the batch flows through the chamber) usually use sand or ceramic beads as the media.

Roller mills have large, closely placed rollers capable of grinding very thick pigment suspensions. Adjoining rollers are turned in opposite directions and at high speeds. The point where adjoining roller surface separate is subjected to sufficient shear to pull the pigment agglomerate apart.

High-speed dispersers (HSDs) are a third general type of mill. HSDs use blades attached to rotating shafts to disperse the pigment, much as an egg beater is used to disperse flour. HSDs are currently the most widely used grinding equipment. HSDs or similar stirring devices are generally used for the letdown regardless of the type of mill used in the grinding step. See also **Ball, Pebble, And Rod Mills**.

Application Methods

Coatings can be applied in a variety of ways depending upon the nature of the substrate and the viscosity of the coating. Brush, roller and pressure pads are popular methods of application for architectural and industrial maintenance coatings. Advantages of these methods include lack of capital investment and the ability to apply coatings on site. Disadvantages include their labor intensity and their limitation to use *ambient cure* coatings. Air, and especially airless, spray equipment can apply coatings much faster than

a brush or roller, but this method requires more equipment and is not as adaptable. Spraying is used for architectural, industrial maintenance, wood furniture, automotive refinish and other coatings.

Electrostatic Spraying. In this method, a paint with a negative charge is applied to a substrate with a positive charge. This is the method of choice for automotive, metal furniture, appliance, machinery, and metal container coatings. The equipment for electrostatic spray costs more than regular spray equipment, but the transfer efficiency can be much higher. A drawback is that electrostatic spraying can be used only if the object to be painted can hold an electrical charge and does not have deep crevices.

Electrodeposition. Another way of using electricity to paint is electrodeposition (ED). In this method, the object to be coated is dipped into a vat of charged aqueous coating. An opposite electrical charge is then applied to the object and the paint is attracted to the surface of the charged object. Having been painted, the object is removed from the vat, rinsed, and baked. Electrodeposition requires a very large capital investment, does not allow for color changes, works only for conductive (metal) objects, and is only suitable for coatings that are baked. Ambient cure paints do not have the long-term stability needed for ED. Nevertheless it is the greatly preferred application method for automotive primers and many other metal products because of its high transfer efficiency—desirable for both environmental and economic reasons.

Dip Tanks. This method, which does not use electricity, is especially suitable for small objects. The main disadvantage to dipping is the difficulty of getting an even coat without *drips*.

Roller Coaters and Sheet Coaters. These are often used in coil coating where very large, flat surface areas need to be painted quickly. In these methods, the objects to be painted are passed between a doctor blade and applicator rolls. These methods are suitable only for coatings that are to be baked.

Surface Preparation of the Substrate. This is extremely important for all methods of paint and coatings application. The failure of a paint system is often due *not* to the paint itself, but because of a failure in surface preparation. For example, an anticorrosive paint applied to a rusty surface will not be effective if the rust falls off taking the new paint with it. For wood and plastic surfaces, old paint or a weathered surface layer may have to be removed. For older metal objects, the removal of corrosion is often required. Sandblasting is one method to remove both the old paint and any corrosion. For new metal objects, a phosphate or chromate layer is often chemically bonded to the metal to provide a surface to which a coating can easily adhere.

Paints for Specific Functions

Paints are often separated into the types of jobs they perform. *Primers* are meant to be applied to bare substrates and then covered with a topcoat. As such, they must have good adhesion and good recoatability, but color and light stability are usually unimportant. When used over metal, primers are usually expected to provide corrosion protection. *Sealers* are similar to primers except they are used over porous substrates. Sealers eliminate the leaching of material from the substrate and also prevent paint components from migrating to the substrate. *Surfacers* are highly pigmented paints that are applied in a thick layer to mask surface irregularities and to allow good adhesion by a topcoat. *Fillers* are a type of surfacer that is used to fill holes. *Stains* are low-solids coatings applied to wood to accentuate its grain. Most interior stains require a topcoat.

Some finishes do not require a primer. Varnishes are clear, tough, and usually have a glossy finish. Exterior varnishes give wood some protection from sunlight. *Shellacs* are a type of varnish which offers the advantages of a quick dry and easy sanding, but which is sensitive to water and has a limited shelf life.

Topcoats are usually applied over an undercoat (i.e., primer, stain, etc.). A topcoat must protect its undercoat from environmental damage and should provide the appearance characteristics desired for the particular application. Topcoats are available in a variety of colors, textures, and glosses. One specialized topcoat is *lacquer*, which is a solution of resin in organic solvents. Lacquers dry, but do not cure. Because of their high VOCs, the use of lacquers is declining. *Enamel* is a term used to describe a glossy, opaque topcoat.

A unique two-coat, topcoat system is used in the automobile industry. A basecoat is applied to a primed surface to provide opacity, color, and a metallic appearance, while the clearcoat provides gloss and a mirrorlike finish (referred to as *distinctness of image*).

Various regulatory agencies in the United States and other countries have set limits on the use of low-volatile organic coatings. These are widely used in the chemical, petrochemical, and metallurgical industries to resist corrosion. Presently, high-temperature paints and coatings are largely silicone in nature. These are considered the best-performing coatings for smokestacks, boilers, mufflers, furnaces, incinerators, combustion chambers, and jet engines. High solids polyorganosiloxane polymers (silicone resins) are used to protect steel piping and other equipment where high temperatures accelerate deterioration of ferrous substrates. They also are used on storage tanks where appearance is an issue, as in the case of oil refinery tanks.

In addition to their high-temperature properties, high solids polyorganosiloxane polymers are resistant to numerous chemicals. For example, electric power generation frequently creates sulfuric acid as a byproduct. The process often involves extremely high temperatures as well. Silicone-based coatings currently appear to be the only materials capable of withstanding such conditions.

Special-purpose Coatings

These coatings include the use of materials (generic coatings) for purposes other than their contribution to protecting and decorating a structure or product. There is a multitude of such uses, and only a few can be described here because of space limitations.

Electronic Microstructure Fabrication. A microstructure may be defined as a pattern formed on or imbedded in the surface of some substrate material. Microstructure implies that the transverse dimensions of the patterns are in the microscopic and submicroscopic range, factors that determine the scale of electronic circuit integration. With the progress of electronic component miniaturization, such ranges have advanced from small-scale integration (SSI) to medium-scale integration (MSI) to large-scale integration (LSI) and to very-large-scale integration (VLSI). As of the early 1990s, such integration has progressed to millions and billions of transistors (e.g., on one integrated circuit). See also **Microelectronics.**

Patterns on microstructures may be formed in layers or insulators deposited on a surface or may consist of chemical or physical modification of shallow regions of the substrate. Traditionally, the most important use of microstructure fabrication has been the creation of large numbers of transistors, diodes, resistors, and capacitors fabricated with the interconnections that enable them to perform useful electronic functions on a single piece or "chip," usually silicon. Recent trends in miniaturization include two additional classifications (i.e., *application-specific* integrated circuits (ASICs) and *very-high-speed* integrated circuits (VHSICs).

Since the beginning of the concept of integrated circuits several years ago, the "yardstick" of dimension has been the micron (micrometer). A micrometer equals 1/1,000,000 of a meter, or 1/25,000 of an inch, or 1000 nanometers, or 10,000 angstroms. The wavelength of light, by comparison, extends from approximately 4000 to 7000 angstroms. Approximately 150 half-micron-wide lines would fit within the width of a human hair. The "resists" used in the fabrication of microminiaturized components fall into the "coatings" category in the parlance of modern coatings technology.

A *simplified* example will illustrate the process of microstructure fabrication. With reference to Fig. 1, an n-type region has been created by diffusion of a donor impurity into a surface of p-type silicon, forming a $p-n$ junction diode. There is a metal contact to the n-region, and the contact line is insulated from the p-type surface by a layer of silicon dioxide. The diameter of the diode is on the order of 10 micrometers.

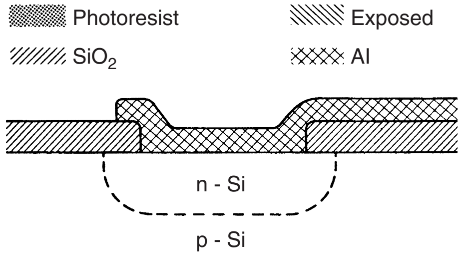

Fig. 1. A diode fabricated on the surface of a wafer of silicon. An n-type region has been created by diffusing a donor impurity through an opening in a layer of SiO_2 on the silicon. Electrical contact is made to the n region by a deposited aluminum conductor. The SiO_2 insulates the silicon from the aluminum

The fabrication begins with the application of a layer of photoresist to the oxidized surface of a silicon wafer. The photoresist is then exposed to light in the region where the diode is to be formed. Photoresist is a polymeric mixture that is deposited as a thin layer, perhaps 1 μm thick, upon an SiO_2 film on a silicon wafer. Irradiation with light in the near UV region of the spectrum modifies the chemical properties of the photoresist, and, in "positive" photoresist, makes it more soluble in certain developers. Thus, one step frequently employed in microstructure fabrication is the projection of the image of a mask onto the photoresist layer. It becomes possible to remove the exposed region of the photoresist by dissolving it with a suitable developer. The SiO_2 layer can then be removed from the areas that were exposed to light by hydrogen fluoride etches. The photoresist is resistant to HF etches and the SiO_2 in the unexposed areas is not affected by the etch. After etching, the remaining photoresist can be removed by a solvent, leaving a silicon substrate covered with SiO_2 only in the unexposed areas. The SiO_2 film acts as a barrier to the contact of impurities in a gaseous phase with the silicon. Thus, when the silicon wafer covered by the patterned SiO_2 film is exposed, to, for example, a gas containing phosphorus at high temperatures, the phosphorus, being very soluble in silicon, diffuses into the exposed areas rapidly. An idealized description of this sequence of process steps is shown in Fig. 2. The effect of this doping is very important in electronics, since phosphorus is a donor impurity and a region of n-type or electron conductivity is produced where it is present.

Many physical phenomena, however, obstruct the formation of the ideal structure depicted in Fig. 2. The technical literature is well supplied with papers devoted to each of the steps illustrated in Fig. 2. None is as straightforward as appears at first sight. It is instructive to discuss them further, since much of the essence of microstructure fabrication is revealed by examining them in detail.

Figure 2(**a**) suggests that the thickness of the photoresist and SiO_2 layers are independent of position. While the layer thickness is not an extremely critical process parameter, its control cannot be entirely neglected, as the time needed for the subsequent developing or etching steps depend on it. The wafers used in modern silicon technology have diameters of three or more inches, and maintaining uniformity of layers and process parameters across a wafer is not a trivial task. Also, very high standards of cleanliness must be maintained, as any particulate contamination will affect the resist adversely.

Figure 2(**b**) shows a well-defined boundary between the exposed and unexposed areas of the photoresist. In fact, the dimensions of the structures produced in modern microelectronics are comparable to the wavelength of the exposing light, so that diffraction prevents such sharp contrast from being achieved. Furthermore, high-resolution projection exposure schemes require that the light be monochromatic to avoid the problems of chromatic aberration in the lenses. The photoresist must be reasonably transparent to insure that its full thickness is exposed to the light. The silicon surface is, however, reflective, so that the interference of the incident and reflected light produces standing waves in the photoresist and nonuniform exposure of the photoresist in the vertical direction. Complicated effects of this kind are clearly important to microstructure fabrication. It must also be apparent that, as the amount of exposure received is a continuous function of position, the time of development required to remove a given region of photoresist will also be a continuous function, and that the profile of the developed photoresist will depend on the time of development. In particular, the size of the opening in the photoresist, to which Fig. 2 is oriented, will depend on the time.

Resists can also be exposed with focused electron beams, as used in electron microscopes, instead of light. The electrons, however, pass through the resist layer into the substrate, where they are scattered, and some eventually return from the substrate to the resist, exposing it at a distance from the intended opening. Great care is needed to allow for the backscattering phenomenon in calculating exposures for nearby openings. Development of the photoresist proceeds somewhat as shown in Fig. 3, with simultaneous lateral and vertical removal of material. The tapered edge of the resist film may be a disadvantage, because the exact point at which the film is thick enough to protect the underlying SiO_2 layer during the succeeding etching step, and thus the size of the hole that will be produced in the SiO_2, is not clearly defined. Prolonging the development beyond the point shown in Fig. 3(**b**) allows continued lateral development and increase in the size of the opening. Also, however, achieving perfect adhesion of the photoresist film to the SiO_2 is difficult, and the developer may invade the interface between the two layers, producing the undesirable result shown in Fig. 3(**d**).

The developed photoresist, Fig. 2(**c**), is then used as a mask to etch the SiO_2 layer. Again, perfection is hard to achieve. Etching for too short a time will leave a certain amount of photoresist in the hole. Etching for too long a time can cause undercutting, as shown in Fig. 4(**c**). After removal of the photoresist, the wafer is exposed to a diffusant, affording additional opportunities for deviations from idealized behavior. Time and temperature of diffusion are important and can produce results resembling Figures 5(**a**) or 5(**b**). Diffusion can proceed rapidly along interfaces in certain cases, leading to junction profiles of the kind shown in Fig. 5(**c**).

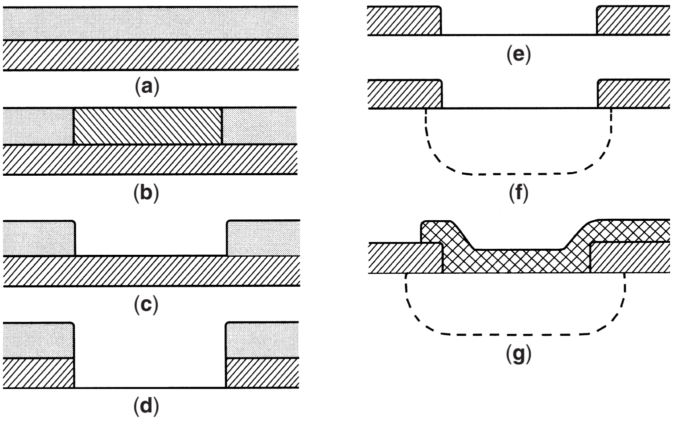

Fig. 2. Process steps used to produce the structure shown in Fig. 1: (**a**) A film of SiO_2 has been formed by oxidizing the silicon and a layer of photoresist has been deposited on the SiO_2. (**b**) Shading shows a region of the photoresist that has been exposed to light and thereby made more soluble. (**c**) The exposed photoresist has been removed. (**d**) An etchant that reacts with the SiO_2, but not with the photoresist, has been removed. (**e**) Another solvent has been used to remove the unexposed photoresist. (**f**) Donor atoms have diffused into the silicon through the opening in the SiO_2 to produce an *n*-type region. (**g**) Additional masking steps, not shown, have permitted aluminum to be evaporated onto the diode in a pattern that forms a contact to the n region of the diode. (See Fig. 1 for legend)

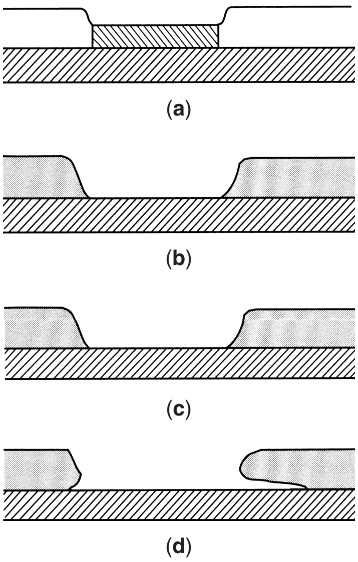

Fig. 3. Development of the photoresist: (**a**) Although exposure increases the solubility of photoresist in the developer, there is only a finite ratio of dissolution of the exposed photoresist to that of the unexposed region. In addition, the exposure received is not a perfect step function at the boundary of the exposed areas. Thus, dissolution proceeds laterally as well as vertically. (**b**) The opening in the photoresist has penetrated to the surface of the SiO_2. (**c**) With continued development the opening continues to enlarge. (**d**) Poor adhesion of the photoresist to the SiO_2 has allowed the development to penetrate the interface. (See Fig. 1 for legend)

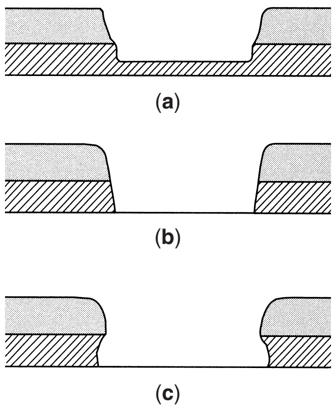

Fig. 4. The opening in the photoresist is used to mask the etching of a hole in the SiO_2: (**a**) An early stage of development. (**b**) The opening in the SiO_2 has reached the silicon. (**c**) Prolonged etching can lead to removal of SiO_2 underneath the photoresist masks. (See Fig. 1 for legend)

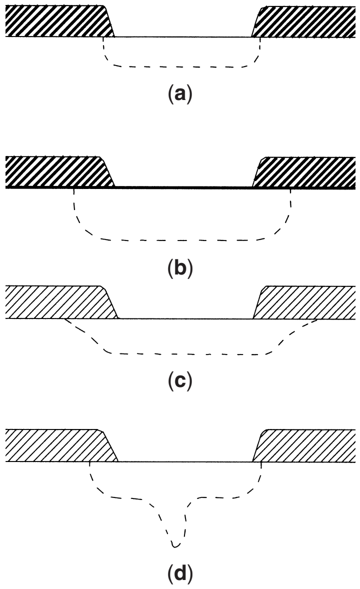

Fig. 5. A donor impurity is diffused into the silicon from a gaseous phase. (**a**) A shallow n region has been created. (**b**) Continued diffusion, longer times, or higher temperatures increase the extent of the n region. (**c**) Surface diffusion has caused spreading of the n region along the SiO_2-silicon interface. (**d**) A crystal defect, such as a dislocation, has provided a path for anomalously high diffusion and led to penetration of the junction to unanticipated distance from the surface. (See Fig. 1 for legend)

Preferential diffusion along crystalline defects can give rise to a profile resembling that shown in Fig. 5(**d**).

Next, a metal connection is to be made to the diffusion-doped region. Aluminum is frequently used for this purpose, as it has high electrical conductivity and does not enter the silicon and alter its properties. The aluminum is also evaporated through a mask that defines the shape and location of the conductor. Examples of the region of contact between the aluminum and the doped semiconductor are shown in Fig. 6. It is seen that the current will be forced to flow through a narrow constriction if the profiles are as shown in Fig. 6(**b**). The high current densities may cause electromigration of the aluminum atoms, leading to the open circuit shown in Fig. 6(**c**).

Also, silicon is somewhat soluble in aluminum. One can thus encounter the situation shown in Fig. 6(**d**), where enough silicon has been dissolved to allow the metal to completely penetrate the doped region, shorting the junction.

None of the problems illustrated in Figs. 2, 3, 4, 5, and 6 is insurmountable. A great many ingenious ways to avoid the difficulties described are known. Sometimes these are guided by physical or chemical knowledge; frequently they are empirical fixes.

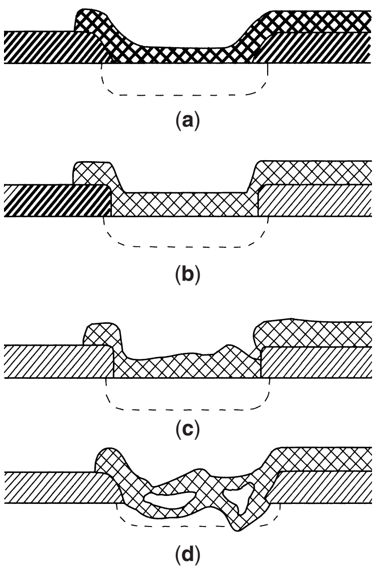

Fig. 6. (**a**) Masking steps, not shown, have permitted the deposition of aluminum in selected areas to form a contact to the n region. (**b**) A sharp vertical profile in the SiO_2 opening may cause a reduction of the cross section of the aluminum conductor where it passes from the SiO_2 insulator to the silicon surface. (**c**) The high current density in the constriction shown in (**b**) has led to electromigration of aluminum atoms and opening of the conductor. (**d**) Solution of silicon in the aluminum has resulted in deformation of the metal-semiconductor interface and penetration of the aluminum through the n region. (See Fig. 1 for legend)

The microstructure engineer must also be aware of constraints that have little to do with chemistry and materials science, but tend to be more closely related to mechanical technology. One of the most difficult of these is registration or alignment. A substrate is usually passed through several process steps in order to form a desired structure. For example, fabricating a transistor may involve diffusing a base dopant through a window in SiO_2, subsequently diffusing an emitter dopant through a somewhat smaller opening in an SiO_2 layer, and finally, using masking layers to form contacts to these transistor elements. It is necessary to ensure that the emitter region is created in the correct position within the previously diffused base region. The mask that is used to define the emitter region lithographically must be precisely located with respect to the geometrical structure already established on the substrate by previous processing steps. This positioning is known as alignment. It may require that separate structures that can be easily located but have no electronic function be provided on the substrate.

Alignment all over a large substrate is made more difficult by dimensional changes that may take place during processing at high temperatures. Materials soften at high temperatures and can deform under the force of gravity or the stresses that accompany temperature gradients and contacts between different materials.

Further, economic factors also constrain the utilization of microstructure fabrication technology. These are the factors that control the cost of production, such as throughput, the rate at which substrates can be processed by the fabrication tools, capital investment required, and demands on operator time and skill. Electron beam exposure, for example, provides high resolution but uses expensive equipment that works slowly. Naturally, all of the elements of cost must be weighed against the value of the product produced.

Chemical Vapor Deposition. Deposition of tungsten, molybdenum, and their silicides by chemical vapor deposition (CVD) is of relatively recent interest in the microelectronics industry. These materials are useful for gates and interconnects in metal oxide semiconductors (MOS) devices. Aluminum, the widely used interconnect material, has a comparatively low melting point (600°C) and a markedly different coefficient of thermal expansion (compared to silicon), so that over a period of years researchers have been seeking an alternative for aluminum.

In using CVD for microelectronics applications, the deposit thickness must be as uniform as possible. This can best be achieved by conducting the deposition in a surface-controlled, not a diffusion-controlled, regime.

In this way, effects of reactor geometry on deposition rates are minimized and irregular-shaped substrates will tend to be uniformly coated.

An allied process is *metal-organic chemical vapor deposition* (MOCVD). In this process, two or more metal-organic chemicals (example: trimethylgallium) or one or more metal-organic sources and one or more hydride sources (example: arsine, AsH_3) are used to form the corresponding intermetallic crystalline solid solution. MOCVD materials technology is a vapor-phase growth process that is used to study the basic physics of novel materials and to grow complex semiconductor device structures, particularly for new optoelectronic and photonic systems. The process is reported in some detail by Dupuis.

Ion Implantation. In this process, alloying elements are introduced into a host material by accelerating the ions to a high energy level and allowing them to strike the surface of the host. The impinging atoms penetrate into the substrate material to a depth of one micrometer or less, depending upon atomic number and energy of the atom. Although it has a number of other applications metallurgically, the process has been of interest in the semiconductor industry primarily in connection with doping substrates with elements in Periodic Table Groups 13 and 15. Use of the process in fabricating a Schottky barrier gate used in a metal-semiconductor field-effect transistor (MESFET) is described in the article on **Semiconductors**.

Multidisciplinary Characteristics of Microstructure Fabrication. Upon observing the practice of microstructure fabrication, one cannot fail to notice a resemblance to certain aspects of modern metallurgy and chemical engineering. For example, the precipitates produced by metallurgical processing have a dimensional scale similar to that of electronic microstructures. Inhomogeneities on a scale of 0.01 ϕm to 10 ϕm control the desirable properties of a structure. This preoccupation with the properties of solids on a microscopic scale produces a common interest in techniques and in interactions with basic science. Thus, both microstructure fabrication and physical metallurgy: (a) rely on phenomena that take place in the solid state; (b) depend on analytical tools that are capable of chemical analyses with the highest possible spatial resolution; (c) involve the motion of atoms through solids, controlled by diffusion, solution, nucleation, and precipitation; (d) involve interface phenomena at the contact between different solids; and (e) are sensitive to crystal defects.

It must further be noted that both metallurgy and microstructure fabrication are practical disciplines, they are oriented toward the economic production of structures that have a useful role in commerce and industry. In this respect both are engineering rather than scientific disciplines. On the other hand, their deep probing of phenomena on an atomic scale and under unusual conditions produce new discoveries and lead to new concepts that enhance basic science.

This is not to say that microstructure fabrication is a branch of metallurgy. The detailed motivation of the two disciplines is rather different, metallurgy concentrating on the mechanical properties of solids, while microstructure fabrication controls the electronic properties of structures made from magnetic and optical materials, semiconductors, metals, and insulators. The basic difference, of course, is that microstructure fabrication involves control of the fabrication process in detail at the dimensional level of the structure, while metallurgical processing exercises control at a much grosser level. The application of lithography, with the attendant use of exposure tools, clean rooms, resists, masks, and etchants is the province of microstructure fabrication. Crystalline defects are usually undesirable in microstructures; the metallurgist can frequently use them to advantage. Metallurgy also encompasses its extractive aspects. There is no doubt that microstructure fabrication is a distinct activity.

The technique of microstructure fabrication has grown up as an art in response to a continuous economic and functional motivation to push to the smaller and smaller. Chemistry, physics, and empiricism are combined into the creation of novel physical structures that have enormous economic impact, that, indeed, form the basis of whole new industries. Progress has been made by adaptation and invention to meet the needs of the moment. By and large, the art has grown rapidly, adapting and improving old methods to new situations and inventing as needed and possible. It is common experience that obtaining reproducible results requires very careful control of all aspects of the fabrication processes, such as temperatures, pressures and time. High standards of cleanliness and reagent purity must be enforced. Seemingly identical apparatuses and starting materials often yield different results. Recipes must be carefully followed, with little understanding of which aspects of a process are critical or what contaminants are important, and why.

The rapid development has outstripped basic understanding of the fundamental mechanisms underlying the techniques. It must be recognized, however, that the optimal exploitation of microstructural technology, the maximization of performance, yields, and utilization of available silicon area will depend on a detailed interpretation of each step in fabrication as a chemical or physical process. Furthermore, unanticipated phenomena are encountered and inject surprises into basic science. A new interdisciplinary field of applied science has emerged.

Photographic Color Film

One of the early examples of coating technology was for building up layers in color film. These films exemplify the use of multiple layers of coatings that are "built in" to the final product. In use, the camera lens also will be coated. See Fig. 7. See also **Photographic Emulsions.**

Adhesives

Commonly, adhesives are applied by coating products and parts that must be held together. Some adhesives require application at the time of usage; others are pre-applied in semi-dry or dry form, but with a "sticky" surface. Adhesives range from natural products, such as glue to plastics and polymers. The epoxies are exemplary of modern adhesives. With the continuing replacement of many metal parts with plastics, adhesives are displacing welding and mechanical fasteners to a dramatic degree. In the final essence, most adhesives must form a binding coating on one form or other. See also **Adhesives**.

Environmental, Health, and Safety Factors

The most significant environmental and health issues affecting the paint and coatings industry are regulations to lower the VOC content for virtually all types of paints and to restrict the use of certain solvents known as hazardous air pollutants (HAPs) under the federal Clean Air Act. Except for the water in a latex paint or in other water-based coatings, solvents used in house paints are mostly all VOCs. Several states, along with the U.S. EPA, have implemented environmental regulations to restrict the VOC content of paints, as mandated by the Clean Air Act. These regulations are aimed at minimizing the emission of organic compounds from paints that contribute to the formation of air pollution in the form of smog or ground-level ozone.

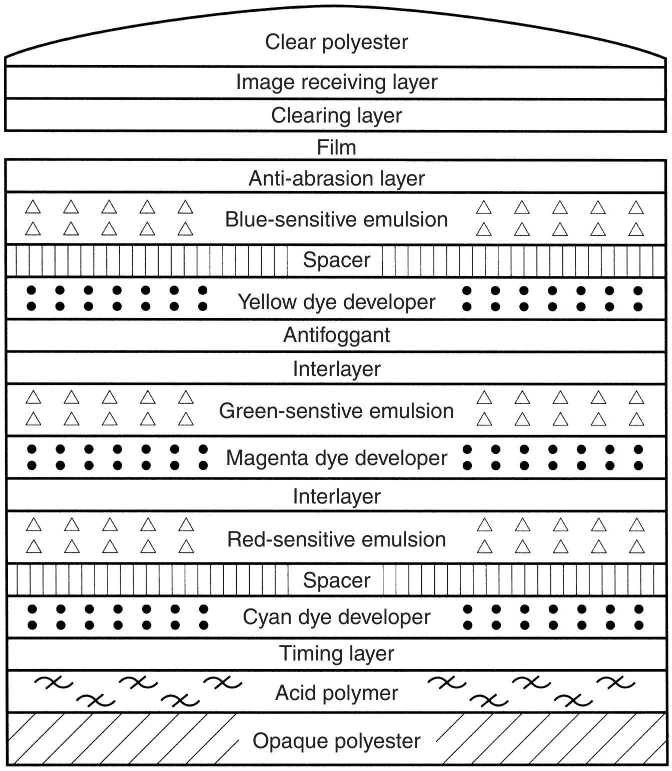

Fig. 7. Schematic sectional view of layers composing the "thickness" of a color photographic film. (*After Cohen*)

Health and safety issues affect both the professional painter and paint manufacturer who as part of the occupation can be exposed to high concentrations of organic solvent for extended periods of time. Environmental issues focus on the contribution of organic solvents to air pollution and other issues such as hazardous waste disposal. Paint companies are reducing their use of organic solvents in the manufacture and development of architectural coatings by offering more water-borne and higher solids alternatives to conventional solvent-borne paints. Some paint manufacturers are offering solvent-free latex paint alternatives to water-borne paints that contain organic solvents. A typical solvent-borne paint may contain 30–60% of organic solvent. By contrast, a water-based paint may only contain 5–10% of organic solvent. This is a significant reduction in solvent content, as water-borne paints are becoming more and more predominant in the architectural coatings market, and are part of the focus for reducing the use of organic solvents in paints.

Restriction on the use of certain types of solvents, listed as HAPs under the Clean Air Act, are forcing paint manufacturers not only to lower the limits on the amount of organic solvents in a paint, but also to eliminate certain types of solvents. Thus paint manufacturers are challenged to comply simultaneously with both VOC and HAP regulations. These Clean Air Act mandates are expected to affect most types of paints and paint manufacturers beginning in 1996.

Another issue affecting the architectural paint industry is the remediation of homes, buildings, and structures that contain lead-based paint. Lead poisoning in children has been linked to ingestion of paint dust or paint chips that contain lead pigments and this has resulted in U.S. government regulations to reduce the lead content in paint to no more than 0.06%.

PALLADIUM. [CAS: 7440-05-3]. Chemical element symbol Pd, at. no. 46, at. wt. 106.4, periodic table group 10, mp 1554°C, bp 2970°C, density 12.02 g/cm^3 (solid), 12.25 g/cm^3 (single crystal) (20°C). Elemental palladium has a face-centered cubic crystal structure. The six stable isotopes of palladium are ^{102}Pd, ^{104}Pd, through ^{106}Pd, ^{108}Pd, and ^{110}Pd. The seven unstable isotopes are ^{100}Pd, ^{101}Pd, ^{103}Pd, ^{107}Pd, ^{109}Pd, ^{111}Pd, and ^{112}Pd. In terms of earthly abundance, palladium is one of the scarce elements. Also, in terms of cosmic abundance, the investigation by Harold C. Urey (1952), using a figure of 10,000 for silicon, estimated the figure for palladium at 0.0091. No notable presence of palladium in seawater has been found. Discovered by Wollaston in 1803.

Electronic configuration $1s^2 2s^2 2p^6 3s^2 3p^6 3d^{10} 4s^2 4p^6 4d^{10}$. Ionic radius Pd^{2+} 0.50 Å (Wyckoff). Metallic radius 1.3755. First ionization potential 8.33 eV; second 19.8 eV. Oxidation potentials $Pd \rightarrow Pd^{2+} + 2e^- 4M HClO_4$, −0.83 V, $Pd + 2OH^- \rightarrow Pd(OH)_2 + 2e^-$, −0.1 V. Further physical properties are given under **Platinum and Platinum Group**.

Pd has some similarities with both Ni and Ag and many with Pt. Pd dissolves more readily in acids than any other member of the platinum group of metals. In aqua regia, the metal dissolves quickly. Even the compact metal dissolves slowly in HCl. In finely divided form, it is quite soluble in all acids. When heated in air at red heat, the monoxide, PdO, is formed. Pd is similarly converted to the dihalides under the same conditions when it is exposed to F_2 or CL_2. The metal is not affected by H_2S.

The black compound, palladium(II) oxide is formed by fusing palladium(II) chloride with $NaNO_3$ to 600°C and then leaching out the salts with water. This strong oxidizing agent is easily reduced to the metal by H_2. The compound is insoluble in water and acids, including aqua regia. The hydroxide, $Pd(OH)_2$, is made by the hydrolysis of palladium(II) nitrate. The compound is soluble in acids, and water is evolved on heating, but even at 500–600°C some water still remains. At this temperature, the compound starts to lose O_2.

Palladium(III) oxide, P_2O_3, is made as a hydrate by careful oxidation of a solution of palladium(II) nitrate either by anodic oxidation or ozone treatment at −8°C. This unstable brown powder reverts to the monoxide in about 4 days. When heated, the compound loses water and may explode as it changes to the monoxide.

Palladium(II) chloride is formed by direct combination of the elements at 500°C. It is the only stable chloride over 500–1500°C. The red crystals are partly soluble in water and completely soluble in HCl. The fraction insoluble in water is probably a polymer. Palladium(II) chloride also is the product obtained by evaporation of a solution of Pd in HCl. Palladium(II) bromide can also be made from the elements.

When KI is added to a solution of palladium(II) chloride, an insoluble diiodide is precipitated. The dark red-black crystals are soluble in excess iodide with formation of the tetraiodide complex ion. Palladium(II) iodide evolves iodine at 100°C, the decomposition to the elements being complete at 330–360°C. The black compound, palladium(III) fluoride, is made by direct combination of the elements. On reduction, the brown difluoride is formed.

Divalent Pd forms many planar complexes with a coordination number of 4. The tetrachlorides are quite soluble. When a solution of palladium(II) chloride is oxidized with chlorite or chlorate ion, Pd(IV) is formed, which has a coordination number of 8. The addition of NH_4Cl to such a solution precipitates ammonium hexachloropalladate(IV) as a red compound. It is somewhat less stable than the platinum analog.

The soluble yellow-brown palladium(II) nitrate is formed by dissolving finely divided Pd in warm HNO_3 and then crystallizing the compound from this solution. The analogous sulfate is similarly formed from H_2SO_4. It crystallizes as a red-brown dihydrate. Both these compounds easily hydrolyze.

Palladium(II) sulfide is precipitated as a brown powder by adding H_2S to a solution of palladium(II) ion. When this sulfide is heated with sulfur at 400°C, the insoluble disulfide is formed. The excess sulfur can be extracted with CS_2 to yield the gray-black crystalline palladium(IV) sulfide. This compound is not soluble in single acids but is soluble in aqua regia.

Some Pd complexes are important analytically or in the refining of Pd. The yellow dimethylglyoxime compound is quantitatively precipitated from a HCl solution of palladium(II) chloride by the addition of an alcoholic solution of dimethylglyoxime. Palladium(II) has a great affinity for nitrogen-containing ligands. The di- and tetramine find use in refining.

Palladium, as with other members of the platinum group, exhibits catalytic activity for various reactions. One of its best known uses is in conjunction with other platinum metals in the catalytic converters of present-day automobiles.

As reported by Chung-Chiun Liu et al. (*Science*, **207**, 188–189, 1980), a palladium-palladium oxide miniature pH electrode has been developed for pH measurement. The miniature wire-form electrode exhibits a super-Nernstian behavior and gives a mean pH response of 71.4 mV per [pH] (standard deviation, 5.3 mV). The electrode may find applications in biological, medical, and clinical studies.

Uses

Alloys for electrical relays and switching systems in telecommunication equipment, catalyst for reforming cracked petroleum fractions and hydrogenation, metallizing ceramics, "white" gold in jewelry, resistance wires, hydrogen valves (in hydrogen separation equipment), aircraft spark plugs, and protective coatings.

PALMITIC ACID. [CAS: 57-10-3]. $CH_3(CH_2)_{14}COOH$, formula weight 256.42, white crystalline powder, mp 64°C, bp -271.5°C, sp gr 0.849. The acid is insoluble in H_2O, moderately soluble in alcohol, soluble in ether. About 60% of the content of palm oil is palmitic acid.

Palmitic acid is present as cetyl ester in spermaceti from which, by hydrolysis, the acid may be obtained; it is present in bee's wax as the melissic ester; and in most vegetable and animal oils and fats, in greater or lesser amounts, as glyceryl tripalmitate or as mixed esters, along with stearic and oleic acids. Palmitic acid is separated from stearic and oleic acids by fractional vacuum distillation and by fractional crystallization. With NaOH, palmitic acid forms sodium palmitate, a soap. Most soaps are mixtures of sodium stearate, palmitate, and oleate.

Representative esters of palmitic acid are: methyl palmitate, $C_{15}H_{31}$ $COOCH_3$, mp 30°C, bp 195°C at 15 mm pressure; ethyl palmitate, $C_{15}H_{31}COOC_2H_5$, mp 24°C, bp 185°C at 10 mm pressure; cetyl palmitate, $C_{15}H_{31}COOC_{16}H_{33}$, mp 54°C; glyceryltripalmitate (tripalmitin), $C_3H_5(COOC_{15}H_{31})_3$, mp 65°C, bp 310°C, approximately.

As the glyceryl ester, palmitic acid is one of the constituents of many vegetable and animal oils and fats.

Palmitic acid finds use in the production of cosmetics, food emulsifiers, pharmaceuticals, plastics, and soaps. One commercial formulation contains 95% palmitic acid, 4% stearic acid, and 1% myristic acid; another preparation contains 50% palmitic acid and 50% stearic acid.

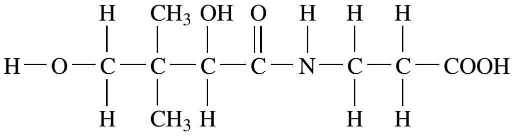
PALMITOLEIC ACID. [CAS: 373-49-9]. Also called *cis*-9-hexadecanoic acid, formula $CH_3\ (CH_2)_5CH{:}CH(CH_2)_7COOH$. This is an unsaturated fatty acid found in nearly every fat, especially in marine oils (15–20%). At room temperature, it is a colorless liquid. Insoluble in water; soluble in alcohol and ether; mp 1.0°C; bp 140–141°C (5 millimeters pressure). Combustible. Palmitoleic acid is used in organic synthesis, and as a standard in chromatographic analysis. See also **Vegetable Oils (Edible)**.

PALM OIL. See **Vegetable Oils (Edible)**.

PANETH TECHNIQUE. Method demonstrating the existence of free radicals (e.g., methyl) or atoms, which is based on the removal of metallic "mirror" by a stream of gas containing the radicals. The reaction products can be collected and assayed.

PANTOTHENIC ACID. Pantothenic acid (PA), also known as vitamin B_5, is essential to all forms of life. Its name is derived from the Greek word *pantos* that means "everywhere", which is appropriate for this widely, distributed vitamin. Pantothenic acid is a constituent of coenzyme A, which participates in numerous enzyme reactions. CoA was discovered as an essential cofactor for the acetylation of sulfanilamide in the liver and of choline in the brain. CoA is particularly important in the initial reaction of the TCA cycle (citric acid cycle) of carbohydrate metabolism and energy production. These factors are described in greater detail in the entry on **Coenzymes**. Pantothenic acid is unique among the vitamin group, in that it was one of the first to be isolated, using as a basis a microbiological assay method. Even more unique is the fact that its structure was largely determined, using a highly quantitative biological yeast test, long before it was isolated or obtained in concentrated form. R.J. Williams and coworkers described it as an acid with an ionization constant lower than that of an alpha-hydroxy acid, but about right for a hydroxy acid in which the hydroxyl group was farther removed from the carboxyl group.

In 1901, Wildiers described Bios, an essential for yeast growth. In 1933, Williams isolated crystalline Bios from yeast and named it pantothenic acid. In 1938, Williams isolated pantothenic acid from liver; and, in 1939, Jukes determined liver antidermatitis factor (chick) to be identical with yeast factor. Also, in 1939, Woolley et al. demonstrated beta-alanine as a vital part of pantothenic acid:



(Pantoic acid) (Beta-alanine)

d (+) Pantothenic acid ($C_6H_{17}O_5N$)

In 1940, Harris, Folkers, et al. reported structure determination and synthesis and crystallization of pantothenic acid. In 1950, Lipmann et al. discovered coenzyme A; and, in 1951, Lynen characterized the coenzyme A structure.

Pantothenic acid participates as part of coenzyme A in carbohydrate metabolism (2-carbon transfer-acetate, or pyruvate), lipid metabolism (biosynthesis and catabolism of fatty acids, sterols, +phospholipids), protein metabolism (acetylations of amines and amino acids), porphyrin metabolism, acetylcholine production, isoprene production.

Distribution and Sources. Particularly high in pantothenic acid content are yeasts, animal glands and organs. Fruits have a low content.

High pantothenic acid content (2.0–10.0 milligrams/100 grams): Beef (brain, heart, kidney, liver), chicken (liver), cod ovary, groundnut (peanut), herring, lamb (kidney), pea (dry), pork (kidney, liver), royal jelly, sheep (liver), wheat bran and germ, yeast.

Medium pantothenic acid content (0.5–2.0 milligrams/100 grams): Avocado, bean (lima), beef, broccoli, carrot, cauliflower, cheese, chicken, clam, kale, lamb, lentil (dry), mackerel, mushroom, oats, pea, pork (bacon, ham), rice, salmon, soybean, spinach, walnut, wheat.

Low pantothenic acid content (0.1–0.5 milligram/100 grams): Almond, apple, banana, bean (kidney), cabbage, grape, grapefruit, honey, lemon, lettuce, lobster, milk, molasses, onion, orange, oyster, peach, pear, pepper (white and sweet), pineapple, plum, potato, shrimp, tomato, turnip, veal, watercress.

Pantothenic acid is produced commercially by synthesis involving the condensation of *d*-pantolactone with salt of β-alanine. Some of the dietary supplement forms include calcium pantothenate, dexpanthenol, and panthenol.

Precursors in the biosynthesis of pantothenic acid include α-ketoiso valeric acid (pantoic acid), uracil (β-alanine), and aspartic acid. Intermediates in the synthesis include ketopantoic acid, pantoic acid, and β-alanine.

Some of the unusual features of pantothenic acid noted by investigators include: (1) it promotes amino acid uptake; (2) it is potentiated by zinc in preventing graying of hair in rats; (3) it promotes resistance to stress of

cold immersion; (4) there is a deficiency of pantothenic acid in tumors; (5) it is required for chick hatchability; (6) it is useful in treating vertigo, postoperative shock, and poisoning with isoniazid and curare; (7) it is useful in accelerating wound healing; and (8) it is useful in treating Addison's disease, liver cirrhosis, and diabetes.

PAPERMAKING AND FINISHING. One of the most important factors in the progress of civilization has been paper, a thin flat tissue composed of closely matted fibers obtained almost entirely from plant sources. In modern life paper finds a variety of uses, for writing, for containers, wrappers, wall covering, and—perhaps most important—in all forms of printing: newspapers, magazines, books.

The art of making paper seems to have been discovered first by the Chinese, who were making paper as early as the beginning of the Christian era. From China the process was carried to Arabia and thence to Europe. Paper was not an important article at first and, since it is not a very durable substance under ordinary conditions, could not compete with parchment or vellum as a medium for the written word. In the fifteenth century writing became more general and the demand for a cheaper material increased. Paper became an important product. At this time paper was made largely from vegetable fibers reclaimed from cloth (especially linen), as had been done since the invention of paper in China. This paper was made entirely by hand, as is done even today in the manufacture of certain expensive types of paper. In making handmade paper, a pulp is formed by soaking the vegetable fibers in water in a vat. From this vat the pulp is dipped out in a mold, the bottom of which is a fine screen. By a deft motion of this mold, the soft pulp is spread over the screen in a thin layer of matted fibers. The water in the pulp drains off, leaving a rather firm mass, which is turned out on a piece of felt. More pieces of half-dried pulp spread on felt are added. The whole pile is then pressed to squeeze out more of the water, press the fibers closer together and form a firm sheet. These are then removed from between the felts, pressed again, and dried. During the final treatment surface sizing is added to render a surface more suitable to receive ink. Sheets of hand-made paper are naturally of limited size and expensive.

To meet the great demand for paper, machine methods were developed. This increased demand for paper also led to the utilization of material that could be obtained in quantities much greater than rags. Out of this developed the vast pulp industry, which today converts vegetable material, mostly soft woods such as spruce and fir, as well as poplar, into a white felt-like mass of fibrous substance, known as pulp. See also **Pulp (Wood) Production and Processing**.

Wet End

A modern paper machine begins with a flow spreader or distributor, conveying a dilute fiber suspension (0.1–1% fibers) to a headbox which delivers a jet of the suspension or slurry through a slice (sluice) across the full width of the machine, almost 400 inches ($\sim$10.2 meters) in some large machines. In the headbox, the fibers are dispersed, and the flow is rectified as well as possible so that the jet is delivered onto a moving endless fine-mesh wire screen with uniform composition, flow rate, and velocity. The pressure in the headbox and its slice opening are adjusted so that the jet velocity matches the speed of the wire screen, which may be up to 4000 feet ($\sim$1220 meters) per minute for newsprint. The proper stock flow per unit width corresponds to the desired *basis weight* of the paper. (Basis weight is weight per unit area and varies with grades and sizes of papers.)

The dispersion of fibers in the headbox is brought about by subjecting the slurry or suspension to shear stresses, usually with turbulence. Various designs have been developed to accomplish this.

As shown in Fig. 1, the most common type of paper machine is the Fourdrinier, in which the moving wire screen is in the form of an endless conveyor belt stretched between two large rolls. The roll situated under the headbox slice is called the *breast roll*. The roll located generally at the end of the straight wire run is the *couch roll*. Drainage of the slurry through the wire screen is induced by several types of driving forces. In the early, slow-speed machines, the principal force was gravity. Later, the hydrodynamic action of table rolls, which support the wire and rotate with it, began to play an important part in drainage as speed increased. More recently, foils came into use, i.e., rigid stationary, hydrodynamically shaped elements which support the wire and exert a pumping action through the wire screen. Other means are perforated or slotted boxes with vacuum over which the wire runs. When only water is drained, they are called *wet boxes*. When applied toward the dry end of the wire screen, they also draw air through the wet paper mat and are called *suction boxes*. Other equipment configurations have been developed to meet these objectives. On all modern Fourdriniers (Fig. 2), a forming board located close to the breast roll is used to scrape off the water, drained initially by gravity, from the bottom of the wire.

An important development in paper forming is the use of a top wire dewatering unit placed above the wire of the Fourdrinier. The top wire units use various dewatering elements such as rolls, foils, and vacuum

(**a**) (**b**)

Fig. 3. Paper formers: (**a**) top-wire former; (**b**) Roll and Blade gap former. (*Valmet Corporation*)

boxes. The top wire units add drainage capacity to an existing Fourdrinier plus improved symmetry through the thickness of the sheet similar to the twin wire formers. An example of this type of former is shown in Fig. 3(a) (*Valmet, SymFormer MB*). See also Fig. 4.

A more recent development is the *roll and blade gap former* (*Valmet SpeedFormer*) shown in Fig. 3(b). In this type of machine, the fiber suspension is confined between two wire screens, and water is removed through both wires either simultaneously or alternately. This two-sided drainage leads to greater symmetry of distribution of fines and other nonfibrous particles through the thickness of the sheet. A significant feature of twin-wire forming is the elimination of the free surface of the fiber-water suspension while the sheet is being formed. This greatly reduces the larger-scale disturbances (waves, streaks, and jumps) which occur at higher speeds on Fourdrinier wires.

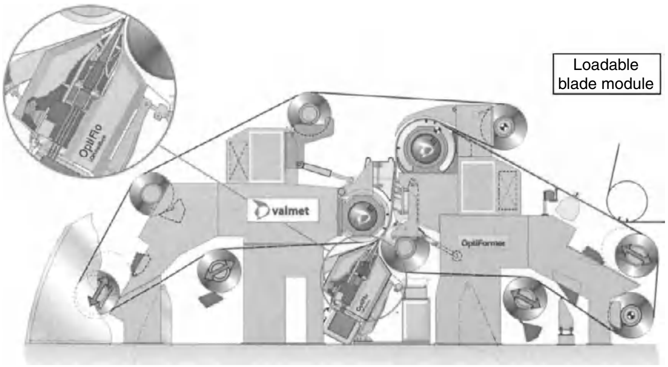

Fig. 4. Roll and blade gap. (*Valmet Corporation*)

Not all the fiber and other solid materials are retained by the forming wire. For this reason and because so much water is used in the papermaking process, the *white water* removed in the sheet-forming process is recirculated in the overall system. A large part of it is added directly to the high-consistency stock and fed back to the headbox, while a small portion goes into a *save-all* device, which recovers much of the solids from the white water. These extracted fibers and other solids are returned and added to the suspension. The clarified water is used in showers for cleaning wires and felts and other purposes so that only a small amount of the reused water eventually is discharged.

Press Section

At the end of the forming system, the *paper web* is transferred from the wire to a *press felt*, a fine-textured, usually synthetic fabric. At this point, the web contains about 4 or 5 parts water to 1 part solids. The wet paper web and one or more press felts pass through two or more press-roll nips, where water is squeezed out. Pressing also compacts the paper mat. This increases the potential interfiber contact areas where bonds will be formed.

The early *plain press* used a pair of metal and rubber-covered solid rolls. The expressed water had to flow out of the nip in the upstream direction, parallel to the paper web, as in an old washing-machine wringer. Nip pressures were then limited by the damage to the wet web (crushing) caused by this lateral flow. Although the plain press was improved in many ways, later development work led to the *fabric press* in which the felt contacting rolls are wrapped with a relatively coarse and incompressible mesh fabric. In another development (Beloit Ventanip press), the felt contacting rolls have narrow, closely spaced circumferential grooves. In both types, the lateral flow is virtually eliminated.

While the development of the modern presses has achieved high performance with simple constructions, the remaining problems of flow resistance and web rewetting leave room for improvement. It is generally recognized that mechanical removal of water is much less costly than

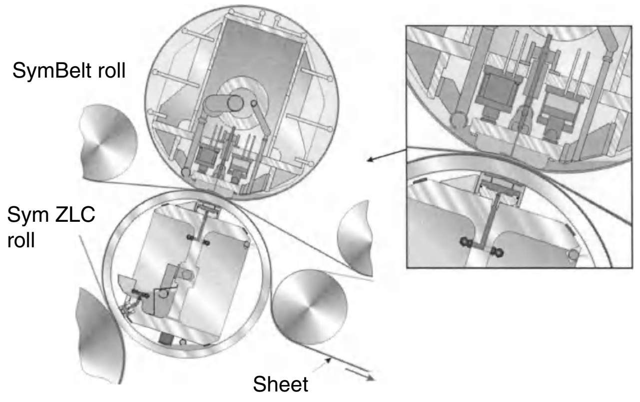

Fig. 5. The basic belt nip press. (*Valmet Corporation*)

drying. This has led to the development of presses with very long nips (*Beloit Extended Nip Press*) as shown in Fig. 5. These presses use a shoe typically of 10 in. (25 cm) width to replace one roll in the roll press configuration and use oil lubrication between the stationary shoe and a moving impervious belt. An additional 20–40% of the remaining water in the sheet can be mechanically removed by these presses with their longer residence time under high pressure.

As the machine speed has continuously has increased the dynamic forces to the web have increased and it has forced to support the web with felts to avoid web breaks. Before 30's typically the web had open draw between press and wire section which was soon replaced with pick-up suction roll arrangement. In this arrangement web is picked up with a suction roll from wire and supported by press felt to the first nip. Most recent fast paper machines are using the same principle of suction roll and supporting fabric not only through press but also through dryer section.

Dryers

After water removal by pressing has been done to the extent practical with present technology, the paper web leaves the press section with 1–2 parts of water to 1 part fibers. Most of this remaining water, down to 5–10%, must be removed by evaporative drying. In the most common method, the paper web is passed over a series of staggered cast-iron drums internally heated by condensing steam at pressures ranging up to approximately 10.2 atmospheres. The paper web is held in contact with the rotating drums by means of dryer felts or fabrics under tension. The diameter of the dryer drums is typically 5–6 feet (1.5–1.8 meters). There may be as many as 100 of them in heavyweight paperboard machines. These dryer drums are shown in the panoramic view. See Fig. 1.

Ventilating devices that blow air of controlled temperature and humidity through the dryer felts into the spaces between adjacent dryers are used. Here the air is confined by the sheet and felt runs. These pocket ventilating systems, together with greater control of the flow patterns within the dryer hood (which usually encloses the entire dryer section) have led to significant improvements in cross-machine uniformity of paper drying. This results in paper and board of improved suitability for modern high-speed converting and printing operations.

Other types of dryers, including radiant heating, dielectric and microwave heating, and high-velocity, hot air impingement, have been developed. These devices are generally applied to drying coated paper where sheet contact to a solid surface may be detrimental during drying. Wider application has been limited because of low thermal efficiencies and high capital costs.

Size Press and Coaters

Many printing grades of paper and paperboard are coated with an aqueous suspension of pigments (such as clay) in adhesives (such as starch) to provide a smoother surface, control the penetration of inks, and improve the pick resistance, appearance, brightness, and opacity. These and other materials are also applied, such as *functional coatings*, to provide such features as water resistance, pressure sensitivity for carbonless copying, and a wide variety of other properties. The appropriate materials may be added to the papermaking furnish during some stage of stock preparation (called *internal sizing*). Application of sizing or coating to one or both surfaces of the formed and dried sheet, rather than as internal sizing, simplifies the sheet-forming process and provides better control of surface properties.

The principal methods of surface coating may be classified as roll, blade, and air-knife coating, according to the method used to apply and control the final coating-layer thickness and smoothness. One version of coater (Beloit Billblade) simultaneously coats and smooths both surfaces of the paper web by running it down through the nip between a blade and a roll while maintaining two puddles, one between the web and the roll and the other between the flexible blade and the web, thus eliminating the necessity for two coating stations.

A more recent development is the short dwell coater (*Beloit Short Dwell*). The coater consists of a captive pond just before the blade that limits the contact time between sheet and coating material as shown in Fig. 6. The back flow assists in removing the boundary layer of air coming in with the sheet. The shorter contact time results in less coating penetration. Superior coating quality and improved runnability, due to fewer web breaks, have been achieved.

After sizing or coating, the solvent, usually water, must be removed from the coating by evaporative drying. With some coating formulations and paper grades, drying can be done on ordinary steam-heated drums without damage to the coated surface, particularly if the surface of the first drum is smooth (sometimes chrome-plated). However, it is often desirable to do the initial drying with air impingement or radiant heating. Surface coating can be done on the machine as a step in the paper-machine operation, as shown in Fig. 1.

Calenders and Winders

Nearly all paper grades are calendered after they have been dried to the desired final moisture content. Ordinary calendering involves passing the paper web through one or more nips between metal rolls with high linear pressures. The calendering process flattens out the paper structure by virtue of the high pressure and "irons" the sheet. Calendering causes bulk reduction, which often is not desired, and surface smoothing, which is desired. The results strongly depend upon moisture content, calender-roll temperature, roll pressure, and speed.

In *supercalendering*, an off-machine operation, the calender rolls consist of alternating chilled-steel and paper-filled rolls, i.e., paper disks clamped on a steel shaft. These roll fillers have to be replaced periodically. Very high pressures are used. The increased pressure and shear forces associated with deformation of the relatively soft paper roll and the very high roll pressures impart a smoother, glossier surface to the web than ordinary calendering with all-metal rolls. This type of calendering is frequently used on coated sheets to provide a glossy coated surface. Recently polymer covered rolls have been replacing paper-filled rolls and due to better durability have given an opportunity to locate this calender as part of papermachine. Fig. 7.

There are other process configurations for the various coating effects and specifications desired.

Other Types of Machines

Although the Fourdrinier machine is used for making almost all grades of paper and board, other designs are sometimes more advantageous. The *cylinder machine*, invented at about the same time as the Fourdrinier, consists of a rotating cylindrical mold covered with a wire screen and partially submerged in a vat. The stock flows into the vat, and a mat is formed on the cylinder under a hydraulic head difference between the stock level in the vat and the white-water level inside the cylinder. The

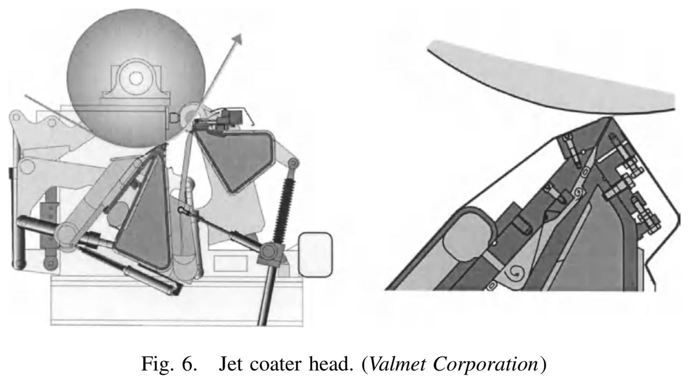

Fig. 6. Jet coater head. (*Valmet Corporation*)

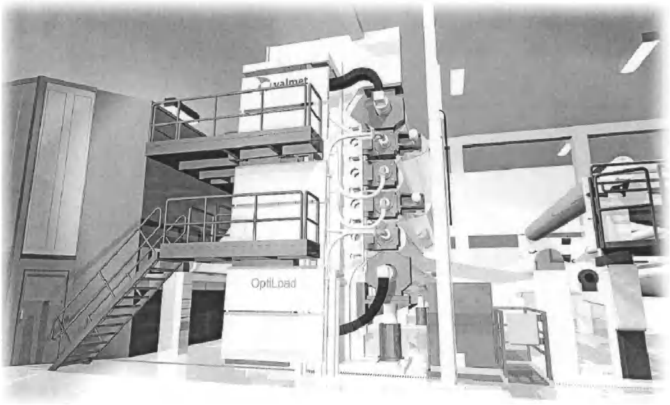

Fig. 7. Multinip calender as part of paper machine. (*Valmet Corporation*)

wet mat is picked up by a felt running through the nip between a couch roll and the cylinder. The cylinder machine is used for making multiply board, employing several vats in series. Because of slow speed and other limitations, the cylinder machine is becoming obsolete. In recent years, several new types of machines have emerged.

The most recent multiply machines use headboxes with simultaneous delivery of two different stocks from the headbox slice (*Beloit Strataflo Headbox*), followed by top wire dewatering units (*Beloit Bel Bond*). A secondary headbox with additional top-wire dewatering follows the first unit on the forming wire. Other versions of multiply formers use mini-fourdiniers on top of the primary forming wire in various configurations.

PARABENS. See **Antimicrobial Agents (Foods)**.

PARA COMPOUNDS. See **Organic Chemistry**.

PARAFFIN. (1) Also called alkane. A class of aliphatic hydrocarbons characterized by a straight or branched carbon chain; generic formula C_nH_{2n+2}. Their physical form varies with increasing molecular weight from gases (methane) to waxy solids. They occur principally in Pennsylvania and mid-continent petroleum. (2) Paraffin Wax.

See also **Organic Chemistry**.

PARAFFINS (Chlorinated). See **Chlorinated Organics**.

PARAMAGNETISM. A physical characteristic of some matter, advantage of which is taken in certain instrumental systems and scientific apparatus. The paramagnetic qualities of oxygen, due to two unpaired electrons per molecule, is used as the basis for some oxygen analyzers. See also **Analysis (Chemical)**. Of the other common gases, only nitric oxide and nitrogen dioxide exhibit paramagnetism.

Three basic magnetic forces exist: (1) paramagnetic, (2) ferromagnetic, and (3) diamagnetic. Ferromagnetic materials are much more permeable than a vacuum and thus positive, aligning with an applied magnetic field. Diamagnetic materials are slightly less permeable, thus negative, aligning across the field. Para- and ferromagnetism diminish with temperature rise, whereas diamagnetism essentially is unaffected.

Precession of electron orbits in atoms and molecules induced by an applied field causes diamagnetism in all matter even when paramagnetism dominates. Unpaired electrons in atoms or molecules cause para- and ferromagnetism. Normally, electrons of opposite spin pair off, netting zero magnetism per pair. Unbalanced spin moment of unpaired electrons yield both para- and ferromagnetism. Paramagnetic matter has unpaired electrons in outer electron shells. Thermal agitation retards atomic or molecular alignment, and thus the net moment is weak. Ferromagnetic matter, such as iron, cobalt, and nickel, has unpaired electrons in the next-to-outer shell. Interatomic forces cause molecular alignment and permanent magnetism results. See also **Magnetism**.

PARA-STATE. 1. In diatomic molecules, such as hydrogen molecules, the para-state exists when the spin vectors of the two atomic nuclei are in opposite (i.e., antiparallel) directions, forming a singlet state, $S = 0$, whereas the ortho-state is the one in which the nuclei are spinning in the same direction.

2. In helium, the para-state is one group or system of terms in the spectrum of helium that is due to atoms in which the spin of the two electrons are opposing each other. Another group of spectral terms, the orthohelium terms, is given by those helium atoms whose two electrons have parallel spins. Because of the Pauli Exclusion Principle, a helium atom in its ground state must be in a para-state.

PARKES PROCESS. A standard process for the separation of silver from lead. From 1 to 2% molten zinc is added to the lead-silver mixture, heated to above the melting point of zinc. A scum containing most of the silver and zinc forms on the surface; this is separated and the silver recovered. The separation of silver is not complete, and the process is repeated several times.

PARTIAL PRESSURE. The pressure exerted by each component in a mixture of gases. In a mixture of perfect gases

$$p_i = \frac{n_i RT}{V}$$

The partial pressure of i is then the same as if component i occupies the same volume at the same temperature in the absence of the other gases. This is the Dalton law, which is treated more fully under that heading.

PARTICLE. Any discrete unit of material structure; the particulate basis of matter is a fundamental concept of science. The size ranges of particles may be summarized as follows: (1) Subatomic: protons, neutrons, electrons, deuterons, etc. These are collectively called fundamental particles. (2) Molecular: includes atoms and molecules with size ranging from a few angstroms to half a micron. (3) Colloidal: includes macromolecules, micelles, and ultrafine particles such as carbon black, resolved via electron microscope, with size ranges from I millimicron up to lower limit of the optical microscope (1 micron). (4) Microscopic: units that can be resolved by an optical microscope (includes bacteria). (5) Macroscopic: all particles that can be resolved by the naked eye.

See also **Carbon Black**; and **Particles (Subatomic)**.

PARTICLE ACCELERATOR. A device in which the speed of charged subatomic particles (protons, electrons) and heavier particles (deuterons, alpha particles) can be greatly increased by application of electric fields of varying intensity, often in conjunction with magnetic fields. It is possible to accelerate electrons and protons to speeds approaching the speed of light if sufficiently high voltage is used. Straight-line (linear) accelerators are used for protons, and doughnut-shaped betatrons for electrons; other types are the Van de Graaf electrostatic generator, the synchrotron, and the cyclotron. Before the development of nuclear reactors, the cyclotron was used to accelerate deuterons for use in bombarding stable nuclei to produce neutrons for inducing artificial radioactivity, fission and formation of synthetic (transuranic) elements.

See also **Cyclotron**; and **Particles (Subatomic)**.

PARTICLE SIZE. This term refers chiefly to the solid particles of which industrial materials are composed (carbon black, zinc oxide, clays, pigments, and the like). The smaller the particle, the greater will be the total exposed surface area of a given mass. Activity is a direct function of surface area; i.e., the finer a substance is, the more efficiently it will react, both chemically and physically. A colloidal pigment is a more effective colorant than a coarse one because of the greater surface area of its particles. A pound of channel carbon black has a surface area of 18 acres, which largely accounts for its powerful reinforcing effect in rubber. Thus, ultrafine grinding of powders is of utmost importance in such products as paints, cement, plastics, rubber, dyes, pharmaceuticals, printing inks, and numerous others.

See also **Carbon Black**; **Colloid Chemistry**; **Particle**; **Sedimentation**; and **Surface Chemistry**.

PARTICLES (Subatomic). For many years, the atom was traditionally described as having a central positively charged nucleus possessing considerable mass, but of minute dimension—this nucleus surrounded by a number of electrons in orbits at a relatively great distance from the nucleus. The number of electrons and their orbital arrangement determined the chemical properties of the atom, with the atoms of each chemical element possessing their own unique configuration. Recognition of the electron, the first elementary (presumably indivisible) particle, by J.J. Thomson and his associates in the 1890s ushered in an era of interest in *subatomic particles*. Ultimately, this led to the discipline of *high-energy physics*.

Organization of Matter—A Chronology[1]

A better understanding of the building blocks of nature has been a goal for many centuries, extending back to the period in Greek history of Anaxagoras of Ionia (500–428 B.C.), who held that "there was an infinite number of different kinds of elementary atoms, and that these, in themselves motionless and originally existing in a state of chaos, were put in motion by an eternal, immaterial, spiritual, elementary being, from which motion the world was produced." The concept of atoms appeared from time to time in medieval works, although the concepts expressed now seem vague. However, they seem to have been based on the idea that there could be a limit to the divisibility of matter and, consequently, the idea of a final indivisible particle out of which large pieces of matter could be built.

Atoms and Molecules. In the early 1800s, it became clear that chemical reactions could be most simply explained if each chemical element was thought of as composed of very small, identical entities characteristic of the chemical element. Thus there arose a rather well-defined idea of a chemical element composed of identical atoms, as distinguished from a compound composed of groups of different atoms combined into molecules. During the later part of the 1800s, the kinetic theory of gases made use of the idea of atoms and molecules in explaining the behavior of gases. During this period, few scientists still doubted the actual material existence and reality of atoms.

Electrons. It is perhaps rather curious that the idea of atoms became really well established only after it became clear that the atoms were not in any true sense indivisible, but that instead they probably had a complex structure that should be investigated. Since these investigations required equipment and methods that had been developed by physicists rather than chemists, the physicists took the lead and the work became known over a long period as *atomic physics*, or the physics of atomic structure. As mentioned previously, this era was inaugurated by Thomson, who first isolated and established the existence of electrons. He showed that electrons have only about 1/2000 the mass of the lightest known atom, hydrogen. He also showed that these particles, as indicated by their name, carry negative electrical charges. It was later shown by Millikan that all the electronic charges are the same. Thus, the identification of electrons as small electrically charged pieces of matter, and as constituents of all matter, became firmly established.

Electrical Neutrality. Since it was clear that normal matter is electrically neutral, it had to be assumed that each atom contained a positive electrical charge, as well as negative electrons. J.J. Thomson developed the picture of a somewhat spherical, jelly-like mass of positive electricity in which electrons are located at various positions, bound by "quasi-elastic" forces.

A principal means of investigating the structure of atoms was the examination of light emitted by the material in the gaseous state. This light was found to consist of a number of discrete wavelengths, or colors. Each of these wavelengths was associated, in the early days of the last century, with a mode of vibration of the electrons in the positive jelly. In particular, Lorentz (University of Leiden) was able to show that such electrons, when placed in a magnetic field, would have their modes of vibration changed in a way that explained the findings of Zeeman, who had made early observations of the wavelengths of the light emitted by a radiating gas in a magnetic field.

During 1910–1911, Sir Ernest Rutherford suggested an experiment, carried out by Geiger and Marsden, in which alpha particles from a radioactive source were scattered from thin foils. The angles at which the alpha particles were scattered were found to be such as could best be described by the close approach of a heavy positively charged particle, the alpha particle, to another heavier and more highly positively charged particle, representing the scattering atom.

Nuclear Atom. From the results of the experiments, Rutherford concluded that the mass in the positive charge of an atom, instead of being distributed throughout the volume of a sphere of the order of 10^{-8} centimeter in radius, was concentrated in a very small volume of the order of 10^{-12} centimeter in radius. He thus developed the idea of a nuclear atom. The atom was pictured as a small solar system with the very heavy and highly charged nucleus occupying the position of the sun, and with electrons moving around it, as planets in their respective orbits.

Although this picture of nuclear atoms served to describe the alpha-particle scattering experiments, it still left many questions unsolved. One of these questions referred to the apparent stability of the atoms. An electron moving around the nucleus would tend to emit radiation, to lose its energy, and thereby to spiral into the nucleus. Why did it not do so? Why did the atoms all seem to be quite stable, and all to be of approximately the same size, even though some contain 90 or more electrons, while hydrogen contains only one?

Electron Motion Around the Nucleus. The first approach to a treatment of these problems was made by Niels Bohr in 1913 when he formulated and applied rules for "quantization" of electron motion around the nucleus. Bohr postulated states of motion of the electron, satisfying these quantum rules, as peculiarly stable. In fact, one of them would be really permanently stable and would represent the ground state of the atom. The others would be only approximately stable. Occasionally an atom would leave one such state for another and, in the process, would radiate light of a frequency proportional to the difference in energy between the two states. By this means, Bohr was able to account for the spectrum of atomic hydrogen in a spectacular way. Bohr's paper in 1913 may well be said to have set the course of atomic physics on its latest path.

Correlation with Chemical Properties. Out of the experimental work on the scattering of alpha particles and the theoretical work of Bohr, there grew a fairly definite picture of an atom that could be correlated with its chemical properties. The chemical properties were determined in the first place by the nuclear charge. The nucleus contained most of the atomic mass and carried an electric charge equal to an integral number of positive charges, each of the same magnitude as an electronic charge. This positive nucleus then accumulated around itself a number of electrons just sufficient to neutralize its positive charge and form a neutral atom.

Atomic Number. The number of positive charges or the number of negative electrons around the nucleus was designated as the atomic number of the atom. These showed a close parallelism with the arrangement of atoms in the periodic system. Through the formulation of a number of rules based upon Bohr's picture of quantized orbits, the periodic system of the elements could be understood. Hydrogen was given one electron, and helium two. The two electrons in helium constituted a "closed shell" which exhibited almost perfect spherical symmetry and chemical inactivity.

Thus, during the years after 1913, the feeling grew that the chemical properties of atoms could be pretty well understood. The idea that there were undiscovered elements, as indicated by gaps in the periodic system, was reinforced. These elements and more have since been discovered.

Quantum Mechanics. It was not until 1925 that Bohr's ideas were developed into a mathematical form complete enough and precise enough to permit their general application, under the name *quantum mechanics*. This development associated with the names of Dirac, Heisenberg, and Schrödinger, provided the basic laws which permit, in principle, the complete and quantitative description of an atom consisting of a heavy positively charged nucleus, and surrounded by enough electrons to make the whole system electrically neutral. See also **Quantum Mechanics**.

Electron Spin. One of the properties of electrons that became evident during the study of optical spectra of atoms was that of *electron spin*. The suggestion was made by Uhlenbeck and Goudsmit in 1925 that one of the features of such spectra could be understood if each electron had associated with it a quantity called spin, which is similar in many ways to angular momentum. Each electron also has a certain magnetic moment which affects the energy in the presence of a magnetic field.[2] This property also has been incorporated into the wave concepts of quantum mechanics.

[1] Some of the concepts mentioned in this brief historical review have long since been abandoned or altered.

[2] Even with acceptance of the spin concept, in terms of high-energy experiments, most scientists believed that spin effects would be observed only in low-energy atomic

In order to learn more about the role of spin in colliding protons, in 1973, using the Zero Gradient Synchrotron (ZGS) at the Argonne National Laboratory, Krisch and colleagues (University of Michigan) scattered beams of polarized protons from targets in which the protons were also polarized, i.e., the spinning was all in the same direction. During the series of experiments, it was found that when the beam and the target were polarized in the same direction, violent proton-proton collisions occurred with much greater frequency than where the beam and target were spinning in a like direction. Under the latter circumstance, it appeared that the particles would pass each other, but would not interact.

Some years later (in the late 1970s), this research group further investigated the spin-collision phenomenon of protons, but used a different accelerator, i.e., the Alternating Gradient Synchrotron (AGS) located at the Brookhaven National Laboratory. The latter apparatus made it possible to study the particles at much higher energy levels: (1) an energy level up to 18.5 GeV (beam and target both polarized; and (2) up to 28 GeV (with only the target polarized). Several unexpected findings were yielded by the experiments:

- Effects of spin appear to oscillate with an increase of collision energy of the protons.
- Spin directions of the particles continue to make a difference even at high energy levels. (Normally, one would reason that at high energy levels, the difference in spin directions and the effects of spinning would become smaller simply because the spin of the proton is believed to be constant and this would tend to be overwhelmed by the higher collision energy. This was not the case and provoked suspicion that much less is known about the proton than formerly believed.)

Out of clues gained from experiments with the AGS, one central question, as posed by researcher Krish in his 1987 paper (reference listed), is posed: What does the observed difference between scattering to the left and to the right mean? Krisch observed that perhaps (as some theorists suggest) both the violence and the energy (28 GeV) of the experiments were much too low for a fundamental theory, such as quantum chromodynamics (QCD), to apply. With higher energies, the scattering difference between left and right may soon be measured at the 70- to 800-GeV proton synchrotrons at Seupukhov, CERN, and Fermilab, and even higher levels of the proposed Superconducting Supercollider (SSC).

See also **Quantum Mechanics**; and **Quarks**.

Neutrons and Protons. By 1932, it had been established that atomic nuclei are made of comparatively small numbers of neutrons and protons. Even prior to the use of particle accelerators and the birth of high-energy physics, other experiments continued to "hint" at the need of additional subatomic particles to satisfy any theory that would unify scientists' understanding of the atom's infrastructure.

A quantum theory of nuclei was made possible by the discovery of the proton and the neutron. The nuclear interaction responsible for holding the nucleus together (against disruptive electrostatic repulsion of the protons) was found to be of an entirely new kind, much stronger than the electric interaction at short distances, but decreasing very much more rapidly with distance. The various complex nuclei differ in the number of protons and neutrons they contain.

By that time, the theory of the interactions between electrons and photons had developed to the point where the electrostatic repulsion or attraction between electrically charged particles could be understood in terms of the exchange of photons between them. In the lowest nontrivial approximation, it gave the Coulomb law for small velocities. The basic interaction was the emission and absorption of "virtual" photons by charged particles.

collisions. In the 1950s, C.L. Oxley (University of Rochester) noted large spin effects in high-energy collisions (several hundred million eV). Experimentation in this area, however, was rather limited until the late 1950s, when researchers (University of California Berkeley) proposed constructing polarized proton targets. In a technique involving low temperatures and strong magnetic fields, it was possible to cause electrons to spin in the same direction and, using another technique (microwave radiation) to cause neighboring protons also to spin in one direction. Interesting experiments followed at some laboratories, but by and large many high-energy physicists in the field considered spin as relatively unimportant and it would be even less important as collision energy levels were increased. This assumption has been disproved. Spin direction does seem to be important to collisions even at high energy levels.

Pions and Other Particles. A similar mechanism could be invoked to explain the short-range nuclear interaction—i.e., it is due to the exchange of particles, which have nonzero masses which are a fraction of nuclear mass. These theoretical considerations predicted the existence of a set of three particles called pions, which were ultimately discovered.

Another kind of particle and another kind of interaction were discovered from a detailed study of beta radioactivity in which electrons with a continuous spectrum of energies are emitted by an unstable nucleus. The corresponding interactions could be viewed as being due to the virtual transmutation of a neutron into a proton, an electron, and a new neutral particle of vanishing mass called the neutrino. The theory provided such a successful systematization of beta decay rate data for several nuclei that the existence of the neutrino was well established more than 20 years before its experimental discovery. The beta decay interaction was very weak even compared to the electron-photon interaction.

Meanwhile, the electron was found to have a positively charged counterpart called the positron; the electron and positron could annihilate each other, with the emission of light quanta. The theory of the electron did in fact predict the existence of such a particle. It was later found that the existence of such "opposite" particles (antiparticles) was a much more general phenomenon than once surmised.

With intensification of particle physics research, many more particles were discovered and a classification of these particles into five families was proposed—the photon family, electron family, muon family, meson family, and baryon family. Most of these particles are unstable and decay within a time which is often very small by normal standards, but which is many orders of magnitude larger than the time required for any of these particles to traverse a typical nuclear dimension. There is a wide variety of reactions between them, but they could be understood in terms of three basic interactions—the *strong* (or nuclear), *electromagnetic*, and *weak* interactions.

The Nuclear Force. The nuclear forces and the interactions between pions and nucleons are strong; the electron-electron and electron-photon interactions are electromagnetic; the beta decay interactions are weak.

As mentioned previously, by 1932 it was known that nuclei are made of comparatively small numbers of neutrons and protons. A new force was discovered (in addition to the electromagnetic and gravitational forces) that held the positive protons and electrically uncharged neutrons together in the nucleus. This nuclear force was very strong, but of limited range. Its "quantum," the particle analogous to the photon in the electromagnetic field, was of nonzero rest mass. This particle, later called the π-meson or pion, was predicted by Yukawa in 1936 and discovered by Lattes, Occhialini, and Powell in 1947.[3] For a short time, it appeared that physicists had achieved a clear, simple, and correct theory of the fundamental constitution of matter. However, shortly thereafter, two new and unpredicted particles were reported. The first of these was another

[3] Even though the meson was first predicted by the Japanese scientist Yukawa in 1935, the development of high-energy physics in Japan proceeded slowly from an experimental standpoint. It was not until 1975 that Japan established the National Laboratory for High Energy Physics (KEK). Rather than following traditional research approaches by way of building a proton synchrotron, for example, scientists at the University of Tokyo, in collaboration with physicists in the United States and Canada and later with CERN, decided to construct a meson facility with a powerful superconducting muon channel. In his report on the evolution of meson science in Japan, Yamazaki (1986 reference cited) lists at least four advantages of opting for a meson facility: (1) It made possible the measurement of μ-e decay time spectra in a much wider time range (0 to 20 μsec) than previously possible without background, enabling muon-spin relaxation functions (mainly long-time behavior) to be determined precisely; (2) extreme external conditions pulsewise (pulsed RF, laser, high magnetic fields) could be applied; (3) because the time of muon arrival is uniquely defined, any time-dependent transient phenomena could be investigated; and (4) rare events could be selected from continuous backgrounds. Beyond the editorial scope here, Yamazaki describes in considerable detail the numerous accomplishments of KEK during the 1980s, including an improved understanding of nuclear structure from the viewpoint of quark structure. As mentioned, since nucleons and mesons are composed of quarks and since nucleons are densely packed in a nucleus, whether the nucleons in nuclei keep their free identities (mass, size, magnetic moment) is a rewarding problem to investigate. Recently, a new type of hypernuclear spectroscopy has emerged from KEK. Yamazaki defines meson science as an interdisciplinary since it uses "second generation" particles (muons and K mesons) for the creation and detection of exotic states in matter. To study this interesting frontier, scientists strongly sense the need for experimental facilities that will provide meson beams a hundred times as strong as those available today. Plans are underway along these lines. See also **Mesons**.

meson, somewhat like the pion but more massive. The second was a hyperon, i.e., a strongly interacting particle heavier than the neutron.

With the continuing discovery of more particles, investigators began to suspect that these particles were not in themselves fundamental or elementary, but that they had an internal structure. This paralleled the experiences of the 1800s when the large number of different types of atoms discovered suggested that atoms must have structure. Properties of particles also suggested an internal structure. For example, the neutron's total electric charge is indistinguishable from zero down to very fine limits, yet the neutron has a sizeable magnetic moment.

The discoverers of neptunium (1940), plutonium (1940), americium (1944), berkelium (1949), californium (1950), einsteinium (1952), fermium (1953), mendelevium (1955), and lawrencium (1961) gained much knowledge in the area of high-energy physics.

Research directed toward creating a nuclear bomb also contributed to an improved understanding of high-energy physics.

Exotic atomic nuclei may be described as structures that do not occur in nature, but are produced in collisions. These nuclei have abundances of neurons and protons that are quite different from the natural nuclei. In 1949, M.G. Mayer (Argonne National Laboratory) and J.H.D. Jensen (University of Heidelberg) introduced a spherical-shell model of the nucleus. The model, however, did not meet the requirements and restrains imposed by quantum mechanics and the Pauli exclusion principle. Hamilton (Vanderbilt University) and Maruhn (University of Frankfurt) reported on additional research of exotic atomic nuclei in a paper published in mid-1986 (see reference listed). In addition to the aforementioned spherical model, there are several other fundamental shapes, including other geometric shapes with three mutually perpendicular axes—prolate spheroid (football shape), oblate spheroid (discus shape), and triaxial nucleus (all axes unequal).

In 1964, M. Gell-Mann and G. Zweig (California Institute of Technology) independently pointed out that all the known hadrons (i.e., particles that interact via the strong nuclear force) could be constructed out of simple combinations of three particles (and their antiparticles). These hypothetical particles had to have slightly peculiar properties (the most peculiar being a fractional electric charge). Gell-Mann called these hypothetical particles *quarks* (referring to a sentence in James Joyce's work *Finnegan's Wake*, "Three quarks for Muster Mark"). The theory proposed postulated that three quarks bind together to form a baryon, while a quark and an antiquark bind together to form a meson. With supposition that the binding is such that the internal motion of the quarks is nonrelativistic (which requires the quarks be massive and sit in a broad potential well), then many quite detailed properties of the hadrons could be explained.

The purpose of the quark model was that of explaining the diversity of the hadrons; not to deal with the internal structure of any particle. But awareness of the model created a natural tendency among investigators to associate newly observed particles (among the poorly understood debris from particle experiments) with the hypothetical quarks. A number of properties of *partons* (a name given by Feynman, California Institute of Technology) were measured, including intrinsic spin angular momentum, and these were found to be consistent with the predictions of the quark model. Such observations, of course, added credence to the model.

In the 1960s, the quest for a grand unification theory—a theory that would explain all elementary particles and all forces acting between them—grew in intensity among most investigators who had the good fortune of discovering so many new particles, accompanied by the realization that the ultimate structure of matter was more complex than envisioned in the earlier years. The instrumental means for research (accelerators with higher and higher energies) were getting ahead of the theoretical aspects of the topic. Many particles resulting from collisions were found in the debris of experiments—their presence without plausible explanations. Many questions were posed—for instance, why four kinds of force, each with its own characteristic strength, the strengths differing by nearly 40 orders of magnitude (electromagnetism with its infinite range, the weak force for all practical purposes extending out only 10^{-15} centimeter)? For a while, prospects of a unified theory were dim, but a number of theories were proposed and given sufficient serious attention to warrant planning of experimental tests. As pointed out by Glashow (Nobel Prize, Physics, 1979, shared with Salam and Weinberg), in his Nobel Lecture, "In 1956, when I began doing theoretical physics, the study of elementary particles was like a patchwork quilt. Electrodynamics, weak interactions, and strong interactions were clearly separate disciplines, taught and separately studied. There was no coherent theory that described them all. Developments such as the observation of parity violation, the successes of quantum electrodynamics, the discovery of hadron resonances, and the appearance of strangeness were well-defined parts of the picture, but they could not be easily fitted together."

In the early years of investigation, the weak force and the electromagnetic force were regarded as indistinguishable. They were of the same strength and possessed the same infinite range, and they were transmitted by four bosons, all of which were massless. The forces manifested a symmetry, that is, they could be interchanged freely. It was believed that no matter which of these forces was applied, the net effect was the same. These views were later to be altered in the light of the process called *spontaneous symmetry breaking*.[4]

The principle of charge conjugation symmetry states that if each particle in a given system is replaced by its corresponding antiparticle, then it would not be possible to tell the difference. For example, if in a hydrogen atom the proton is replaced by an antiproton and the electron is replaced by a positron, then this antimatter atom will behave exactly like an ordinary atom—if observed by "persons also made of antimatter." In an antimatter universe, the laws of nature could not be distinguished from the laws of an ordinary matter universe.

However, it turns out that there are certain types of reactions where this rule does not hold, and these are just the types of reactions where conservation of parity breaks down. For example, consider a piece of radioactive material emitting electrons by beta decay. The radioactive nuclei are lined up in a magnetic field which is produced by electrons traveling clockwise in a coil of wire, as seen by an observer looking down on the coil. Because of the asymmetry of the radio-active nuclei, most of the emitted electrons travel in the downward direction. If the same experiment were done with similar nuclei composed of antiparticles and the magnetic field were produced by positron current rather than an electron current, then the emitted positrons would be found to travel in the upward, rather than in the downward, direction. Interchanging each particle with its antimatter particle has produced a change in the experiment.

However, the symmetry of the situation can be restored if we interchange the words "right" and "left" in the description of the experiment at the same time that we exchange each particle with its antiparticle. In the above experiment, this is equivalent to replacing the word "clockwise" with "counterclockwise." When this is done, the positrons are emitted in the downward direction, just as the electrons in the original experiment. The laws of nature are thus found to be invariant to the simultaneous application of charge conjugation and mirror inversion.

Time reversal invariance describes the fact that in reactions between elementary particles, it does not make any difference if the direction of the time coordinate is reversed. Since all reactions are invariant to simultaneous application of mirror inversion, charge conjugation, and time reversal, the combination of all three is called *CPT* symmetry and is considered to be a very fundamental symmetry of nature.

A relatively recent type of space-time symmetry has been introduced to explain the results of certain high-energy scattering experiments. This is *scale symmetry* and it pertains to the rescaling or "dilation" of the space-time coordinates of a system without changing the physics of the system. Other symmetries, such as chirality, are more of an abstract nature, but aid the theorist in an effort to bring order into the vast array of possible elementary particle reactions.

A feature of quantum field theory is that the quanta of the fields are initially massless. Spontaneous symmetry breaking offers a mechanism by which weak field quanta, for example, can acquire masses. Unification of weak and electro-magnetic forces may be viewed thus in the following manner at short distances (high energies), the masses of the weak field quanta become unimportant and thus original symmetry is restored. Symmetry in this context refers to the properties of the equations of motion of particles in the field theories. Spontaneous symmetry breaking occurs when solutions of the equations do not display full symmetry. Some physicists have likened this to a ball moving on a roulette wheel, whose

[4] Prior to 1956, it was believed that all reactions in nature obeyed the law of conservation of parity, so that there was no fundamental distinction between left and right in nature. However, Yang and Lee pointed out that in reactions involving the weak interaction between particles, parity was not conserved, and that experiments could be devised that would absolutely distinguish between right and left. This was the first example of a situation where a spatial symmetry was found to be broken by one of the fundamental interactions.

equations of motion are symmetrical about the axis of rotation even though it always stops in an asymmetric position.

The first direct evidence that the proton has not only size, but structure was provided by an experiment at the Stanford Linear Accelerator Center (SLAC) in 1970. Previously it had been established that the proton is not a point-like particle, but has a finite size—a diameter of about 10^{-13} centimeter. Although it is only about 1/100,000 the size of an atom, it is still measurable. This is unlike certain other particles, notably the electron, for which no extension has been noted, so that the electron can be regarded as a mathematical point. In the experiment, electrons were raised to an energy of some 20 billion electron volts and struck protons and neutrons in the atoms of a stationary target. The angular distributions of the scattered electrons and of other particles created in the collisions were carefully monitored. Most of the electrons, as expected, passed through the target with little change in direction. An unexpected excess of widely scattered particles was produced, however—much greater than if the proton were diffuse and homogeneous. The excess of the widely scattered particles was attributed to a mass embedded within the proton, estimated at no more than $\frac{1}{50}$ the diameter of the proton. In later experiments, a target was illuminated by means of muons (like electrons but with a mass 200 times greater); and by a beam of neutrinos (which lack both mass and electric charge). The results of the original and later experiments were consistent and the deep scattering of particles was attributed to collisions between the incident leptons and some "hard" constituent of the proton.

Theories and postulations continue to be developed concerning the symmetry of nature. For example, in a 1986 paper, H.E. Haber (University of California, Santa Cruz) and G.L. Kane (University of Michigan) observe that *supersymmetry* could represent the next step in the quest for a few simple laws that explain the nature of matter. Physicists are seeking evidence to test the theory. As described, in supersymmetry, for every ordinary particle that exists there is a so-called "superpartner" having similar properties, with exception of the quantity referred to as *spin*, previously discussed here. In a 1985 paper, C. Quigg (Fermi National Accelerator Laboratory) further describes current theories and hypotheses pertaining to elementary particles and forces and observes that a coherent view of the fundamental constituents of matter and the forces governing them is beginning to emerge. A present goal of physicists is to merge disparate theories into a single comprehensive description of natural events. It is agreed among most high-energy specialists that to reach that goal, greater and greater energy must be brought to the experiments. The Superconducting Supercollider (SSC) would be one of these. The complex concept of CP invariance is described in a 1988 paper by R. Adair (Brookhaven National Laboratory). In this postulate, the claim is made that without CP invariance there would be no matter in the universe. Adair observes that if the approximate symmetry between matter and antimatter that has been observed were perfect, the universe would be elegantly simple but virtually empty of matter and of creatures made up of that matter who could contemplate that elegance. It is proposed that the existence of the universe as currently known comes from a flaw in a symmetry exhibited by a universal mirror (the CP mirror), i.e., a symmetry that requires that the outcomes of some events in nature should remain the same on changing matter to antimatter and viewing the result in a mirror.

Before discovery of the hadron particle (designated *psi* or J), and after much experimental and theoretical effort, physicists had about concluded that three massive, fractionally charged entities (quarks) were the primary building blocks of the universe. However, discovery of the psi particles in 1974 indicated a fourth quark was required. Previously, in the three-quark model, all mesons were made up of one quark and one antiquark; baryons, of three quarks; and all anti-baryons, of three antiquarks. Prior to 1974, all of the known hadrons could be accommodated within this basic scheme. Three of the possible meson combinations of quark-antiquark could have the same quantum numbers as the photon, and hence could be produced abundantly in e^+e^- annihilation. These three predicted states had all been found.

As pointed out by Richter (1977), the first proposal of a theory based on four quarks rather than three was published in 1964 by Amati and others. The motivation at that time was more esthetic than practical, and these models gradually expired for want of an experimental fact that called for more than a three-quark explanation. In 1970, Glashow explained in a paper that a fourth quark was required to explain the nonoccurrence of certain weak decays. The fourth or c quark was assumed to have a charge of $+\frac{2}{3}$, like the u quark, and also to carry $+1$ unit of a previously unknown quantum number, called *charm* by Glashow, which was conserved in both the strong and electromagnetic interactions, but not in the weak interactions. Discovery of the psi particles demonstrated a more compelling need for the fourth quark. Richter observes that the four-quark model of hadrons seemed to account, in at least a qualitative fashion, for all of the main experimental information that had been gathered about the psions, and by the early part of 1976, the consensus for charm had become quite strong.

In 1977, the *upsilon particle* was found as the result of energetic collisions between protons and copper nuclei. The upsilon particle has a mass three times greater than any other subatomic entity yet detected (early 1980s). Researchers on this experiment from Columbia University, the State University of New York (Stony Brook), and the Fermi National Accelerator Laboratory reported that, with a mass at its lower energy state equivalent to 9.0 GeV and masses in excited states equivalent to 10 and 10.4 GeV, the upsilon particle has been interpreted as consisting of a massive new quark (the fifth) bound to its antiquark. Confirming experiments were also conducted at the Deutsches Elektronen Synchrotron (DESY) located near Hamburg, Germany. The quantum attribute of the fifth quark was named "bottom." With a fifth quark reported, many physicists felt that finding a sixth quark ("top") was highly probable.

In 1979, the Nobel Prize (Physics) was awarded to Glashow and Weinberg (both of Harvard) and Salam, a Pakistani physicist, in recognition of the significance of the theory which unites the weak force with the electromagnetic force. But most scientists recognize this finding as only a milestone in a series of predictions that include the existence of new particles so massive that they cannot be expected to appear at the energies thus far available to physicists.

The chemists of the nineteenth century once thought that all material substances were comprised of only 36 elements.[5] Over the years, these expanded to over 100 elements. Fifty years ago, it was proclaimed that the elements were made of electrons, protons, and neutrons. Then, commencing in the 1940s, many other particles were found, as described here. Then for a while it seemed that elementary matter could be reduced to three particles—the quarks. But quarks have multiplied in number, with a sixth quark now seriously proposed. Will there be too many quarks? Perhaps hypothetical particles will be proposed from which the quarks are comprised. Possibly the ultimate answer will lie with the "mathematical groups that order the particles rather than in truly elementary objects."

In the late 1980s and thereafter, the *superstring* theory was drawing the attention of most theoretical physicists. Out of this theory may emerge the long sought concept that will account for all four fundamental forces. Quantum theories have been formulated for three of the four known forces of nature—strong, weak, and electromagnetic interactions. This comprises one of two basic foundations. The other, of course, is Einstein's general theory of relativity, which relates the force of gravity to the structure of space and time. A quantum theory of gravity is missing. Some scientists currently feel that there is much potential for the string theory to bring this unification about. String theory was first proposed by Y. Nambu (University of Chicago) in 1970. Traditional models of elementary particles are based on quantum field theory, which involves dimensionless points and quantum numbers, but with no specified internal structure. In studying one of the alternatives to the foregoing, a dual resonance model, Nambu observed that it was equivalent mathematically to the interaction of bits of string. The dual resonance model had been constructed to show how one hadron should scatter off another. The theory envisions the strings about 10^{-35} meter long (10^{20} times smaller than the diameter of a proton). As observed by M. Green (Queen Mary College, University of London) in a 1986 paper (reference listed), string has extension; it can vibrate like a violin string. The harmonic, or normal, modes of vibrations are determined by the tension of the string. In quantum mechanics, waves and particles are dual aspects of the same phenomenon. Thus, each vibrational mode of a string corresponds to a particle. It is envisioned that two strings interact when they touch their tips together and are fused into one—or one string may split into two parts. Strings can absorb energy in a collision and may ripple and rotate (at the speed of light). The original string theory initially was limited to providing a satisfactory "explanation" for describing bosons (pi meson and rho meson), i.e., particles that have integral numbers of spin angular momentum units. Attempts to describe particles with half-integral spin, such as fermions (proton, neutron), failed. However, in 1976,

[5] Line of thought suggested by L.M. Lederman (Columbia University) in a paper on "The Upsilon Particle," *Sci. Amer.*, **239**, **4**, 80 (1978).

a suggestion was made by Scherk, a French physicist, to the effect that a string model could represent a fermion, but with the proviso that a fermion was matched by a corresponding boson. Incidentally, this is the type of correspondence required by the principle of supersymmetry. One of several difficulties that lie ahead for the superstring theory is that of matching its mathematical concepts (26 dimensions—25 space and 1 time) with the real world of 4 dimensions. As one physicist has observed (E. Witten, Princeton University), it is a complete mystery what string theory is at a fundamental level.

State of the Science (Early 1990s)

In terms of comprehending the ultimate nature of matter, most scientists would agree that tremendous progress has been made over the past century and a half, but that a grand unifying theory of particles and their structures and interaction may continue to elude researchers for many years.

Number of Particle Families. How many families of matter may exist? Three, four, or more? An acceptable number among researchers today is three. Three family entities make up matter—the stars, the planets, molecules, and the atoms in the paper upon which this is printed. These fundamental particles are the "up" quark, the "down" quark, and the electron. Some other researchers are not quite so confident. One is reminded of the quotation from Jonathan Swift:

So, naturalists, observe, a flea
Hath smaller fleas that on him prey:
And these have smaller still to bite'em
And so proceed ad infinitum.

Within the limitations of contemporary knowledge, there are three families of fundamental particles, the approximate properties of which are given in Table 1. In 1991, G. Feldman (Harvard University) and J. Steinberger (CERN and 1988 Nobelist for discovery of the muon nutrino) observed, "Many questions remain unanswered. Why are there just three families of particles? What law determines the masses of their members, decreeing that they shall span 10 powers of 107? These problems lie at the center of particle physics today. They have been brought one step closer to solution by the numbering of the families of matter."

In their reference listed, Feldman and Steinberger describe how experiments at CERN and SLAC, using electron-positron collisions, showed that there are only three families of fundamental particles in the universe.

By contrast, as D. Cline (University of California) observed in 1988, "Several theorists think a new quark should exist in the vicinity of 246 GeV. One of the notable features of the standard model is its prediction that at high enough energies the various forces begin to unify. In particular, the electromagnetic force and the weak and strong nuclear forces should become a single 'grand unified' force. The forces should be unified at the incredible energy of 10^{15} GeV, considerably beyond what can ever be attained by an accelerator on earth. The extrapolation of measured values of fundamental parameters from low energies to the grand-unified energy scale would require the existence of a new massive quark for consistency."

Nuclear Equation of State. In a late 1991 paper, H. Guthrod (Institute of Heavy-Ion Research, Darmstadt) and H. Stöcker (University of Frankfurt) are developing a nuclear equation of state in order to clarify the "new" states of matter and conditions that may occur inside a supernova and the organization of the universe. The authors observe, "Nuclear matter in its normal phase resembles a liquid. Increasing the temperature or density 'boils' nuclei into the hadron gas phase. Under extreme density but low temperature, nucleons could become 'frozen,' forming condensates, further heating or compression may produce the plasma phase, which would consist of free quarks and gluons. The gas and plasma phases may exist simultaneously over a wide region. Particles that have strange quarks, such as multistrange, metastable objects ('memos') and strangelets, may also form."

This approach parallels our consideration of the equation of state that applies to "ordinary" matter, such as gases, liquids, and solids that exist in macrostructured materials. See also **Equation of State**.

TABLE 1. THREE FAMILIES OF FUNDAMENTAL PARTICLES

	Charge	Mass in billions of electron volts (GeV)		
		Electron Family	Muon Family	Tau Family

Particle Accelerators

Subatomic particles, such as electrons, positrons, and protons, can be accelerated to high velocities and energies, usually expressed in terms of center-of-mass energy, by machines that impart energy to the particles in small stages or nudges, ultimately achieving in this way very high-energy beams, measured in terms of billions and even trillions of electron volts. Thus, in terms of their scale, particles can be made to perform as powerful missiles for bombarding other particles in a target substance or for colliding with each other as they assume intersecting orbits. Because the particles are empowered with high energy, their smashing encounters are conducive to breaking the particles into their constituents. Instruments or machines used to arrange these particle encounters are known as *particle accelerators* and are very large, their dimensions frequently measured in terms of a few miles or kilometers. Thus, in a sense, it is ironic that the largest tools of science are required to seek knowledge concerning the smallest particles of matter that make up the universe and the earth. Theoretically, if at some future date sufficient energy can be imparted to two particles, their head-on collision will yield a complete fireball of disintegration, such that the absolute, indivisible particles of matter will be lain bare. A further division of matter then would be theoretically impossible. This is a goal of many particle physicists and perhaps achievable within a relatively few decades. Or, on the other hand, would then new theories be formulated to show that the true absolutes have indeed not yet been found?

Electromagnetic forces are used to accelerate particles, requiring that the particles must have an electric charge. Protons (+1) and electrons (−1) are commonly used as the media for particle-physics experiments, although not exclusively. The particles must be accelerated within a vacuum because otherwise they would collide with the molecules of air. The tube-shaped enclosures for the speeding particles are maintained under a vacuum of about 10^{-9} torr. The particles are set in motion by an electric field, which in the simplest configuration is an applied high voltage across a pair of electrodes. The positive electrode attracts electrons; the negative electrode attracts protons. It may be pointed out that an acceleration of this kind occurs in the ordinary television receiver. This basic principle, which applied to the early accelerators, remains the basis of the current operating and planned accelerators of the future. A simple electrode arrangement cannot sustain a potential of over a few million volts because of breakdown of insulation and arcing, and thus is confined to the simplest kind of accelerator where high energies are not required. In a practical sense, particles must be provided with energy in a large number of stages or "nudges." Thus, as in a *linear accelerator* (linac), the stages are strung out along a straight path, each stage requiring a radio-frequency oscillator which sets up an alternating electric field which is connected to each set of electrodes. Many radio-frequency cavities are formed along the line, and to provide the correct parity so that the particles will be accelerated rather than retarded the oscillators for the successive cavities must be synchronized. Effectively, an electromagnetic wave that travels continuously through the evacuated chamber is set up. It has been suggested by one physicist that the particle "rides the electrical wave as a surfer rides a water wave." In a less costly arrangement, known as the *synchrotron*, the particles are made to follow a circular or closed curve rather than a linear course. Groups of particles may circle a ring of this kind several million times while they are increasing their energy and velocity. Only one or a few radio-frequency cavities are required because energy is picked up each time the particle completes a revolution.

In addition to linear accelerators and synchrotrons, the accelerated particles of which ultimately are directed to strike a fixed target, there are *colliding-particle machines* in which particles are made to collide head-on.

These machines are similar to synchrotrons except one bunch, or cluster of particles, travels in one direction while another bunch travels in the opposite direction. Where the colliding particles have the same rest mass and, after acceleration, have the same energy, the center-of-mass energy is the sum of the two beam energies. Thus, two beams with energies of 50 GeV (billion electron volts), for example, can provide the colliding force of one beam of 100 GeV against a fixed target. As will be shown later, head-on collision apparatus requires the use of storage rings, and systems are arranged in various configurations. Electron-positron storage rings are particularly efficient for creating new elementary particles from high-energy collisions.

The energy acquired by the particles in an accelerator is expressed in electron volts (eV), the amount of energy gained by any particle bearing a charge equal to that of an electron when it falls through a potential difference of 1 volt. Thus, 10^3 eV = 1 keV (kiloelectron volt); 10^6 eV = 1 MeV (megaelectron volt or one million eV): 10^9 eV = 1 GeV (gigaelectron volt or one billion eV); and 10^{12} eV = 1 TeV (teraelectron volt or one trillion eV). The large accelerators have been in the GeV range. Plans call for machines in the TeV range. Inasmuch as the mass and energy can be freely interconverted, the mass of a particle is usually expressed in terms of its energy equivalent in eV. The mass of the proton thus is 938 MeV.

High-energy machines require a supply not only of the type of particle desired, but also particles that have been preliminarily accelerated. Electrons are comparatively easy to generate as inputs to accelerators, as by the Cockcroft-Walton generator. Protons are obtained by ionizing hydrogen atoms.

As early as 1928, E.O. Lawrence constructed one of the first particle accelerators out of laboratory glassware. This was only a few inches in diameter. Principles remain essentially the same even today, but the size of accelerators has increased tremendously. They no longer are parts of laboratories, but rather the detection and laboratory aspects of modern accelerators are appended around the accelerator. Modern accelerators cost many millions of dollars and a major installation requires numerous scientists and scores of support people, aided by a number of digital computers. In the future, costs may become so high that several countries, working together, will have to support particle-physics research facilities, as already exemplified by the European Organization for Nuclear Research (abbreviation CERN for the former name, *Conseil EuropÉen pour la Recherche NuclÉaire*) with facilities located in Geneva, Switzerland, and adjacent land in France.

Particle Generators. Direct voltage for charging particles may be obtained in two basic ways: (1) by means of a cascade process, such as the cascade rectifiers or voltage-multiplying circuits; and (2) by charging up a terminal through actual transportation of the charge.

The Cockcroft-Walton generator is of the first type and consists of several stages of a voltage-doubling circuit together with an ion source and a suitably designed discharge tube. Although it is possible to use electrons, these accelerators are usually used as positive-ion sources and can provide dc currents up to about 10 mA and energies up to about 1.5 MeV without special pressure tanks. With this type of accelerator, Cockcroft and Walton were able, in 1932, to induce the first nuclear reaction using artificially accelerated protons. The reaction was: $^1H + ^7Li \longrightarrow ^8Be \longrightarrow 2^4He$. See Fig. 1.

The second method is employed in the *electrostatic*, or *Van de Graaff*, generator where a row of corona points sprays charge onto a moving belt that carries the charge to the field-free region inside a spherical metal terminal. Currents of about 1 mA for electrons, and up to about 500 μA for positive ions, are obtained in the range 1 to 5 MeV with a precision of about 0.1%. The whole apparatus is enclosed in a pressure tank and operated at about 10 atmospheres. In this form, the maximum energy is close to 10 MeV and is limited by breakdown between the terminal and its surroundings. However, double the energy can be attained by accelerating negative ions to the positively charged terminal; then, through electron-stripping, positive ions are created which can be accelerated again as they pass from the terminal to ground. Such tandem Van de Graaff generators, in two- and three-stage variations, can provide particles in the 10 to 30 MeV range, with high precision. See Fig. 2.

An electric field may also be produced by a time-varying magnetic field. The changing magnetic flux in the central core of a pulsed cylindrical electromagnet induces a transverse electric field that accelerates the particles. These travel in a doughnut-shaped vacuum chamber located between the poles of the magnet surrounding the core. The magnetic field between these poles keeps the particles traveling in a circle, but it must be carefully designed to keep the particle orbits within the vacuum chamber during each pulse. Although betatrons can accelerate positively charged particles, they have been used for electrons. The electrons can be extracted, but they usually bombard an inner target to produce beams of X-rays, which can be as intense as 1400 roentgens/minute at a distance of 1 meter from the target. Pulsing rates vary from 30 to 60 times per second.

Other types of accelerators use various forms of rf electric fields, at relatively low voltage, which are applied many times in a given direction

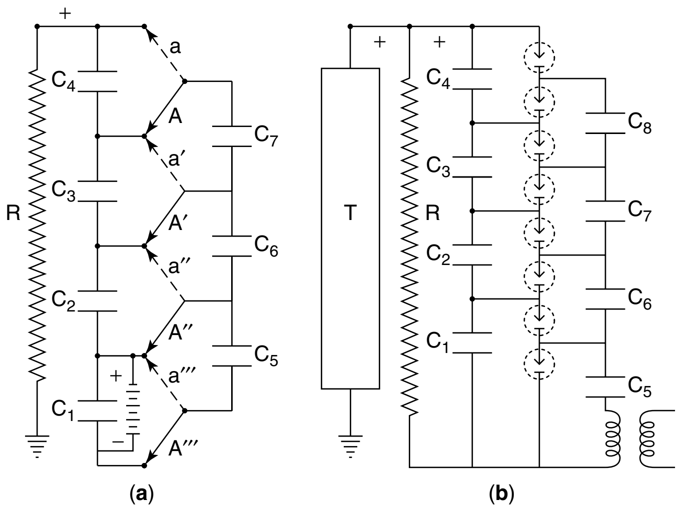

Fig. 1. Cockcroft and Walton scheme in which rectified A.C. voltage is used to charge a series of capacitors to a high D.C. potential, which is then applied to the acceleration of charged nuclear particles. The principle of operation can best be described by the apparatus using mechanical switches shown in A. Condensers of equal capacity are represented by C_1, C_2, C_3, etc. If the switch blades are down, the battery B is connected across condensers C_1 and C_5. On moving the blades up (dashed lines), condenser C_5 transfers half its charge to C_2. When the blades are moved down again, C_2 transfers half its charge to C_6 and C_5 is recharged to full capacitance. A continuous up and down motion of the blades results in a transfer of charge up the condenser bank until every condenser is charged to the voltage of the battery. The total voltage applied to the discharge tube, symbolized here by the resistance R, is the sum of the voltage across the condensers C_1, C_2, C_3 and C_4 in series. In the actual apparatus (part B), an alternating voltage was applied through a transformer and the switching action was accomplished by the use of rectifier tubes

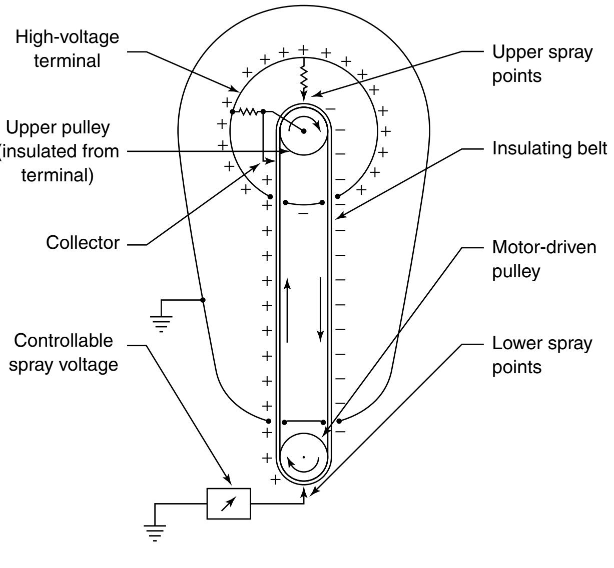

Fig. 2. Diagram of Van de Graff electrostatic belt generator

to the particles and are prevented from influencing them when the rf field is reversed.

Linear Accelerators. The linear accelerator (*linac*) has the advantage that the accelerated beam is easily extracted for experimental use. In principle, it is capable of producing well-focused beams of higher intensity than are available from circular machines of the synchrotron type. It does, however, require very high power levels at frequencies where conversion equipment is relatively expensive. For a given final energy, a linear accelerator will usually be materially more expensive than a synchrotron.

The rf fields used for acceleration are set up in a long cylindrical cavity whose axis is to be the axis of the accelerated beam. Hence, for acceleration the field pattern must have a major electric field component parallel to the axis. This requirement is satisfied by the TM_{01} waveguide mode in which a paraxial electric field has its maximum strength at the axis and falls to zero at the cavity wall. Azimuthal magnetic fields lie in planes normal to the axis, have small values near the axis and increase to maximum values at the cavity walls. Usually the field pattern is maintained by coupling to these magnetic fields by loops or apertures excited by external power sources. Corresponding to the high rf magnetic field at the wall, paraxial currents flow in the walls and are responsible for a major function of the power loss in the system. When high electric fields are required on the axis to accelerate to high energy in reasonable distances, the wall currents are correspondingly high.

Both standing wave and traveling wave patterns can be used in linear accelerators. If traveling waves are used, the phase velocity of the waves must be made equal to the velocity of the particles accelerated; as the particle velocity increases, the phase velocity must also increase. But, phase velocities in simple waveguides always are greater than the velocity of light, and loading must be introduced to reduce the phase velocity to the desired value. This can be accomplished by the introduction at intervals of washer-shaped irises.

The operating principles of a linear accelerator are shown in Fig. 3.

Synchrotrons. A particle is made to follow a circular (or other closed curve) orbit by arranging a number of magnets in a ring. The principle is illustrated by Fig. 4. Two kinds of magnets are required. Dipole magnets (two poles) generate a uniform magnetic field. Spaced around the ring, these magnets bend the particle trajectory. To keep a concentrated beam of particles, quadrupole magnets (two north poles and two south poles), which have no effect on deflecting the particles, are used to focus them. Acting like lenses, these magnets form the particles into a narrow beam. Depending upon the size and general configuration of a synchrotron, radio-frequency cavities may be variously interspersed among the magnets where the actual acceleration occurs. Special magnets are used for injecting particles into the ring and for extracting the accelerated beam of particles.

The first substantial synchrotron was built as early as 1952. Known as the *Cosmotron*, it was installed at Brookhaven National Laboratory on Long Island, New York. The device achieved energies up to 3 GeV. Two years later, the *Bevatron*, with energies up to 6.2 GeV, was installed at the University of California at Berkeley. A shortcoming of these earlier designs was the magnet system, which provided inadequate focusing of the beam. A system of strong focusing was introduced to later-generation synchrotrons. As pointed out by R.R. Wilson (1980). “The shape of the magnetic field can be described mathematically as being partly uniform (the dipole component) and partly a gradient in a direction transverse to the orbit of the beam (the quadrupole component). The quadrupole component was made stronger and was alternated in sign, so the oscillations of the particles around the desired orbit were more frequent, but of smaller amplitude. As a result of this alternating gradient, the aperture of the magnets and the bore of the vacuum chamber could be smaller. It is the invention of the synchrotron and of strong focusing that has made the very large accelerators of today economically feasible.” Synchrotrons with this design are known as *alternating gradient synchrotrons* (AGS).

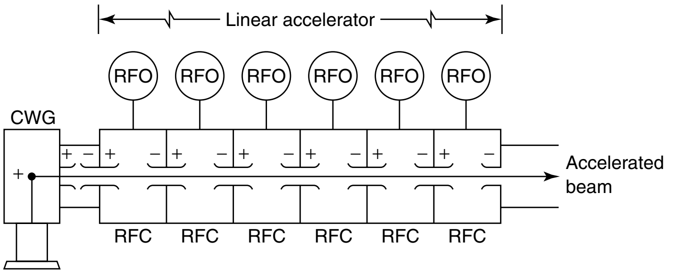

Fig. 3. Principle of linear accelerator (linac). Partially accelerated electrons from a source, such as a Cockcroft-Walton generator, are further accelerated by stages as the electrons pass through radio-frequency cavities, powered by rf oscillators. Each particle receives a small “push” as it passes from one cavity to the next until the final desired accelerated beam is produced. The machine must be carefully synchronized. CSG = Cockcroft-Walton generator; RFO = radio-frequency oscillator; RFC = radio-frequency cavity

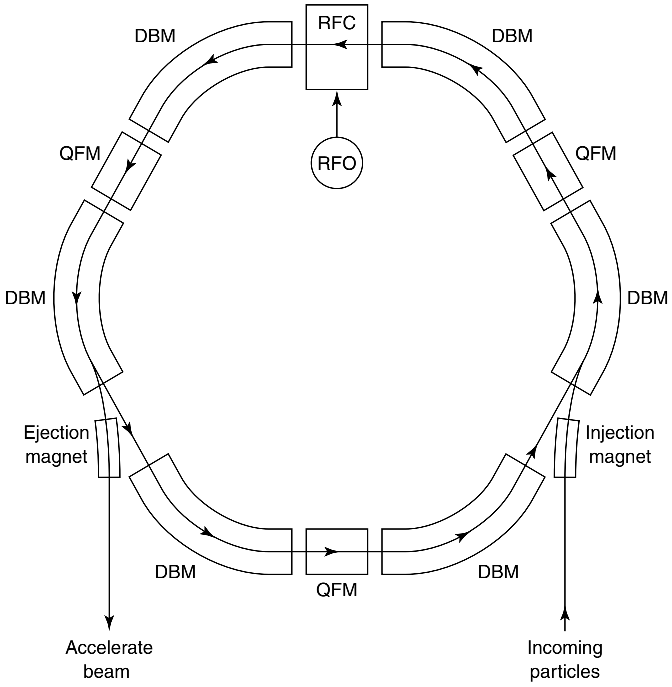

Fig. 4. Principle of synchrotron. One radio-frequency cavity (there may be several) provides a small “push” each time a particle passes through it. Unlike the linear accelerator, the synchrotron requires only one or few rf cavities. Dipole bending magnets keep the particles on their proper course. Focusing magnets keep the particles in a narrow beam, thus preventing undesired scattering. Particles enter the machine through an injection magnet and leave through an ejection magnet. DBM = dipole bending magnet; QFM = quadrupole focusing magnet; RFC = radio-frequency cavity; RFO = quadrupole focusing magnet; RFC = radio-frequency cavity; RFO = radio-frequency oscillator

The operation of a synchrotron is cyclic, i.e., a bunch of particles will be injected, with the bending magnets precisely adjusted to cause the particles to closely follow the curvature of the evacuated chamber. But, as the particles increase in energy, the field strength in the bending magnets must also be increased. Upon achieving their desired or maximum possible energy level, the particles are extracted—possibly going directly to bombard a target, or to supply an even more powerful synchrotron for further acceleration. When experiments with the first group or bunch of particles have been completed, the magnetic field is reduced to its original level, after which the next bunch or group of particles is added. The term *synchrotron* stems from the fact that the particles automatically synchronize their motion with the rising magnetic field and the rising frequency of the accelerating voltage. It is interesting to note that some accelerators (linacs or synchrotrons), which in their day may have been regarded as most powerful, may later be used as preliminary particle accelerators, as feeders to larger machines of later designs. Thus, instead of dismantling the older machines, in some cases the cost of a more powerful machine can be reduced. An example is shown in Fig. 5. Another example at CERN in Geneva, Switzerland will be cited later. Once the particles in a synchrotron have reached full energy, they are nudged out of their orbit by a special ejection magnet.

The linacs and synchrotrons described thus far are for use with *fixed targets*. The advantages of colliding-particle machines will be described shortly. What, then, are the reasons for continuing to bombard fixed targets? The fixed-target configuration provides the creation of a variety of

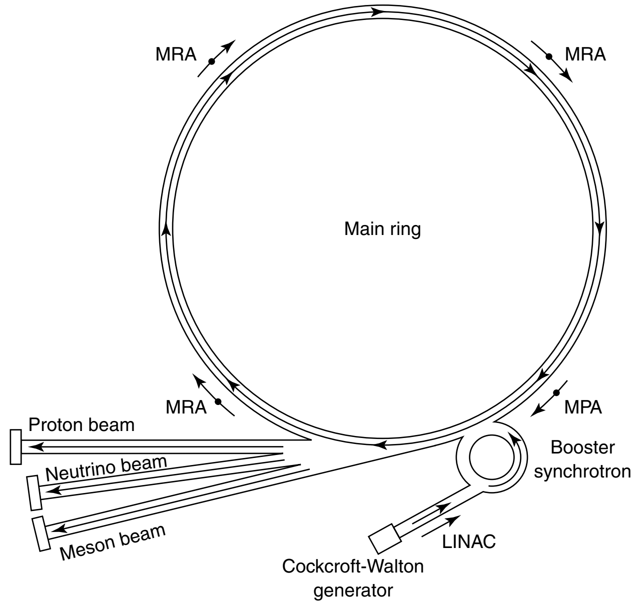

Fig. 5. An early fixed-target accelerator comprised of a large main-ring synchrotron with four stages of acceleration (MRA); a booster synchrotron; a linear accelerator (linac), and a Cockcroft-Walton generator. Protons are accelerated to 0.75 MeV in the Cockcroft-Walton generator; to 300 MeV in the linac; to 8 GeV in the booster synchrotron; and to 400–500 GeV in the main-ring synchrotron. Experiments are not limited to accelerated protons, but also can be conducted with beams of secondary particles (mesons and neutrinos) which are knocked out of the target by impacting protons

secondary beams (neutrinos, muons, pions and other mesons, antiprotons, and massive particles called hyperons). Fixed-target machines also are effective in furnishing particles to larger accelerators and storage rings. When particles are beamed at a fixed target, an interaction is assured. In contrast, since in a colliding-particle configuration the great majority of particles will simply pass each other without colliding, the number of events of interest may only occur at the rate of comparatively few per day.

Colliding-Particle Machines. As mentioned earlier, the effective beam energy essentially can be doubled when particles can be made to collide head-on with each other. This is shown dramatically by the graph of R.R. Wilson (1980) and given in Fig. 6. Wilson had made an effective comparison of the resolving power of an accelerator with that of a microscope. In a microscope, the ultimate limit to resolution is the wavelength of radiation that illuminates the specimen. Thus, a visual lightwave microscope is limited to distinguishing objects of 10^{-5} centimeter or larger. Since a particle can be described (quantum mechanics) as a wave, the wavelength is inversely proportional to the momentum of the particle. Thus, one objective in accelerator design is improvement of resolution by reduction of particle wavelength. The early large accelerators had an effective resolution of about 10^{-16} centimeter (1/1000 the diameter of the proton).

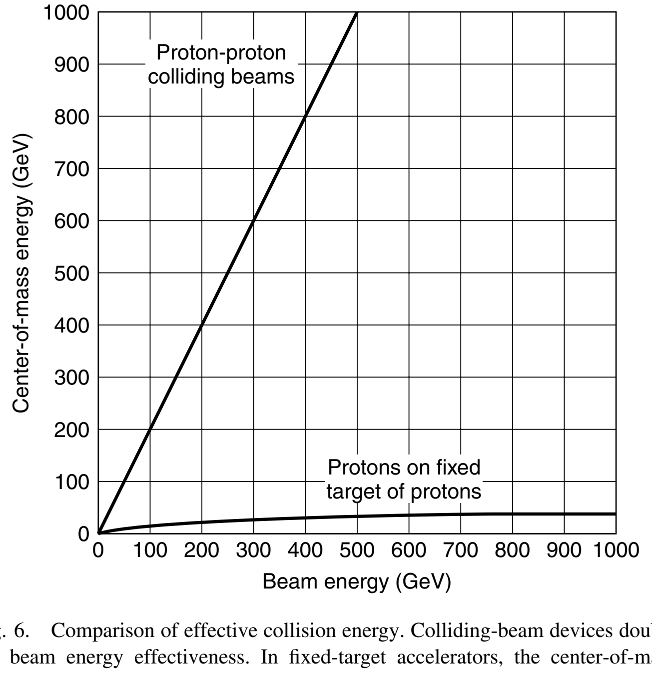

Fig. 6. Comparison of effective collision energy. Colliding-beam devices double the beam energy effectiveness. In fixed-target accelerators, the center-of-mass energy is proportional to the square root of the beam energy (at low energy) and at higher-energy levels, this rises even more slowly because of relativistic effects. (*After R.R. Wilson*)

When a particle and its antiparticle, such as an electron and a positron, or a proton and an antiproton, are used in head-on collision experiments, acceleration of the particles can be accomplished in one ring. This is because electrons and positrons, for example, behave in the same way in terms of their response to magnetic and electric fields. Thus, both particles can be injected into the same ring, one to follow an orbit in a clockwise direction; the other in a counterclockwise direction. Upon injection of a cluster of each type of particle, collisions occur at two points diametrically opposed. This arrangement provides maximum utilization of the equipment.

Other advantages of using a particle and its antiparticle, particularly the electron and the positron, is that when collisions occur, a less confusing splash of debris occurs.

When advantage of the single-ring, head-on collision approach cannot be taken, then *storage rings* are required. These rings are designed much like synchrotrons. Their primary purpose usually is not to accelerate the particles, but rather to maintain or "store" their energy while they continue to circulate in orbits in the ring. Just sufficient energy (usually furnished by a single radio-frequency cavity) is added to overcome losses, mainly due to synchrotron radiation. The storage rings are physically arranged tangentially to the main synchrotron ring so that precision transfer of particles from the storage rings to the main ring can be affected. Another concept was introduced in the early 1970s at the European CERN facility, where two interlaced rings that store counter-rotating proton beams are used. These rings cross over at eight points around their circumference. There are seven interaction zones that will accommodate detectors.

Scientists at the National Laboratories of the National Committee for Nuclear Energy (C.N.E.N.) at Frascati, Italy pioneered the first electron-positron ring in 1959. Each beam of the machine was 0.25 GeV and yielded a center-of-mass energy of 0.5 GeV. This ring was later moved to the Orsay laboratory outside Paris, France. The number of such rings grew quite rapidly.

Synchrotron Radiation

The electromagnetic radiation emitted as a result of continual acceleration toward the axis of rotation of charged particles moving in a magnetic field is generally known as synchrotron radiation because it was first observed during the operation of electron synchrotrons. The rate of emission of synchroton radiation varies with the fourth power of the particle energy, inversely with the radius of curvature, and inversely with the fourth power of the rest mass. Because of the rest mass relationship, no significant quantity of this radiation is formed from proton trajectories in magnetic fields, but an easily measurable loss of energy to synchrotron radiation occurs when electrons with high kinetic energies spiral through a magnetic field. Many microwave radiations observed in radio-astronomy measurements are believed to have been formed as synchrotron radiation.

At the beam energies that have been attained to date, synchrotron radiation is not a major factor in designing a proton accelerator, but it is the principal limitation on the energy of electron accelerators. Lessening the curvature of a synchrotron and thus increasing the circumference will reduce synchrotron radiation. For this reason, the radiation is practically negligible in a linear accelerator (linac). Synchrotron radiation energy loss in a storage ring must be made up by providing additional energy from one or more radio-frequency cavities. However, synchrotron radiation is not entirely wasted energy. The effect of the radiation is to damp out small excursions of the electrons away from their main trajectory, making a beam of electrons easier to control than a beam of protons.

Aside from its effects in high-energy experimentation, synchrotron radiation is of interest and value primarily as a source of tunable coherent x-rays. As summarized in a 1985 paper by Atwood, Halbach, and Kim

(Lawrence Berkeley Laboratory), a modern 1- to 2-billion-eV synchrotron radiation facility (based on high-brightness electron beams and magnetic undulators) would generate coherent, laser-like, soft x-rays of wavelengths as short as 10 angstroms. The radiation would also be broadly tunable and subject to full polarization control. Radiation with these properties could be used for phase- and element-sensitive microprobing of biological assemblies and material interfaces as well as research on the production of electronic microstructures with features smaller than 1000 angstroms. These short wavelength capabilities, which extend to the K-absorption edges of carbon, nitrogen, and oxygen, are neither available nor projected for laboratory XUV lasers. Higher-energy storage rings (5 to 6 billion eV) would generate significantly less coherent radiation and would be further compromised by additional x-ray thermal loading of optical components.

Much interest and limited application of synchrotron radiation by medical professionals appeared in the late 1980s. Synchrotron radiation is intense and its brilliance extends continuously over a broad bandwidth from infrared to hard x-rays. For example at the Stanford Synchrotron Radiation Laboratory, the output in the x-ray region is more than 100,000 times that of the most powerful x-ray tube. The natural collimation of synchrotron radiation can be monochromatized by different crystals and by adjusting the angle at which the crystal intercepts the radiation, the energy of the monochromatic beam can be selected. The tunability and intensity of the monochromatic radiation are currently making transvenous angiographic applications possible. See also **X-Ray Scan and Other Medical Imagery**.

Third-Generation Synchrotrons. The first run of experiments at the new, $500-million European Synchrotron Radiation Laboratory (ESRF), located in the DauphinÉ Alps, was scheduled to commence in the early 1990s. The facility will provide the brightest continuous x-rays in the world, but have been eclipsed by a new Japanese facility in the mid-1990s. The ESRF will generate x-rays two orders of magnitude more brilliant than any prior facility. Stronger x-ray sources are of an advantage to biologists, physicists, chemists, and other researchers because of their shortened exposure time and increased resolution. As pointed out by one American physicist who plans to use the facility, "We'll be able to get a picture in minutes, seconds, or fraction of a second and there will be much less specimen damage when the photons enter and leave a specimen in a millisecond."

A large variety of experiments was scheduled, representing numerous scientific disciplines. Another similar but slightly larger facility was scheduled for the Riso National Laboratory in Roskilde, Denmark, sometime in 1996.

The most powerful synchrotron now is at Harima Science Garden City, approximately 60 mi (96 km) west of Osaka, Japan. It will be known as the SPring-8 (Super Photon Ring-8 GeV). It is envisioned that it may be able to fulfill the x-ray crystallographer's dream—that is, x-ray holography. Hiromichi Kamitsubo, project head, states, "X-ray holography would enable the direct visualization, not just see complex x-ray diffraction patterns of the structure of materials—as if we were seeing them with a microscope." Three-dimensional holograms created in a photosensitive material require high-powered and coherent x-rays. The SPring-8 will have an energy rating of 8 GeV, with a main ring circumference of 4708 ft (1435 m) and 80 beam lines. Estimated cost is $1 billion.

Superconducting Super Collider (SSC)

As mentioned earlier, the ultimate fate of the SSC will be determined by economic and political factors. Generally, the scientific community in the United States and worldwide, in fact, looks to the SSC for important information on the structure of matter. Specific goals include:

(1) *The origin of mass.* As explained by Quigg and Schwitters, the current model of the weak interactions, previously mentioned, suggests that a similar situation may be realized in the universe. The field involved is not a magnetic field, but rather what is called a Higgs field. A major objective of the SSC will be to clarify the exact nature of the Higgs field and its interactions with other matter. It is currently assumed that the Higgs field pervades the universe because the total density is minimized in its presence. To change the magnitude of the field significantly (or to manifest one of its particles), sufficient energy density must be supplied to overcome an assumed natural tendency of the field to return to its normal universal background value. The energy levels of the SSC is expected to be sufficient for this.

(2) *Families of particles*. Quigg and Schwitters observe that one theoretical approach to understanding particle families postulates new symmetries under which different families are interchanged. A facet of this concept involves combining family symmetry and gage symmetries of the strong, weak, and electromagnetic interactions into one all-encompassing symmetry, but hidden by the presence of suitable background Higgs fields. Implementing such symmetries could lead to a new class of "family interactions" mediated by heavy bosons that may be created at the levels made possible by the SSC.

(3) *Chirality* (a peculiar asymmetry in the weak interactions of the observed quarks and leptons) can be investigated.

(4) *Supersymmetry* will be investigated, and may lead to unified field theories that include gravity.

(5) *Compositeness* is a characteristic of some particles initially investigated at CERN. Better understanding of the cosmos through SSC experiments is also envisioned. The SSC will make it possible to simulate the conditions that prevailed about 10^{-15} second after the primordial Big Bang explosion when the temperature of the universe was estimated about 10^{17} K.

All of the foregoing factors are explained in considerable detail in the Quigg and Schwitters reference listed.

The new accelerator complex will be based on the accelerator principles and technology that were developed for construction of the Fermilab Tevatron, coupled with extensive experience with superconducting magnets gained over the past two decades. The energy of the SSC will be equal to 20 times that of the Tevatron collider, with a total collision energy of 40 TeV. Racetrack in shape with a circumference of 87 km (52 mi), the SSC will utilize 10,000 helium-cooled superconducting magnets. The SSC will utilize an injector system consisting of a linear accelerator followed by two circular accelerators. The diameter of the main ring used in the final acceleration phase will be about 30 km (18.7 mi), depending upon details yet to be developed pertaining to the magnets that will be used to guide the protons. The superconducting magnet system will require many hundreds of miles of cryogenic plumbing, including several hundred thousand vacuum joints to assure the establishment and maintenance of superconductivity conditions. The linear dimensions of the SSC will be roughly 15 times those of the Tevatron and about 4 times those of the electron-positron collider being constructed by CERN. As suggested by Quigg and Schwitters (Fermi National Accelerator Laboratory) in a 1986 paper, technological fallout from construction of the SSC would include: (1) large-scale industrialization of superconducting wire fabrication and cryogenic refrigerator manufacture, making such technologies available to future power distribution and transportation systems; (2) improved tunneling techniques for future application to public works and transportation projects; (3) large-volume storage of helium, a potentially critical and nonrenewable resource; and (4) computer control and mechanical alignment systems extending over very large areas.

The SSC may furnish answers to critical scientific questions.

PARTICULATE MATTER. Solid or liquid matter that is dispersed in a gas, or insoluble solid matter dispersed in a liquid, that gives a heterogeneous mixture.

PASCHEN-BACK EFFECT. In a strong magnetic field, the anomalous Zeeman effect changes into a pattern similar to the normal effect, and this is known as the Paschen-Back effect. Each energy level with a given value of L, the electronic orbital angular momentum splits into $(2L+1)$ components characterized by the magnetic quantum numbers $M_L = L, L-1, \ldots, -L$, and each level with a given value of M_L splits into $(2S+1)$ components with quantum numbers $M_s = S, S-1, \ldots, -S$, where S is the resultant electron spin. The selection rules are $\Delta M_L = 0, \pm 1$, $\Delta M_s = 0$. Lines with $\Delta M_L = 0$ are plane polarized with electric vector parallel to the direction of the applied magnetic field; those with $\Delta M_L = \pm 1$ are plane polarized with components perpendicular to the field. See also **Atomic Spectra**; and **Hyperfine Structure**.

PASSIVITY. When iron is immersed in concentrated nitric acid, there is no visible reaction (Keir, 1790), although dilute nitric acid results in a marked reaction with iron. Upon removal of the iron from the concentrated nitric acid and immersion in copper sulfate solution, the iron is not plated by copper, although this occurs with ordinary iron. Iron in such a condition is described as passive iron, and the phenomenon is known as passivity. See also **Iron Metals, Alloys, and Steels**

PASTEURIZATION. Heat treatment of milk, fruit juices, canned meats, egg products, etc. for the purpose of killing or inactivating disease-causing organisms. For milk, the minimum exposure is 62°C for 30 min or 72°C for 15 sec, the latter being called flash pasteurization. Although this treatment kills all pathogenic bacteria and also inactivates enzymes that cause deterioration of the milk, the shelf life is limited. To prolong storage life, temperatures of 80–88°C for 20–40 sec must be used. Complete sterilization requires ultrahigh pasteurization at from 94°C for 3 sec to 150°C for 1 sec. In-can heating at 116°C for 12 min and 130°C for 3 min is also employed for maximum stability and long storage life. Some meat products are pasteurized by α-radiation.

See also **Milk and Milk Products**.

PASTEUR, LOUIS (1822–1895). Pasteur was a French chemist and microbiologist who made important contributions to biology, medicine, chemistry, and industry.

As a small child, Pasteur showed traits of becoming a scientist. He was fascinated by the local chemist, that made medicine for sick customers. He patiently and carefully observed the things the chemist did and then went home and made drawings of the herbs and roots the man used. Even before finishing high school, Pasteur's study of chemical crystals won attention of the scientific world. Most of what Pasteur is famous for is his work concerning the effects of microbes. He found that living organisms, microbes, cause fermentation. His discovery was important both for theoretical science and for industry. Pasteur's studies showed microbes could be killed by heat. His discovery made winemaking a more scientific process. Pasteur applied the same idea to milk. The process of keeping milk free from bacteria is named pasteurization after him.

During the 1800s the theory of spontaneous generation was raging in the scientific circles. Pasteur's work proved that food and other organic matter does not spontaneously generate microbes and settled the controversy.

Pasteur also discovered a vaccine to prevent rabies and another vaccine to prevent anthrax. Pasteur's greatest achievement was the founding of the science of microbiology.

See also **Fermentation**.

J.M.I.

PATENTABILITY. The qualifications for obtaining a patent on an invention of chemical process. These are (1) the invention must not nave been published in any country or in public use in the U.S., in either case for more than 1 year before the date of filing the application; (2) it must not have been known in the U.S. before date of invention by the applicant; (3) it must not be obvious to an expert in the art; (4) it must be useful for a purpose not immoral and not injurious to the public welfare; (5) it must fall within the five statutory classes on which patents may be granted, i.e., (a) composition of matter, (b) process of manufacture or treatment, (c) machine, (d) design (ornamental appearance), or (e) a plant produced asexually. Special regulations relate to atomic energy developments and subjects directly affecting national security (Robert Calvert). Note: In 1980, the Supreme Court in al landmark decision upheld the patentability of synthetic bacteria created by recombinant DNA techniques.

PATERNO-BUCHI REACTION. Formation of oxetanes by photochemical cycloaddition of carbonyl compounds to olefins.

PATHFINDER ELEMENT. An element present in small proportions less than 1% generally metallic in nature, associated with ore deposits at the time of formation. Mapping of the concentration variation of the selected element serves to locate the main ore deposit. Examples are zinc as the pathfinder for lead, copper, and silver ores, and molybdenum associated with copper deposits.

PATHWAY. A sequence of reactions, usually of a biochemical nature, in which more-complex substances are converted to simple end products, as in the degradation of the components of foods to carbon dioxide and water. Its course is determined largely by preferential factors involving coenzymes and other catalysts. An example is the TCA cycle, which is the common pathway in the degradation of foodstuffs and cell constituents to carbon dioxide and water.

PATINA. Variously used to refer to an ornamental and/or corrosion-resisting film on the surface of copper, copper alloys, including bronzes, and also sometimes iron and other metals. Such a film is formed by exposure to the air or by a suitable chemical treatment.

See also **Copper**.

PATTINSON PROCESS. Process for the removal of silver from lead. The silver-lead mixture is melted in one of a series of pots and allowed to cool slowly. The lead, that is free from silver or poorer in silver separates out as crystals, which are removed, leaving the silver-rich lead in the molten state. From a number of such operations in series, a lead rich in silver is obtained, collected, and the silver recovered.

See also **Parkes Process**.

PAULI EXCLUSION PRINCIPLE. The statement that any wave function involving several identical particles must be antisymmetric (must change sign) when the coordinates, including the spin coordinates, of any identical pair are interchanged. If the particles in a system can be considered as occupying definite quantum states, it follows from the principle that no more than one particle of a given kind can occupy a particular state; hence the name, exclusion principle. The principle applies to fermions, but not to bosons. Since electrons, protons, and neutrons are fermions, the Pauli exclusion principle must be used in the assignment of particles to quantum states in theories of atomic and nuclear structure.

PAULING, LINUS CARL (1901–1994). Dr. Linus Pauling was a famous American chemist. He was born in Portland, Oregon and his father was a pharmacist. When he was four, his family moved to Condon, Oregon. On the south edge of town, there was a creek and Pauling sent much time exploring the creek bed and collecting minerals. Eventually Pauling would establish structures for these minerals at the California Institute of Technology.

Pauling enrolled in Oregon Agricultural College (Oregon State University) and was majoring in chemical engineering, but when his mother became ill, he quit school and began working. Because he had show outstanding promise, he was offered a position to be an instructor of quantitative analysis at the college. He taught the class and graduated with a degree in chemical engineering. He attended Cal Tech graduate school. His Ph.D. dissertation was on the crystal structure of different minerals. Pauling received a Guggenheim fellowship to study at the University of Munich where he began applied the concept of quantum mechanics to chemical bonding. Then he took an assistant professorship in chemistry at Cal. Tech and published his paper "The Nature of the Chemical Bond." In 1931, he received the Langmuir Prize of the American Chemical Society for his noteworthy work. In 1933, he was made a member of the National Academy of Sciences. He was 32 years old at that time and he was the youngest appointment ever made.

His serious interest molecular biology began about 1935. He was intrigued by the question of how protein molecules were constructed. As a professor at the California Institute of Technology, he was known for giving "baby toy lectures" because he made models of molecules out of string, rod- and-ball structures, and plastic bubbles in different colors, shapes, and sizes. One day, working with paper, he sketched atoms and chemical bonds and folded them in different ways and discovered the basic structure of the protein molecule.

Pauling, with the help of C.D. Coryell, analyzed the effects of the oxygenation of hemoglobin molecules by measuring their magnetic susceptibility. In 1936, along with A.E. Mirsky, Pauling developed a theory of native, denatured, and coagulated proteins. And in 1950, he and R.B. Corey described the structure of several molecules including muscles, fingernails, hair, and other tissues.

During World War II, Pauling chose not to work on the Manhattan Project for the development of the atomic bomb. He became worried about the radiation the atomic bomb produced and helped organize the Pasadena Federation of Atomic Scientists, a group of scientists working for safe control of nuclear power. He also joined the Emergency Committee of Atomic Scientists, known as the Einstein Committee since it was chaired by Albert Einstein. The aim of the committee was to educate people about atomic weapons. In 1947, he was awarded the presidential Medal of Merit by President Truman for his work on crystal structure, nature of chemical bond, and his efforts to bring about world peace.

In 1954, Pauling received the Nobel Prize in chemistry for his research into the nature of the chemical bond and its application to the elucidation of the structure of complex substances. On October 10, 1962 he was awarded the Nobel Peace Prize for his efforts towards nuclear test ban treaty.

Pauling, in recent years, researched the chemistry of the brain and mental illness, the cause of sickle-cell anemia, and the effects of large doses of Vitamin C on the common cold and on cancer. On August 19, 1994, Pauling, himself, died of cancer at the age of 93.

J.M.I.

PAULI, WOLFGANG ERNST (1900–1958). Pauli was an Austrian theoretical physicist. After WWII, he became an American citizen. When just 20 years of age he wrote "The Theory of Relativity." Later he wrote articles on "Quantum Theory" and "Principles of Wave Mechanics." He is most remembered for formulating the "Pauli exclusion principle". This principle says that two electrons in an atom can never exist in the same state. This is important concept for modern physics. Pauli was awarded the Nobel Prize in physics in 1945 for this discovery.

See also **Pauli Exclusion Principle**; and **Quantum Mechanics**.

J.M.I.

PCB. See **Biphenyl and Terphenyls**.

PEARSON'S SOLUTION. A dilute sodium arsenate solution containing 0.1% anhydrous sodium arsenate.

PEAT. Semicarbonized residue of plants formed in water-saturated environments (bogs and marshes). It occurs in surface layers 3–10 ft thick and has a water content of 85%. Before peat can be used for chemical or fuel purposes it must be field-dried to a water content of 30–40%. Since the dried product is susceptible to autoignition, storage conditions must minimize this risk. Peat is easily converted to hydrocarbons and is an excellent source of natural gas; when dry it can be used directly as a fuel. The U.S. has peat sources second only to those of the former U.S.S.R., located in Alaska, the north-central states, and Maine, where processing on a large scale is planned. Their total energy content is said to be equivalent to 240 billion barrels of petroleum. The peat can be gasified for production of methanol after mechanical dewatering. Experimental conversion studies have been under way for some time. Substantial quantities of oil, ammonia, and sulfur can be obtained as by-products. See also **Coal**.

PEBBLE MILL. A jacketed steel cylinder rotating on a horizontal axis and containing flint or porcelain pebbles as the grinding medium. Its operation is similar to that of a ball mill. It is used for grinding and mixing of dry chemicals, pigments, food products, and the like. Pebble mills are usually lined with alumina, buhrstone, or similar material to protect the walls from wear.

PECHMANN PYRAZOLE SYNTHESIS. Formation of pyrazoles from acetylenes and diazomethane. The analogous addition of diazoacetic esters to the triple bond yields pyrazolecarboxylic acid derivatives.

PECTINS. A *pectic substance* is a group designation for those complex carbohydrate derivatives that occur in or are prepared from plants and contain a large proportion of anhydrogalacturonic acid units, which are thought to exist in a chainlike combination. The carboxyl groups of polyglacturonic acids may be partially esterified by methyl groups and partly or completely neutralized by one or more bases. The general term *pectin* (or *pectins*) designates those water-soluble pectinic acids of varying methyl ester content and degree of neutralization which are capable of forming gels with sugar and acid under suitable conditions. The term *protopectin* is applied to the water-insoluble parent pectic substances which occur in plants and which upon restricted hydrolysis yield pectin or pectinic acids. *Pectic acids* is a term that is applied to pectic substances mostly composed of colloidal polyglacturonic acids and essentially free from methyl ester groups. The salts of pectic acids are either normal or acid *pectates*. The term *pectinic acids* is used for colloidal polygalacturonic acids containing more than a negligible proportion of methyl ester groups. Pectinic acids, under suitable conditions, are capable of forming gels with sugar and acid, or, if suitably low in methosyl content, with certain metallic ions. The salts of pectinic acids are either normal or acid *pectinates*.

Pectins occur commonly in plants, particularly in succulent tissues, and are characterized by the polygalacturonic acids that are fundamental to their structure. The pectins are important emulsifying, gelling, stabilizing, and thickening agents used in the preparation of numerous food products. About 75% of the pectins produced are used in making fruit jams, jellies, marmalades, and similar products. Additional uses include the preparation of mayonnaise, salad dressings, malted milk beverages, frozen dessert mixes, and frozen fruits and berries (to prevent leakage upon thawing), among others. The addition of a dilute pectin solution to milk coagulates the casein. In many food products, the use of pectins as stabilizers is preferred, since they blend better into the flavor complex than do many gums, starches, or a number of carbohydrate derivatives. Pectin jellies do not melt at temperatures below 49°C, a distinct advantage over gelatin gels that require refrigeration. Pectins also have a number of nonfood uses, including pharmaceuticals and cosmetics.

The location of various pectin substances in plant tissues is well established. Pectins make up most of the middle lamella in unripe fruit and are to be found in the cell walls and in small proportion in all plant tissues. The genesis and fate of pectins in plant tissues have not been fully determined.

Citrus peel, apple pomace from juice manufacture, and beet pulp left over from the manufacture of sucrose are common commercial sources of pectins. After some preliminary purification of the raw material, the extraction is usually performed with hot dilute acid (pH = 1.0–3.5 in a temperature range of 70–90°C). The pectin is then precipitated from the extract with ethanol or isopropanol, or with metal salts (copper or aluminum). The metal ions have to be subsequently removed by washing

with water or acid ethanol. Specific formulas for denatured ethanol for use in pectin manufacture are used. The precipitates are purified, dried, and pulverized to form the yellowish-white powder of commerce.

Pectin substances in solution behave as typical colloids. See also **Colloid Systems**. Dry, purified pectins are light in color and soluble in hot water to the extent of 2–3%. The pH of pectin solutions is usually 2–3.5.

The proportion of sugar which pectin will form into a firm jelly determines the *jelly grade* of the pectin. In a jelly, jam, or marmalade, the proportions of total solids of sugars, the pH, and the proportion and nature of the pectin used will determine the extent of jellification obtained. The use of pectin in fruit jams and related products is approved by most food regulators because the addition is believed to compensate for an incidental natural deficiency.

In pectic acids, all carboxyl groups are free, or at least not present as the methyl ester. Under suitable conditions, pectins will form jellies with sugar and acid, whereas the low-ester pectins will form *gels* with traces of polyvalent ions. The general structure of pectin is:

PEDERSEN, CHARLES JOHN (1904–1989). An American born in Korea, Pedersen received a M.S. from M.I.T. in 1927. In 1987 he was awarded the Nobel Prize for Chemistry for his work in elucidating mechanisms of molecular recognition, which are fundamental to the enzymic catalysis, regulation and transport. He reported that alkali metal ions could be bound by crown ethers into a more rigid, layered structure, in which the alkali metal ion was bound into the center of the ring. This field of study is called host-guest chemistry.

PEGMATITE. The term *pegmatite*, derived from the Greek word meaning "joined together," was first applied by Haüy in 1822 to a peculiar interpenetrating growth of quartz and feldspar sometimes called graphic granite from its resemblance to written characters, particularly those of the Hebrew language. Pegmatite is also used to designate those coarse-grained dikes and sheets, chiefly of granite or syenite, that are apophyses of stocks or batholiths, or of the residual magma, during their congelation. The individual minerals may often reach great size. Granite pegmatites are chiefly composed of alkali feldspar and quartz with some muscovite or biotite but may carry such minerals as tourmaline, topaz, beryl, fluorite, apatite, garnet, lepidolite, etc. See also **Mineralogy**.

PELLET. A small unit of a light, bulky material compressed into any of several shapes and sizes, usually either spherical of rectangular. The operation is performed on a pellet mill, which consists essentially of a pair of steel rollers around which rotates a circular perforated metal die. Material is fed into the chambers above and below the inner face of the die. As the die turns, in contact with the rollers, the latter also turns, thus compressing the material and forcing it through the holes in the die at the point of tangency, where the extruded segment is sheared off by knives. Pelletizing is advantageous for fluffy particulates that are difficult to handle in loose form, e.g., carbon black, clays, plastic molding powders, etc. Binding materials called excipients are often used.

PELLIZZARI REACTION. Formation of substituted 1,2,4-triazoles by the condensation of amides and acylhydrazines. When the acyl groups of the amide and acylhydrazine are different, interchange of acyl groups may occur, with formation of a mixture of triazoles.

PELOUZE SYNTHESIS. Formation of nitriles from alkali cyanides by alkylation with alkyl sulfates of alkyl phosphates.

PENETRANT. Any agent used to increase the speed and ease with which a bath or liquid permeates a material being processed by effectively reducing the interfacial tension between the solid and liquid. Penetrants are widely used in the textile, tanning, and paper industries for improving dyeing, finishing, etc., operations. Sulfonated oils, soluble pone oils, and soaps are popular among the older penetrants, and the salts of sulfated higher alcohols are typical of the synthetic organics developed for this purpose.

See also **Wetting Agent**.

PENICILLIN. See **Antibiotics**.

PENNING DISCHARGE. A direct-current discharge where electrons are forced to oscillate between two opposed cathodes and are restrained from going to the surrounding anode by the presence of a magnetic field. It is sometimes referred to as a pig discharge since the device was originally used as an ionization gage (Penning ionization gage). It is used as a plasma-beam source by permitting the plasma to stream out along the magnetic field through a hole in one of the cathodes.

PENNING EFFECT. An increase in the effective ionization rate of a gas due to the presence of a small number of foreign metastable atoms. For instance, a neon atom has a metastable level at 16.6 volts and if there are a few neon atoms in a gas of argon which has an ionization potential of 15.7 volts, a collision between the neon metastable atom with an argon atom may lead to ionization of the argon. Thus, the energy which is stored in the metastable atom can be used to increase the ionization rate. Other gases where this effect is used are helium, with a metastable level at 19.8 volts, and mercury, with an ionization level at 10.4 volts.

PENTAERYTHRITOL TETRANITRATE (PETN). See **Explosives**.

PENTLANDITE. The mineral sulfide of iron and nickel corresponding to the formula $(Fe, Ni)_9S_8$. It is isometric, appears in granular masses; hardness, 3.5–4; specific gravity, 5.0; color, bronze-yellow; opaque. Occurs with pyrrhotite, millerite, and nickeline. The best known deposit of pentlandite is at Sudbury, Ontario, Canada, where it is associated with a nickel-bearing pyrrhotite

PENTOSAN. A complex carbohydrate (hemicellulose) present with the cellulose in many woody plant tissues, particularly cereal straws and brans, characterized by hydrolysis to give five-carbon-atom sugars (pentoses). Thus the pentosan xylan yields the sugar xylose ($HOH_2C{\bullet}CHOH{\bullet}CHOH{\bullet}CHOH{\bullet}CHO$) that is dehydrated with sulfuric acid to yield furfural ($C_5H_4O_2$).

See also **Carbohydrates**.

PENTOSE PHOSPHATE CYCLE. See **Carbohydrates**.

PEPTIZATION. Stabilization of hydrophobic colloidal solutions by addition of electrolytes which provide the necessary electric double layer of ionic charges around each particle. Such electrolytes are known as peptizing agents. The ions of the electrolyte are strongly adsorbed on the particle surfaces. Stable solutions of nonionizing substances acquire a charge in contact with water by preferential adsorption of the hydroxyl ions, which may be considered peptizing agents. The term is also loosely applied to the softening or liquefaction of one substance by trace quantities of another, analogous to the digestion of a protein by an enzyme (pepsin).

PEPTONE. A secondary protein derivative that is water-soluble, not coagulated by heat, and not precipitated on saturation of its solutions with ammonium sulfate.

PERCHLORIC ACID AND PERCHLORATES. When in a +7 valence state and combined with oxygen, chlorine forms a family of

compounds known as the perchlorates. The perchlorate anion, ClO_4^-, as progenitor is derived from perchloric acid. [CAS: 7601-90-3]. $HClO_4$ is one of the strongest of the mineral acids. The perchlorates are more stable than the other chlorine oxyanions, i.e., chlorates, ClO_3^-; chlorites, ClO_2^-; or hypochlorites, OCl^-. See also **Hypochlorites**. Essentially, all of the commercial perchlorate compounds are prepared either directly or indirectly by electrochemical oxidation of chlorine compounds. The perchlorates of practically all the electropositive metals are known, except for a few cations having low charges.

The most outstanding property of the perchlorates is their oxidizing ability. On heating, these compounds decompose into chlorine, chlorides, and oxygen gas. Aqueous perchlorate solutions exhibit little or no oxidizing power when dilute or cold. However, hot concentrated perchloric acid is a powerful oxidizer and whenever it contacts oxidizable matter extreme caution is required. The acidified concentrated solutions of perchlorate salts must also be handled with caution. Ammonium perchlorate (AP), [CAS: 7790-98-9], is one of the most important perchlorates owing to its high (54.5%) O_2 content and the absence of residue on decomposition. These properties, along with a long shelf life, make it a useful rocket propellant. See also **Rocket Propellants**.

Actual perchlorate production is difficult to determine in any given year, because AP is classified as a strategic material. Future production is expected to depend mostly on space programs.

Properties

Chlorine Heptoxide. The anhydride of perchloric acid is chlorine heptoxide. [CAS: 10294-48-1]. Cl_2O_7 is also known as dichlorine heptoxide. It is obtained as a colorless oily liquid by dehydration of perchloric acid using a strong dehydrating agent such as phosphorus pentoxide, P_2O_5.

$$2\ HClO_4 + P_2O_5 \longrightarrow Cl_2O_7 + 2\ HPO_3 \qquad (1)$$

The Cl_2O_7 decomposes spontaneously on standing for a few days. The acid dehydration reaction requires a day for completion at −10°C and explosions can occur. Upon ozonation of chlorine or gaseous ClO_2 at 30°C, Cl_2O_7 is formed.

Chlorine heptoxide is more stable than either chlorine monoxide or chlorine dioxide; however, the Cl_2O_7 detonates when heated or subjected to shock. It melts at −91.5°C, boils at 80°C, has a molecular weight of 182.914. It is soluble in benzene, slowly attacking the solvent with water to form perchloric acid; it also reacts with iodine to form iodine pentoxide and explodes on contact with a flame or by percussion. Reaction with olefins yields the impact-sensitive alkyl perchlorates.

Perchloric Acid. Pure anhydrous perchloric acid, $HClO_4$, is quite unstable. In aqueous solution, however, $HClO_4$ is a familiar and useful reagent. The acid is the strongest simple acid and the perchlorate ion the least polarizable negative ion known. Perchloric acid is commonly obtained as an aqueous solution, although the pure anhydrous compound can be prepared by vacuum distillation as a colorless liquid, which freezes at −112°C and boils at 16°C at 2.4 kPa (18 mm Hg) without decomposition. The pure acid cannot be distilled at ordinary pressures and explodes at 90°C after standing at room temperature for 10–30 days. The aqueous solution can be concentrated by boiling at 101 kPa (1 atm) at 203°C, at which point an azeotropic solution is attained which contains 72.4% $HClO_4$.

A number of hydrates of perchloric acid, $HClO_4 \bullet nH_2O$, where $n = 1$, 2, 2.5, 3, and 3.5, are known. These are commonly referred to as the hydronium or oxonium perchlorates, $H_3O^+ClO_4^-$, because of the analogy between the x-ray patterns of these species and ammonium perchlorate.

The combination of oxidizing effect, acidic strength, and high solubility of salts makes perchloric acid a valuable analytical reagent. It is often employed in studies where the absence of complex ions must be ensured.

Ammonium Perchlorate. Ammonium perchlorate is a colorless, crystalline compound having a density of 1.95 g/mL and a molecular weight of 117.5. It is prepared by a double displacement reaction between sodium perchlorate and ammonium chloride, and is crystallized from water as the anhydrous salt. The perchlorates, especially those of the light metals and ammonium ion, are favored as solid oxidizers for rocket propellants.

A newer approach developed for producing commercial quantities of high purity AP involves the electrolytic conversion of chloric acid, [CAS: 7790-93-4] to perchloric acid, which is neutralized by using ammonia gas:

Alkali Metal Perchlorates. The anhydrous salts of the Group 1 (IA) or alkali metal perchlorates are isomorphous with one another as well as with ammonium perchlorate. Crystal structures have been determined by optical and x-ray methods. With the exception of lithium perchlorate, the compounds all exhibit dimorphism when undergoing transitions from rhombic to cubic forms at characteristic temperatures. Potassium perchlorate, [CAS: 7778-74-7]. $KClO_4$ is discovered, is used in pyrotechnics and has the highest percentage of oxygen (60.1%).

The alkali metal perchlorates are either white or colorless, and have increasing solubility in water in the order of $Na > Li > NH_4 > K > Rb > Cs$. The high solubility of sodium perchlorate, $NaClO_4$, makes this material useful.

Group 11 (IB) Perchlorates. Copper and silver perchlorates have been studied quite extensively. Copper(I) perchlorate, [CAS: 17031-33-3], $CuClO_4$, and copper(II) perchlorate, [CAS: 13770-18-8], $Cu(ClO_4)_2$, form a number of complexes with ammonia, pyridine, and organic derivatives of these compounds. The copper perchlorate is an effective burn-rate accelerator for solid propellants.

Gold forms organic perchlorate, [CAS: 42774-61-8], complexes as well as complexes with silver, e.g., $(C_6H_5)_3AgAu(C_6F_5)_2ClO_4$.

Alkaline-Earth Perchlorates. Anhydrous alkaline-earth metal perchlorates can be prepared by heating ammonium perchlorate in the presence of the corresponding oxides or carbonates. The alkaline-earth perchlorates are unusually soluble in organic solvents.

Group 12 (IIB) Perchlorates. The zinc perchlorate, [CAS: 13637-61-1], cadmium perchlorate, [CAS: 13760-37-7], mercury(I) perchlorate, CAS: 13932-02-0, and mercury(II) perchlorate, [CAS: 7616-83-3], all exist.

Group 13 (IIIA) Perchlorates. Perchlorate compounds of boron and aluminum are known. Boron perchlorates occur as double salts with alkali metal perchlorates. Aluminum perchlorate, [CAS: 14452-95-3], $Al(ClO_4)_3$, forms a series of hydrates.

Group 3 (IIIB) and Inner Transition-Metal Perchlorates. The rare-earth metal perchlorates of yttrium and lanthanum have been reported, as have tetravalent cerium perchlorate, [CAS: 14338-93-3], $Ce(ClO_4)_4$, and uranium perchlorate.

Group 14 (IVA) Perchlorates. Perchlorates containing organic carbon have been reported, as have diazonium perchlorates, oxonium perchlorates, and the perchlorate esters. Extreme caution must be used in working with organic perchlorates; many decompose violently when heated, contacted with other reagents, or subjected to mechanical shock.

Group 4 (IVB) Perchlorates. Titanium tetraperchlorate, [CAS: 13498-15-2], is known.

Group 15 (VA) Perchlorates. Nitrogen perchlorates have been used as oxidizers in rocket propellants. Hydrazine perchlorate, [CAS: 13762-80-6], $NH_2NH_3ClO_4$, and hydrazine diperchlorate, $ClO_4NH_3NH_3ClO_4$, have been investigated as oxidizers for propellant systems.

Other Group 15 perchlorates include nitronium perchlorate, NO_2ClO_4, also called nitryl or nitroxyl perchlorate; nitrosyl perchlorate, [CAS: 15605-28-4], $NOClO_4$; and phosphonium perchlorate, $P(OH)_4ClO_4$.

Group 5 (VB) Perchlorates. Vanadyl perchlorate, [CAS: 67632-69-3], $VO(ClO_4)_3$, has been prepared.

Group 16 (VIA) Perchlorates. A perchlorate compound perchloryl sulfate, [CAS: 43059-05-8], $SO_4(ClO_4)_2$ was produced by the low temperature electrolysis of a 12-N H_2SO_4 and 3-N $HClO_4$ solution. This compound is a strong oxidizer; reaction with toluene, acetone, benzene, or alcohol at room temperature produces an exothermic and explosive reaction. The $SO_4(ClO_4)_2$ is soluble in Freon and CCl_4 without reaction.

Group 6 (VIB) Perchlorates. Both divalent and trivalent chromium perchlorate compounds, [CAS: 13931-95-8]; [CAS: 13527-21-9], have been reported. Chromyl perchlorate has been suggested for a gas-generating system operating at −45°C.

Group 17 (VIIA) Perchlorates. Fluorine perchlorate, [CAS: 37366-48-6], $FClO_4$, is formed by action of elemental fluorine and 60–70% aqueous perchloric acid solution. The compound is normally a gas. It melts at −167.5°C and boils at −15.9°C. It is extremely reactive and explosive in all states.

The perchloryl fluoride, [CAS: 7616-94-6], $FClO_3$, the acyl fluoride of perchloric acid, is a stable compound. Normally a gas having a melting point of −147.7°C and a boiling point of −46.7°C, it can be prepared by electrolysis of a saturated solution of sodium perchlorate in anhydrous

hydrofluoric acid. Some of its uses are as an effective fluorinating agent, as an oxidant in rocket fuels, and as a gaseous dielectric for transformers.

Other Transition Element Perchlorates. Both divalent and trivalent manganese perchlorate compounds, [CAS: 13770-16-6]; [CAS: 13498-03-8] are known. Perchlorates of Fe, Co, Ni, Rh, and Pd have been produced as colored crystals.

Manufacture

Perchloric Acid. Several techniques have been employed in the manufacture of perchloric acid, including thermal decomposition of chloric acid, anodic oxidation of chloric acid, irradiation of chlorine dioxide solutions, electrolysis of hydrochloric acid, oxidation of hypochlorites by ozone, ion exchange, and electrodialysis of perchlorate salts.

Perchlorates. Historically, perchlorates have been produced by a three-step process: (1) electrochemical production of sodium chlorate; (2) electrochemical oxidation of sodium chlorate to sodium perchlorate; and (3) metathesis of sodium perchlorate to other metal perchlorates. The advent of commercially produced pure perchloric acid directly from hypochlorous acid means that several metal perchlorates can be prepared by the reaction of perchloric acid and a corresponding metal oxide, hydroxide, or carbonate.

Shipping and Handling

Perchloric acid and perchlorates are classified as strong oxidizers and emit toxic fumes when decomposed; contact with combustible, flammable, or reducing materials must be avoided. Perchloric acid and perchlorates must be shipped in accordance with the U.S. Department of Transportation hazardous material regulations. Handling these compounds requires the procedures and safety precautions specified by the product supplier. Perchlorates contain a self-sustaining source of oxygen, thus fires involving perchlorates must be extinguished with water. A class of more hazardous compounds is formed by mixing inorganic perchlorates with finely divided metals, sulfur, or organic compounds and must be handled with the same precautions as explosives.

Economic Aspects

Anhydrous perchloric acid is not sold commercially. Aqueous solutions of perchloric acid are sold at low concentrations for analytical standard applications and at concentrations up to 70%. The price for 70% perchloric acid varies and starts at $2.70/kg, depending on the quantity and level of impurities. The U.S. domestic capacity of ammonium perchlorate is roughly estimated at 31,250 t/yr. The actual production varies, based on the requirements for solid propellants. Environmental effects of the decomposition products, which result from using solid rocket motors based on ammonium perchlorate-containing propellants, are expected to keep increasing public pressure until consumption is reduced and alternatives are developed. Approximately 450 t/yr of NH_4ClO_4-equivalent cell liquor is sold to produce magnesium and lithium perchlorate for use in the production of batteries.

Uses

Perchloric acid is used in analytical chemistry for the determination of trace metal constituents in oxidizable substances as well as in the production of high purity metal perchlorates; it has also been introduced as a stable reaction media in the thermocatalytic production of chlorine dioxide. Perchlorates are primarily used in ammonium perchlorate as an oxidizer in the formulations of propellant for solid rocket motors. Perchlorates are used in the production of explosives, pyrotechnics, and in solid, slurried, and gelled blasting formulations. Both magnesium and lithium perchlorates are used in dry batteries. Other perchlorates have found application in oxygen-generation systems, adhesive bonding of steel plates, and the recovery of potassium from brines such as $KClO_4$.

PERFECT GAS. A perfect gas may be defined by the following two laws: The Joule law: the energy per mole, U, depends only on the temperature; the Boyle law: at constant temperature, the volume V occupied by a given number of moles of gas varies in inverse proportion to the pressure.

By combination of these two laws we obtain the equation of state for perfect gas:

$$pV = nRT \tag{1}$$

where R is the gas constant, T, the absolute temperature. (It is also called the *perfect gas law.*)

The perfect gas is an abstraction to which any real gas approximates according to the nature of the gas and the conditions. For a given temperature and composition, the perfect gas condition is approached when the density tends to zero. From a molecular point of view, the perfect gas laws correspond to the behavior of a system of molecules whose interactions may be neglected in expressing the thermodynamic equilibrium properties. However, even at a low density, the transport properties depend essentially on the interactions.

The thermodynamic properties of a perfect gas are, of course, especially simple. For example, the difference between the molar heat capacities at constant pressure and constant volume is equal to the gas constant R,

$$C_p = C_v = R \tag{2}$$

The value of R is 0.08205 liter-atm. degree^{-1} mole^{-1}, which in cgs units is equal to 8.314×10^7 $\text{g cm}^2\,\text{sec}^{-2}$ degree^{-1} mole^{-1}. This relationship, Formula (2), applies only approximately to real gases.

However, the way in which either C_p or C_v depends on the temperature can be calculated only from statistical mechanics.

PERFUME. A blend of pleasantly odorous substances (usually liquids) obtained from the essential oils of flowers, leaves, fruit, roots, or wood of a wide variety of plants, either by steam distillation or solvent extraction. Flower oils (rose, jasmine) are extracted with a nonpolar solvent to give a waxy mixture called a *concrete*; the wax is then removed by a second solvent (an alcohol), which is then in turn removed to form an absolute. It is necessary that all the solvent be eliminated to obtain the finest perfumes. The center of this industry has long been in Grasse, France. Perfume materials are also derived from animal sources (musk, ambergris) and from resinous extracts (terpenes and balsams); they are also made synthetically. Cologne and toilet water are weak alcoholic solutions (5% or Less) of perfumes. Fine perfumes may contain as many as 30 ingredients, and their blending is an art rather than a science. The largest volume use of perfumes is in soaps, lotions, shaving creams, and cosmetics.

See also **Odorant**.

PERIDOTITE. The term peridotite is derived from peridor, the French word for olivine.

It is a coarse-grained igneous rock related to gabbro, which consists of olivine and pyroxene in varying proportions. Certain peridotites contain spinel, chromite, or mica as accessories.

Rocks consisting essentially of olivine alone are known as dunites, the name coming from the occurrence of this rock in the Dun mountains of New Zealand. In the United States, this mineral is found in North Carolina, South Carolina, and Georgia, where corundum is associated with the dunite in commercial quantities. The olivine of peridotites alters readily to the mineral serpentine, often to such an extent that the rock itself is called a serpentine. As mentioned above, the peridotites may contain chromite or other valuable minerals, often to such an extent that they may be commercially exploited, for nickel, platinum, and precious garnet.

Kimberlite from which diamonds are secured is commonly called a mica peridotite but is more closely related to the lamprophyres. See also **Kimberlite**.

PERIODIC LAW. Originally stated in recognition of an empirical periodic variation of physical and chemical properties of the elements with atomic *weight*, this law is now understood to be based fundamentally on atomic *number* and atomic *structure*. A modern statement is; the electronic configurations of the atoms of the elements vary periodically with their atomic number. Consequently, all properties of the elements that depend on their atomic structure (electronic configuration) tend also to change with increasing atomic number in a periodic manner.

PERIODIC TABLE OF THE ELEMENTS. When the chemical elements are arranged in a matrix on the basis of increasing atomic numbers, a pattern of periodicity among the physical and chemical characteristics emerges. See Fig. 1. By no means is the resulting matrix perfect, but the resemblance of characteristics among groups of elements arranged in this manner is indeed both striking and illuminating. Attempts to classify the elements date back to the early work of de Chancourtois (1862) and Newlands (1863), but the discovery of the relationship between atomic-number groupings and characteristics was made by Dmitri Mendeleev in 1869. One year later, Lothar Meyer independently showed the periodicity of the elements in terms of atomic volumes. Meyer defined the latter characteristic as the atomic weight divided by the specific gravity of the element in the solid state.

Although there have been numerous refinements to Mendeleev's early tabulation, fortified by the discovery and isolation of several elements then unknown the fundamental principles of the matrix are the same. The conventional table is shown in the upper right in Fig. 2. The information also can be presented in polar fashion as shown in Fig. 2. It is interesting to note that as one proceeds clockwise around the circle the atomic numbers appear consecutively and that 18 sectors of the circle become the bases for families or groups of elements.

Notation for designating the grouping of the elements was changed and officially accepted in the mid-1980s. The new notations are used in Fig. 2. They are summarized in Table 1.

Thus, the members of the alkali metals (Group 1), alkaline earths (Group 2), halogens (Group 17), and so on, all bear resemblance, one element to the other, within any given group. There are two significant breakpoints in any representation of periodicity, namely, commencing with atomic number 57 (lanthanum) and atomic number 89 (actinium). Attempts to place the elements which follow—in the one case, atomic numbers 59 through 71, and in the other case, atomic numbers 90 through 103,

TABLE 1. REVISED CHEMICAL ELEMENT GROUP NOTATION VERSUS PRIOR SCHEMES

Lanthanides and Actinides not included in group numbering.

in the underlying geometric matrix (whether tabular or circular) do not succeed. These separate groups are known as the *Lanthanides* (rare earths) and the *Actinides*, respectively. Upon completion of the Lanthanide series (with lutetium, atomic number 71), the orderly geometry resumes with hafnium, atomic number 72 (Group 4) and continues through actinium, atomic number 89. The probable positions of elements 104 and 105 are indicated in Groups 4 and 5, respectively.

An amazing result of Mendeleev's pioneering classification was the prediction of elements yet to be discovered. Mendeleev found that he could maintain geometric logic of his table only if he allowed for some blank spaces in his table. He further reasoned that elements later would be discovered that would occupy these vacant positions and, thus, Mendeleev predicted the existence of gallium, scandium, and germanium. In fact, Mendeleev gave a preliminary name to scandium, calling it eka-boron and predicted the probable properties of the element. The element later

was isolated by Lars Fredrik Nilson in 1879. Mendeleev lived to see his prediction confirmed.

In retrospect, with a much fuller understanding of the underlying electronic and particle structure of the elements, most aspects of the periodicity of the elements come as no surprise, but the fact remains that Mendeleev, Meyer, and others made these striking observations without benefit of over 100 years of additional knowledge. The periodicity of the elements is demonstrated by the accompanying graph which plots atomic weights along the abscissa versus an arbitrary ordinate for various observed physical characteristics. See also **Chemical Elements**.

PERITECTIC TEMPERATURE. Temperature in a peritectic system at which there is equilibrium between the solid and the remaining melt, the composition of which conforms to the peritectic point, at which the temperature line meets the liquids curve.

PERKIN, SIR WILLIAM HENRY (1838–1907). An English chemist who was the first to make a synthetic dyestuff (1856). He studied under Hofman at the Royal College of London. Perkin's first dye was called mauveine, but he proceeded to synthesize alizarin and coumarin, the first synthetic perfume. In 1907 he was awarded the first Perkin Medal, which has ever since been awarded by the American Division of the Society of Chemical Industry for distinguished work in chemistry. Not withstanding the fact that Perkin patented and manufactured mauve dye in England, the center of the synthetic dye industry shifted to Germany, where it remained until 1914.

See also **Hofmann, August Whilhelm (1818–1892)**.

PERLITE (or Pearlstone). An unusual form of siliceous lava composed of small spherules of about the size of bird shot or peas. It is grayish in color with a soft pearly luster. The spherules often show a concentric structure and are believed to be formed as a result of a peculiar spherical cracking developed while cooling. They may be confused with oölites, which are classified as concretions.

PERMAFIL. A mixture in which the liquid undergoes complete polymerization and hardens without the necessity of any evaporation. Anaerobic permafils harden out of contact with air.

PERMANENT-PRESS RESIN. A thermosetting resin used as a textile impregnant or fiber coating to impart crease resistance and permanent hot-creasing to suitings, dress fabrics, etc. Chemicals such as formaldehyde and maleic anhydride are the basis of these products. The resin is "cured" after the fabric has been tailored into a garment. A permanent-press fabric that requires no resin has been developed (a blend of polyester with cotton or rayon).

See also **Maleic Anhydride, Maleic Acid, And Fumaric Acid**.

PERMEATION. As applied to gas flow through solids, the passage of gas into, through, and out of a solid barrier having no holes large enough to permit more than a small fraction of the gas to pass through any one hole. The process always involves diffusion through the solid and may involve various surface phenomena, such as sorption, dissociation, migration, and desorption of the gas molecules.

PERMENORM. Nickel-iron alloy produced by magnetic annealing and drastic cold reduction and used for mechanical rectifiers and low-frequency amplifiers. This alloy has a rectangular hysteresis loop that eliminates arcing at the contacts of mechanical rectifiers, as well as other desirable properties.

PERMUTATION. Given n distinguishable objects or elements, each different arrangement of the elements is a permutation. The number of permutations is $n(n-1)(n-2)\cdots 3\cdot 2\cdot 1 = n!$ Several different symbols, such as ${}_nP_n$, $P_{n,n}$ or $P(n,n)$ are used to indicate this result. If the n things are taken r at a time ($r < n$),

$$ {}_nP_r = n(n-1)(n-2)\cdots(n-r+1) = \frac{n!}{(n-r)!} $$

When n_1 of the elements are all alike of the first kind, n_2 of the second kind, etc., so that $n_1 + n_2 + \cdots n_m = n$, the number of permutations is

$$ \frac{n!}{n_1!n_2!\cdots n_m!} $$

This result also applies if the elements are separated into m parts with n_i elements in the i th part. If the number of elements in each of the m parts is not specified, but each part must contain at least one element, the number of permutations is

$$ \frac{n!(n-1)!}{(n-m)!(m-1)!} $$

This number is increased to

$$ \frac{(m+n-1)!}{(m-1)!} $$

if empty parts are permitted.

A *combination* is an arrangement of objects or elements, where the order of arrangement is not distinguished. Thus, given the three letters a, b, c, the possible permutations are (abc), (acb), etc., six in number, but there is only one combination. With symbols as before,

$$ {}_nC_r = \frac{n(n-1)(n-2)\cdots(n-r+1)}{r!} = \frac{n!}{r!(n-r)!} $$

This number is identical with the $\binom{n}{r}$, the coefficient in the binomial series. Moreover, ${}_nC_r = {}_nP_{n-r}$; ${}_nP_r = r!{}_nC_r$.

The number of combinations of n different elements into m specified parts, with empty parts allowed, is m^n; of n identical elements into m different parts with empty parts is

$$ \frac{(n+m-1)!}{n!(m-1)!} $$

but when at least one element is in each part, the number is

$$ \frac{(n-1)!}{(m-1)!(n-m)!} $$

Finally, the total number of combinations of n things taken 1, 2, 3, ..., n at a time is $\sum_{i=1}^{n} {}_nC_i = 2^n - 1$.

PERMUTATION GROUP. Its elements, $n!$ in number, are the various permutations or rearrangements of a standard arrangement of n symbols of objects. A typical element is

$$ S = \begin{pmatrix} s_1 & s_2 & \cdots & s_n \\ 1 & 2 & \cdots & n \end{pmatrix} $$

meaning that the operation S replaces 1 by s_1, 2 by s_2, etc. If another element is indicated by T, then ST, the rearrangement designated by T followed by S, the resulting permutation is also in the group.

A permutation sending s_1 into s_2, s_2 into s_3, etc., and finally s_n into s_1 is called a *cycle* on n letters. It is usually written as $(s_1, s_2, \ldots, s_n)$. The degree of a cycle equals the number of symbols permuted. A cyclic permutation of degree two is a *transposition*. Any permutation may always be written as a product of transpositions, either even or odd in number. The permutation is then said to be even or odd.

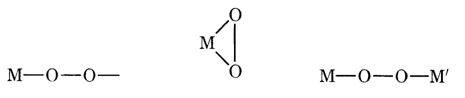
The group of all permutations of n letters or objects, of order $n!$, is called the *symmetric group*. The even permutations of n objects form a *subgroup* of the symmetric group. Its order is $n!/2$ and it is called the *alternating group*.

Every group is *isomorphous* to some permutation group. It is easy to find a representation of a permutation group by using a permutation matrix. Each row and column of such a matrix has but one non-zero element and that is unity. The row and column thus designate the initial and final locations of the object permuted.

See also **Permutation**.

PEROVSKITE. The mineral perovskite is calcium titanate, essentially $CaTiO_3$, with rare earths, principally cerium, proxying for Ca, as do both ferrous iron and sodium, and with columbium substituting for titanium. It crystallizes in the orthorhombic system, but with pseudo-isometric character; fracture subconchoidal to uneven; brittle; hardness, 5.5; specific gravity, 4; luster, adamantine; color, various shades of yellow to reddish-brown or nearly black; transparent to opaque. It is found associated with chlorite or serpentine rocks occurring in the Urals, Baden, Switzerland, and Italy. It was named for Von Perovski.

PEROXIDES AND PEROXIDE COMPOUNDS (Inorganic). A peroxide or peroxo compound contains at least one pair of oxygen atoms, bound by a single covalent bond, in which each oxygen atom has an oxidation number of −1. The peroxide group can be attached to a metal, M, through one (**1**) or two (**2**) oxygen atoms, or it can bridge two metals (**3**):



(**1**) (**2**) (**3**)

Peroxides should be distinguished from several other types of compounds having similar names. The higher oxides of lead, manganese, and other elements, although sometimes called peroxides, are not peroxides as

defined herein because these contain no oxygen–oxygen bond. Similarly, compounds such as the perchlorates and permanganates are not peroxides. It is preferable for true peroxides to be designated by the prefixes *peroxo* or *peroxy*. In the IUPAC nomenclature, *peroxo* is used for inorganic compounds, *peroxy* for organic compounds.

All the simple peroxides form hydrogen peroxide on contact with water. Many inorganic peroxides tend, as does H_2O_2, to decompose evolving oxygen.

Group 1 (1A) Peroxides

Peroxides of all the alkali metals having the formula M_2O_2 are known. There are several general methods of preparation: reaction of the metal and oxygen, reaction of the metal monoxide and oxygen, thermal decomposition of the superoxide, and reaction of alkaline solutions of the metal and hydrogen peroxide.

Alkali metal peroxides are stable under ambient conditions in the absence of water. They dissolve vigorously in water, forming hydrogen peroxide and the metal hydroxide. They are strong oxidizing agents and can react violently with organic substances. Only lithium peroxide and sodium peroxide have been commercialized.

Lithium Peroxide. Lithium peroxide, Li_2O_2, is used in space technology because it absorbs carbon dioxide and liberates oxygen. This peroxide, also used for hardening certain plastics, is a white or pale yellow solid, stable at ambient temperature, and not hygroscopic.

Lithium peroxide is a strong oxidizer and can promote combustion when in contact with combustible materials. It is a powerful irritant to skin, eyes, and mucous membranes. Five grams of many lithium compounds can be fatal.

Sodium Peroxide. Sodium peroxide, Na_2O_2, is a pale yellow solid, stable at ambient temperature, and hygroscopic. Its melting point is 460°C.

The commercial product is a powder containing a minimum of 96% Na_2O_2 and approximately 20% active oxygen. It is made commercially by oxidizing the molten metal with either oxygen or air enriched in oxygen. As of the mid-1990s, sodium peroxide has only a few special applications, including chemical analysis and the extraction of platinum from its ores by the Leidie process.

Although neither inflammable nor self-igniting, sodium peroxide is highly inflammable when mixed with oxidizable substances. Such mixtures burn violently, even in the absence of air.

Sodium peroxide is a powerful irritant to skin, eyes, and mucous membranes; protective clothing should be worn when handling it.

Group 2 (IIA) Peroxides

All the elements of Group 2 form peroxides, with the exceptions of beryllium and radium. There are two general methods of preparation: reaction of the metal or monoxide with oxygen, and reaction of the hydroxide with aqueous hydrogen peroxide. These peroxides are more stable in the presence of water than the Group 1 peroxides, primarily because of insolubility in water. Calcium peroxide is used on a large scale; magnesium, strontium, barium, and zinc peroxides have small-scale uses; whereas cadmium and mercury peroxides have no commercial uses at all. A general account of these peroxides is available.

The materials are generally made by triturating the oxides, or hydroxides, with aqueous hydrogen peroxide and drying the solid products. The commercial products are typically mixtures of the peroxides with varying amounts of hydroxides, oxides, carbonates, hydrates, and peroxohydrates.

Magnesium Peroxide. Magnesium peroxide and MgO_2, used in medicine as a stomach antacid and as an antiseptic, has not been prepared in the pure state. The product is a white powder containing about 25% MgO_2 and 7% active oxygen. This material is sparingly soluble in water but reacts with water slowly, forming hydrogen peroxide and liberating oxygen gas.

There are minor uses for magnesium peroxide in household products, veterinary medicine, and metallurgy. Magnesium peroxide is a strong oxidizer and can cause fire when in contact with combustible materials. It is a powerful irritant to skin, eyes, and mucous membranes.

Calcium Peroxide. Commercial material contains either 60 or 75% CaO_2, the remainder is a poorly defined mixture of calcium oxide, hydroxide, and carbonate.

An important application of calcium peroxide is for curing the polysulfide sealants used in double-glazing window units. Calcium peroxide is also used at several gold mines in Australia to increase the recovery of gold and reduce the consumption of cyanide. Solid calcium peroxide can also be used in the heap-leaching of lean gold ores. A proprietary form of calcium peroxide for this purpose is sold by FMC (United States) under the trademark PermeOx.

PermeOx is also used to improve the bioremediation of soils contaminated with creosote or kerosene, to deodorize sewage sludges and wastewater, and to dechlorinate wastewater and effluents. See also **Odor Modification**.

Calcium peroxide has several horticultural and agricultural applications, particularly in Japan. Usually used in the form of granules, it acts by providing extra oxygen for germinating plants and other organisms.

Calcium peroxide has been used for many years as a dough conditioner in the United States, but not in Europe, where this use is not permitted. Another industrial application of calcium peroxide is as an oxidizing agent in the production of certain titanium–aluminum alloys.

Calcium peroxide is among the safest of the inorganic peroxides, presenting no significant hazard with regard to skin contact or absorption, inhalation, and ingestion; but it may be irritating to the skin under humid conditions. Airborne dust is irritating to the eyes, nose, throat, and lungs, but poses no significant long-term inhalation hazard.

Strontium Peroxide. Commercial strontium peroxide contains about 85% SrO_2 and 10% active oxygen. The only substantial application for this compound is in pyrotechnics. Strontium peroxide produces a red color in flames.

Strontium peroxide is a strong oxidizer and can cause fire when in contact with combustible materials. It is a powerful irritant to skin, eyes, and mucous membranes.

Barium Peroxide. The commercial product is a dull yellow powder containing about 90% BaO_2 and about 8.5% active oxygen. The principal use is in pyrotechnics, but there are also small uses in the curing of polysulfide rubbers and in the production of certain titanium–aluminum alloys.

Barium peroxide is a strong oxidizer and can cause fire when in contact with combustible materials. It is a powerful irritant to skin, eyes, and mucous membranes. Consequently, it is also toxic via the subcutaneous route; protective clothing should be worn during handling. The LD_{50} value (mouse, oral) is 50 mg/kg.

Group 12 (IIB) Peroxides

Zinc Peroxide. The commercial product is a pale yellow powder containing about 55% ZnO_2 and 9% active oxygen. It is stable in dry air but loses its oxygen in moist air and on heating. It is insoluble in water but dissolves in dilute acid, liberating hydrogen peroxide.

Zinc peroxide is used as an accelerator in rubber-compounding, as a curing agent for synthetic elastomers, and as a deodorant for wounds and skin diseases. Zinc peroxide is a powerful irritant to skin, eyes, and mucous membranes. The systemic toxicity is similar to that of zinc oxide, for which the LD_{50} (rat, oral) is 7950 mg/kg.

Zinc peroxide is a strong oxidizer and can cause fire when in contact with combustible materials.

Group 13 (IIIB) Peroxides

Boron Compounds

Nomenclature. The naming of sodium perborate, one of the most important commercial boron compounds, has long been confused. The tetrahydrate has more recently come to be called the hexahydrate. The crystallographically derived names are used to avoid confusion. The commercial or common names are also given.

Sodium Peroxoborate Hexahydrate. The compound sodium peroxoborate hexahydrate (sodium perborate tetrahydrate), $Na_2[B_2(O_2)_2(OH)_4] \cdot 6H_2O$, was formerly written as $NaBO_3{\cdot}4H_2O$. This material has been an important commercial bleaching agent for many years. The commercial product is a white, crystalline powder having an active oxygen content of at least 10%. It melts at about 60°C; however, if water vapor is free to escape during heating, the crystals do not melt but are converted to the anhydrous peroxoborate.

Sodium peroxoborate hexahydrate is an important ingredient of many household detergents, working best at temperatures above 60°C. It is also used in dishwasher detergents, denture cleaners, as well as foot and bath salts. Organic chemists have been using sodium peroxoborates as oxidants since the 1980s.

The toxicity of sodium peroxoborate hexahydrate in solution is equivalent to those of sodium borate and hydrogen peroxide. The LD_{50} (mouse, oral) is 1060 mg/kg. Local use of high concentrations in the mouth can cause chemical burns and other problems.

The product is considered nonhazardous for international transport purposes. However, it is an oxidizing agent sensitive to decomposition by water, direct sources of heat, catalysts, etc.

Sodium Peroxoborate Tetrahydrate. The compound sodium peroxoborate tetrahydrate (sodium perborate trihydrate), $Na_2B_2(O_2)_2[(OH)_4] \cdot 4H_2O$, was formerly written as $NaBO_3 \cdot 3H_2O$.

Sodium peroxoborate tetrahydrate is the most stable of the three peroxoborate hydrates under ambient conditions. It has, however, never been commercialized because it is slow to dissolve in water.

Sodium Peroxoborate. Sodium peroxoborate (sodium perborate monohydrate), $Na_2[B_2(O_2)_2(OH)_4]$, formerly written as $NaBO_3 \cdot H_2O$, is known only as a microcrystalline powder, made by dehydrating the hexahydrate.

The commercial product has an active oxygen content of at least 15%. This product has replaced the hexahydrate in some household detergents and other domestic products because it dissolves faster and has a greater content of active oxygen per unit volume of granular product.

The toxicity of sodium peroxoborate is similar to that of the hexahydrate. Sodium peroxoborate is a severe eye irritant, but not a skin irritant. Absorption through large areas of abraded or damaged skin can give systemic boron poisoning. The maximum eight-hour time-weighted average exposure is 5 mg/m^3.

The product is considered nonhazardous for international transport purposes. However, it is an oxidizing agent sensitive to decomposition by water, direct sources of heat, catalysts, etc. Decomposition in the presence of organic material is rapid and highly exothermic.

Anhydrous Sodium Perborate. Anhydrous sodium perborate, $NaBO_3$, is an ill-defined, powdery material. It should perhaps be regarded more as an amorphous assemblage of radicals than as a defined compound.

Anhydrous sodium perborate effervesces in water. It is used mainly as an ingredient in denture-cleaning formulations. No toxicological data have been reported on this product, except that in humans, swallowing large amounts can cause nausea, vomiting, and diarrhea. Anhydrous sodium perborate is irritating to eyes, skin, and mucous membranes. It is also mutagenic to *E. coli*.

Group 14 (IVB) Peroxides

Peroxocarbonates. Peroxocarbonates contain the C—O—O— group and should be distinguished from the carbonate peroxohydrates.

There are international transport regulations controlling the transport of sodium percarbonate, which assigned it to Class 5.1, oxidizing substances, however, no such compound has ever been commercialized, and sodium carbonate peroxohydrate is treated as nonhazardous. The origin of this item is not known.

Peroxosilicates. No solid peroxosilicates are known.

Peroxotin Compounds. Older literature records some tin peroxides or peroxohydrates, but these claims have not been substantiated. In contrast, organometallic peroxotin compounds are well established.

Group 15 (VB) Peroxides

Peroxonitrous Acid and Its Salts. Peroxonitrous acid HOONO, is an isomer of nitric acid, HNO_3, to which it rapidly converts. The half-life of peroxonitrous acid at 0°C is 10 s; at 27°C, 0.23 s. It has been known since 1904 that the yellow solution made by mixing nitrous acid and hydrogen peroxide at low temperature contains a stronger oxidant than either ingredient alone, but the chemistry involved was not put on a sound basis until 1994. Additional preparatory methods are also available.

Peroxonitrous acid can decompose by two pathways: isomerization to nitric acid, and dissociation into the hydroxyl radical and nitrogen dioxide.

Peroxonitrite is believed to be present in the crystals of nitric trihydrate that form in the stratosphere and in Martian soil. See also **Extraterrestrial Materials**. Peroxonitrous acid may be present in mammalian blood and other biochemical systems.

Peroxophosphoric Acids and Their Salts. In its usual impure form (H_3PO_4 is the main contaminant), peroxomonophosphoric acid is a viscous, colorless liquid. It is not produced or used commercially and the salts that have been prepared are unstable and impure.

Pure peroxodiphosphoric acid, $H_4P_2O_8$, has not been obtained, but its properties in aqueous solution are understood.

Tetrapotassium peroxodiphosphate, $K_4P_2O_8$, is a colorless, crystalline solid, soluble in water to 42.2 wt % at 0°C and 51.2 wt % at 40°C.

Tetrapotassium peroxodiphosphate is being investigated as an ingredient in toothpaste as an anticalculus agent and bactericide. However, the peroxodiphosphates are not useful commercial products at present.

Arsenic Peroxides. Arsenic peroxides have not been isolated; however, elemental arsenic, and a great variety of arsenic compounds, have been found to be effective catalysts in the epoxidation of olefins by aqueous hydrogen peroxide. Transient peroxoarsenic compounds are believed to be involved in these systems.

Group 16 (VIB) Peroxides

Peroxosulfuric Acids and Their Salts. Two kinds of peroxosulfuric acid are known: peroxomonosulfuric and peroxodisulfuric acids. Neither is available commercially in the pure state.

Peroxomonosulfuric acid, H_2SO_5, when pure, forms colorless crystals that melt with decomposition at 45°C. Peroxomonosulfuric acid is a strong oxidizing agent. It hydrolyzes rapidly at pH <2 to hydrogen peroxide and sulfuric acid. It is usually made and used in the form of Caro's acid.

Caro's Acid. Caro's acid is the equilibrium mixture that results from mixing hydrogen peroxide and sulfuric acid. These liquids mix instantly, generating a considerable amount of heat.

Because the product is decomposed by heat, it is essential either to remove the heat of reaction quickly or to use the product quickly. The first option is known as the isothermal process; the second option, perfected and commercialized in the early 1990s, is known as the adiabatic process.

Caro's acid is finding increasing application in hydrometallurgy, pulp bleaching, effluent treatment, and electronics.

Peroxomonosulfates. When oleum is mixed with hydrogen peroxide and the mixture is partially neutralized by potassium hydroxide, a triple salt crystallizes out. The commercial product is a white, finely crystalline powder containing a minimum of 4.7% active oxygen. It is used because it is stable and safe, despite being a powerful oxidant. Its main use is in denture cleaners. It is also used in dishwashing detergents and toilet bowl cleaners, in the metal-fabricating industry as a mild etchant and pickling agent, in the electroplating industry for detoxifying cyanide solutions, and in the textile industry for rendering wool shrink-resistant and nonfelting.

In general, peroxomonosulfates have fewer uses in organic chemistry than peroxodisulfates. However, the triple salt is used for oxidizing ketones to dioxiranes, which in turn are useful oxidants in organic chemistry.

Potassium hydrogen monoperoxosulfate monohydrate $KHSO_5 \cdot H_2O$, related to the triple salt, is not made commercially. This compound is reported as toxic and irritating to eyes, skin, and mucous membranes. Although undoubtedly correct, this description probably better relates to the triple salt.

Peroxodisulfuric Acid. Also called persulfuric acid, and Marshall's acid, peroxodisulfuric acid, $H_4S_2O_8$, when pure, forms colorless crystals that melt with decomposition at 65°C. Peroxodisulfuric acid is a strong acid but not stable. It is seldom isolated but is synthesized and used in solution.

Peroxodisulfates. The salts of peroxodisulfuric acid are commonly called persulfates, three of which are made on a commercial scale: ammonium peroxodisulfate, $(NH_4)_2S_2O_8$; potassium peroxodisulfate, $K_2S_2O_8$; and sodium peroxodisulfate, $Na_2S_2O_8$. The peroxodisulfates are all colorless, crystalline solids, stable under dry conditions at ambient temperature but unstable above 60°C. All the peroxodisulfates are made commercially by electrolytic processes.

The peroxodisulfate ion in aqueous solution is one of the strongest oxidizing agents known. The principal use of the peroxodisulfate salts is as initiators for olefin polymerization in aqueous systems, particularly for the manufacture of polyacrylonitrile and its copolymers. See also **Acrylonitrile Polymers**. Etching of printed circuit boards and removal of photoresists are also important applications. Bleaching of textiles and natural fibers and finishing of furs are both long-established applications. Other established applications include curing grouts for soil stabilization initiating polymerization of graphite filament coatings, cleaning metal surfaces prior to plating or adhesive bonding, and regenerating active carbon.

An expanding development is the use of peroxodisulfates as oxidants in organic chemistry.

The three peroxodisulfates are all toxic and irritating to skin, eyes, and mucous membranes. The LD_{LO} value for sodium peroxodisulfate using iv administration in rabbits is 178 mg/kg.

Other Metal Peroxides

Transition-Metal Peroxides. Transition-metal peroxides, as isolated species, have no place in chemical technology because they are too dangerously explosive.

Transition metals can be divided into two groups according to the characteristics of their peroxides. The first group comprises those metals that, in their highest oxidation states, have no *d* electrons, e.g., Ti^{4+} and W^{6+}. These metals form peroxides from hydrogen peroxide. The peroxo species act as electrophiles.

The other group of transition metals comprises those metals that retain *d* electrons in their normal valence states, e.g., Co^{3+} and Pt^{2+}. These metals form peroxides from dioxygen or from hydrogen peroxide.

Actinide Peroxides. Many peroxo compounds of thorium, protactinium, uranium, neptunium, plutonium, and americium are known. Uranium peroxide has found several applications in the nuclear energy industry.

Peroxohydrates

Peroxohydrates are crystalline adducts containing molecular hydrogen peroxide. Peroxohydrates are usually made by simple crystallization from solutions of salts or other compounds in aqueous hydrogen peroxide. They are fairly stable under ambient conditions, but traces of transition metals catalyze the liberation of oxygen from the hydrogen peroxide.

Sodium Carbonate Peroxohydrate. Known commercially as sodium percarbonate, sodium carbonate peroxohydrate does not contain the C−O−O−C group and is not a peroxocarbonate. The stoichiometry is $2Na_2CO_3{\cdot}3H_2O_2$. The material is made commercially by three processes: batch crystallization, continuous crystallization, and fluid-bed reaction.

The commercial product is a white powder containing a minimum of 13% of active oxygen and up to 15% of anhydrous sodium carbonate. The solubility in water at 20°C is about 150 g/L.

The principal use of sodium carbonate peroxohydrate is as a bleaching agent in domestic and laundry detergents. It is used also for industrial textile-bleaching, tripe-bleaching, and in denture cleaners. It can also be used as a convenient oxidant in organic chemistry.

The LD_{50} (rat, oral) of sodium carbonate peroxohydrate is 1034 mg/kg. The occupational exposure limit is 10 mg/m^3 per 40-hour week. The compound is a skin and eye irritant; inhalation of dust can cause irritation to the mucous membranes and the respiratory system. Decomposition in the presence of organic material can be rapid and highly exothermic.

Other Peroxohydrates. Other peroxohydrates include those of potassium, rubidium, and cesium carbonates, $M_2CO_3{\cdot}3H_2O$; ammonium carbonate peroxohydrate, $(NH_4)_2CO_3{\cdot}H_2O_2$; and urea peroxohydrate, $CO(NH_2)_2{\cdot}H_2O_2$.

Urea peroxohydrate is an irritant to skin, eyes, and mucous membranes. The U.S. Food and Drug Administration approves it as an over-the-counter drug.

Peroxopolyoxometallates

Polyoxometallates, derived from both isopoly acids and heteropoly acids, are important homogeneous oxidation catalysts. The metals involved are vanadium, niobium, tantalum, molybdenum, and tungsten. The reactions involved are the oxidation of a wide range of organic compounds by hydrogen peroxide or organic hydroperoxide.

Superoxides

The superoxides are ionic solids containing the superoxide, O_2^-. Superoxides of all of the alkali metals have been prepared. Alkaline-earth metals, cadmium, and zinc all form superoxides, but these have been observed only in mixtures with the corresponding peroxides. The tendency to form superoxides in the alkali metal series increases with increasing size of the metal ion.

Metal superoxides are yellow-to-orange solids. Strong oxidizing agents, they react vigorously with most organic materials and reducing agents, and oxidize many metals to their highest oxidation states.

Sodium superoxide, NaO_2, is a yellow solid. No applications are known.

Potassium superoxide, KO_2, is a canary yellow solid that melts at 450−500°C when pure. Potassium superoxide, a strong oxidizing agent, is similar to the Group 1 metal peroxides. Potassium superoxide is produced commercially by spraying molten potassium into an air stream, which may be enriched with oxygen.

Mine Safety Appliances Co. (MSA) manufactures potassium superoxide in the United States for use in self-contained breathing equipment. There are several published uses for potassium superoxide in organic chemistry, e.g., for oxidizing aromatic compounds and for initiating anionic polymerization.

On contact with skin and mucous membranes, potassium superoxide is converted to potassium hydroxide, which is corrosive and irritating. The reaction with moisture is exothermic and may induce further decomposition with the production of oxygen.

Other superoxides include rubidium superoxide, RbO_2; cesium superoxide, CsO_2; calcium superoxide, $Ca(O_2)_2$; strontium superoxide, $Sr(O_2)_2$; and barium superoxide, $Ba(O_2)_2$. These superoxides are not produced commercially.

Ozonides

The ozonides are characterized by the presence of the ozonide ion, O_3^-. They are generally produced by the reaction of the inorganic oxide and ozone. Sodium ozonide, NaO_3; potassium ozonide, KO_3; rubidium ozonide, RbO_3; and cesium ozonide, CsO_3, have all been reported. Ammonium ozonide, NH_4O_3, and tetramethylammonium ozonide, $(CH_3)_4 \cdot NO_3$, have been prepared at low temperatures. Whereas the inorganic ozonides are of potential importance as solid-oxygen carriers in breathing apparatus, they are not produced commercially.

Economic Aspects

All of the large-tonnage peroxo compounds, e.g., sodium peroxoborate hexahydrate, sodium peroxoborate, and sodium carbonate peroxohydrate, are made by hydrogen peroxide producers using captive hydrogen peroxide. The world demand for active oxygen provided by these products is fairly stable, rising with the gross national product.

PEROXIDES AND PEROXIDE COMPOUNDS (Organic). Organic peroxides are compounds possessing one or more oxygen-oxygen bonds. They are derivatives of hydrogen peroxide, HOOH, in which one or both hydrogens are replaced by a group containing carbon (R, R′), i.e., ROOH or ROOR′. The ultimate source of the oxygen-oxygen linkage in organic peroxides is oxygen; either from direct air oxidation or from reactions of organic compounds with peroxidic materials derived from oxygen, e.g., hydrogen peroxide, alkali metal peroxides, ozone, or other organic peroxides. Organic peroxides are intermediates or products in air oxidation of many synthetic and natural organic compounds. They are involved in many biological processes including development of rancidity in fats, loss of activity of vitamin products, and firefly bioluminescence. Some biological products contain a peroxide group. Organic peroxides are also involved in gum formation in lubricating oils, prepolymerization of some vinyl monomers, and degradation of olefin polymers.

Almost all organic peroxides are thermally and photolytically sensitive owing to the facile cleavage of the weak oxygen−oxygen bond. This cleavage is a unimolecular (first-order) reaction. The thermal decomposition rates are affected by the structure of the organic peroxide and the decomposition conditions.

Thermal decomposition of peroxides initially forms oxygen-centered free radicals from the oxygen−oxygen bond homolysis. These radicals are reactive intermediates generally having very short lifetimes, i.e., half-life

times less than 10^{-3} s. Because they form useful free radicals, they are used commercially as initiators for free-radical reactions.

Approximately 100 different organic peroxides in well over 300 formulations are commercially produced throughout the world as free-radical initiators for polymerizing vinyl monomers, grafting of monomers onto polymers, curing agents for unsaturated resins, rubber, and elastomers, cross-linking of thermoplastics (e.g., polyethylene), modification/degradation of polypropylene, halogenations, anti-Markovnikov additions to terminal olefins (e.g., formation of primary mercaptans), and telomerizations. Some are used as bleaching agents (i.e., for grain flours and fabrics), olefin epoxidizing agents, and active species in a variety of other applications, e.g., the use of BPO as the active antibacterial component in acne medications.

Organic peroxides can be classified according to peroxide structure. There are seven principal classes: hydroperoxides; dialkyl peroxides; α-oxygen substituted alkyl hydroperoxides and dialkyl peroxides; primary and secondary ozonides; peroxyacids; diacyl peroxides (acyl and organosulfonyl peroxides); and alkyl peroxyesters (peroxycarboxylates, peroxysulfonates, and peroxyphosphates).

Hydroperoxides

There are two main subclasses of hydroperoxides: organic (alkyl) hydroperoxides, i.e., ROOH, and organomineral hydroperoxides, i.e., $R_mQ(OOH)_n$, where Q is silicon, germanium, tin, or antimony. The alkyl group in ROOH can be primary, secondary, or tertiary. Except for ethylbenzene hydroperoxide, only *tert*-alkyl hydroperoxides are commercially important.

Physical Properties. Some physical properties of alkyl hydroperoxides (in order of increasing carbon content) are listed in Table 1.

Alkyl hydroperoxides can be liquids or solids. Those having low molecular weight are soluble in water and are explosive in the pure state. Alkyl hydroperoxides are stronger acids than the corresponding alcohols and have acidities similar to those of phenols. *tert*-Alkyl hydroperoxides can be purified through their alkali metal salts.

Hydroperoxides exist as hydrogen-bonded dimers in nonpolar solvents and readily form hydrogen-bonded associations with ethers, alcohols, amines, ketones, sulfoxides, and carboxylic acids. Other physical properties of hydroperoxides have been reported in the literature.

Chemical Properties. Hydroperoxides can react with or without cleavage of the oxygen–oxygen bond. Reactions resulting in scission of the oxygen–oxygen bond involve heterolytic, homolytic, or metal-promoted oxidation–reduction reactions.

Alkyl hydroperoxides are reduced readily to the corresponding alcohols; many such reductions are quantitative and useful for analytical methods. Alkyl hydroperoxides have been used as oxidizing or hydroxylating reagents in organic syntheses.

Bases, such as potassium or sodium hydroxide, piperidine, and pyridine, react with primary and secondary hydroperoxides to form aldehydes or ketones. *tert*-Alkyl hydroperoxides form stable alkali metal salts with caustic; however, when equimolar amounts of the hydroperoxide and its sodium salt are present in aqueous solution, rapid decomposition to *tert*-alcohol and oxygen occurs.

Acids react with alkyl hydroperoxides in two different ways, depending on the hydroperoxide structure and the acid strength.

$$R_3COOH \xrightarrow[H]{+} R_3C{-}OOH \longrightarrow H_2O_2 + R_3\overset{+}{C} \longrightarrow \textit{tert}\text{-alcohol or olefin}$$

$$R_3COOH \xrightarrow{H^+} R_3CO{-}OH \longrightarrow H_2O$$

$$+\, R_2\ \overset{+}{C}\ \ OR \longrightarrow \text{alcohol or phenol and a carbonyl compound}$$

Hydroperoxides are photo- and thermally sensitive and undergo initial oxygen–oxygen bond homolysis, and they are readily attacked by free radicals undergoing induced decompositions.

Hydroperoxides are decomposed readily by multivalent metal ions, i.e., Cu, Co, Fe, V, Mn, Sn, Pb, etc., by an oxidation-reduction or electron-transfer process. Depending on the metal and its valence state, metallic cations either donate or accept electrons when reacting with hydroperoxides. Either one or two electrons may be transferred depending on the metal. With most transition metals, e.g., Cu, Co, and Mn, both valence states react with hydroperoxides via one electron transfer. Thus, a small amount of transition-metal ion can decompose a large amount of hydroperoxide and, consequently, inadvertent contamination of hydroperoxides with traces of transition-metal impurities should be avoided.

The reactions of *tert*-alkyl hydroperoxides with ferrous ion generate alkoxy radicals. These free-radical initiator systems are used industrially for the emulsion polymerization and copolymerization of vinyl monomers, e.g., butadiene–styrene. Alkyl hydroperoxides are among the most thermally stable organic peroxides. However, hydroperoxides are sensitive to chain decomposition reactions initiated by radicals and/or transition-metal ions. Such decompositions, if not controlled, can be autoaccelerating and sometimes can lead to violent decompositions when neat hydroperoxides or concentrated solutions of hydroperoxides are involved.

Organomineral hydroperoxides undergo thermal and photolytic homolyses:

$$R_3QOOH \xrightarrow[\Delta\ \text{or}]{h\nu} R_3QO + OH$$

Synthesis. Hydroperoxides have been prepared from several types of peroxygen compounds including hydrogen peroxide or sodium peroxide, ozone, oxygen, and other organic peroxides. Hydrogen peroxide (H_2O_2) and its anions are powerful nucleophiles and react with reagents RX to form ROOH and HX, where X can be sulfate, acid sulfate, alkane- and arenesulfonate, chloride, bromide, hydroxyl, alkoxide, perchlorate, etc. RX can also be an alkyl orthoformate or *tert*-alkyl carboxylate.

Electron-rich olefins react with hydrogen peroxide under acidic conditions to form hydroperoxides, presumably by means of a carbonium ion intermediate, e.g., *tert*-butyl hydroperoxide from isobutylene.

Organomineral hydroperoxides have been prepared from hydrogen peroxide and organomineral halides, hydroxides, oxides, peroxides, and amines. If HX is an acid, ammonia is used to prevent acidic decomposition.

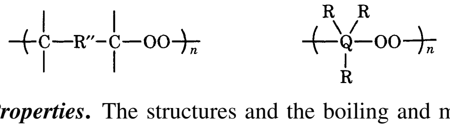
$$R_mQX_n + nH_2O_2 \longrightarrow R_mQ(OOH)_n + nHX$$

Many hydroperoxides have been prepared by autoxidation of suitable substrates with molecular oxygen. These reactions can be free-radical chain or nonchain processes, depending on whether triplet or singlet oxygen is involved.

Many organic peroxides of metals have been hydrolyzed to alkyl hydroperoxides. Saponification of *tert*-alkyl peroxyesters yields alkyl hydroperoxides and carboxylic acids or their alkali metal salts.

Dialkyl Peroxides

Dialkyl peroxides have the structural formula R–OO–R′, where R and R′ are the same or different primary, secondary, or tertiary alkyl, cycloalkyl, and aralkyl hydrocarbon or hetero-substituted hydrocarbon radicals. Organomineral peroxides have the formulas $R_mQ(OOR)_n$ and R_mQOOQR_m, where at least one of the peroxygens is bonded directly to the organo-substituted metal or metalloid, Q. Dialkyl peroxides include cyclic and bicyclic peroxides where the R and R′ groups are linked, e.g., endoperoxides and derivatives of 1,2-dioxane. Also included are polymeric peroxides, which usually are called poly(alkylene peroxides) or alkylene–oxygen copolymers, and poly(organomineral peroxides), where Q = As or Sb.



Physical Properties. The structures and the boiling and melting points of several dialkyl peroxides are listed in Table 2; a comprehensive list is given in the literature.

Metalloid peroxides behave as covalent organic compounds and most are insensitive to friction and impact but can decompose violently if heated rapidly. Most solid metalloid peroxides have well-defined melting points and the more stable liquid members can be distilled (Table 3).

Chemical Properties. Acyclic di-*tert*-alkyl peroxides efficiently generate alkoxy free radicals by thermal or photolytic homolysis. Primary and secondary dialkyl peroxides undergo thermal decompositions more rapidly than expected owing to radical-induced decompositions. Such radical-induced peroxide decompositions result in inefficient generation of free radicals.

The low molecular weight primary dialkyl peroxides are shock-sensitive and explosive, with sensitivity decreasing with increasing molecular weight. Decomposition products from primary and secondary dialkyl

peroxides include aldehydes, ketones, alcohols, hydrogen, hydrocarbons, carbon monoxide, and carbon dioxide.

Because di-*tert*-alkyl peroxides are less susceptible to radical-induced decompositions, they are safer and more efficient radical generators than primary or secondary dialkyl peroxides. They are the preferred dialkyl peroxides for generating free radicals for commercial applications.

The susceptibility of dialkyl peroxides to acids and bases depends on peroxide structure and the type and strength of the acid or base. In acidic environments, unsymmetrical acyclic alkyl aralkyl peroxides undergo carbon–oxygen fission, forming acyclic alkyl hydroperoxides and aralkyl carbonium ions. The latter react with nucleophiles, X^-.

Substitution reactions on dialkyl peroxides without concurrent peroxide cleavage are known e.g., the nitration of dicumyl peroxide and the chlorination of di-*tert*-butyl peroxide.

The polymeric peroxides, $(-OOCH_2CXH-)_n$, where $X = H$, C_6H_5, $CH{=}CH_2$, etc., are viscous liquids or amorphous solids having as many as 10 repeating units. These compounds usually explode when heated. The products obtained from the thermal or photodecomposition show that cleavage of both oxygen–oxygen and carbon–carbon bonds occurs. The type and amounts of products formed depend on the decomposition conditions and the structure of the peroxide.

Unsaturated aliphatic endoperoxides form bis(epoxides) and/or epoxy aldehydes upon thermolysis. The endoperoxides of polynuclear aromatic compounds are crystalline solids that extrude singlet oxygen when heated, thus forming the parent aromatic hydrocarbon. Endoperoxides undergo carbon–oxygen cleavage in acids and oxygen–oxygen bond cleavage in bases, and they are more easily reduced than dialkyl peroxides.

1,2-Dioxetanes have very low activation enthalpies (ca 109 kJ/mol), therefore, they are unstable at low temperatures and generally cleave thermally or photochemically at the oxygen–oxygen and carbon–carbon bonds. Upon fragmentation, chemiluminescence occurs and two carbonyl compounds are produced in the absence of trapping agents. 1,2-Dioxetanes are reduced to diols, epoxides, or allylic alcohols; the dioxetane structure and the reducing system determine which product forms or predominates.

Dioxiranes are three-membered cyclic ring peroxides that are expected to be very unstable owing to ring strain. They are effective oxygenating agents for epoxidations of olefins, allenes, polycyclic aromatic hydrocarbons, enols, and α,β-unsaturated ketones; for insertions of oxygen into X–H

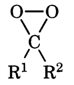
(4) (5)

Fig. 1. Varieties of α-oxygen-substituted hydroperoxides and dialkyl peroxides. R^1, R^2, $R^3 = H$ or alkyl; X, Y = OH, OOH, OR^4, $OSiR_3$, or OOR^5; R^4, R^5 = alkyl; and R^3 and R^5 may also be acyl, $C(=O)R^6$

bonds of alkanes, primary and secondary alcohols, aldehydes, and silanes; and for oxidations of sulfides (to sulfoxides and sulfones), imines (to nitrones), and primary amines (to nitro compounds). In these reactions, the dioxirane transfers oxygen to the substrate and generates the ketone from which the dioxirane was derived.



Most organomineral peroxides are hydrolytically unstable and readily hydrolyze to alkyl hydroperoxides or hydrogen peroxide:

$$R_mQ{-}OO{-}QR_m \xrightarrow{H_2O} 2R_mQ{-}OH + H_2O_2$$

Consequently, most organomineral peroxides must be prepared and stored under anhydrous conditions.

Basic hydrolysis of secondary alkyl-substituted silicon and germanium peroxides results in oxygen–oxygen bond cleavage.

The reduction of alkyl-substituted silicon and tin peroxides with sodium sulfite and triphenylphosphine has been reported. Alkyl-substituted aluminum, boron, cadmium, germanium, silicon, and tin peroxides undergo oxygen-to-metal rearrangements, as in the following equations:

$$R_3Si{-}OO{-}SiR_3 \longrightarrow R_2Si(OR)OSiR_3$$

$$R_2B{-}OO{-}R \longrightarrow RB(OR)_2$$

Organomineral peroxides also undergo thermal and photo-induced homolysis, yielding free radicals that are effective for initiating polymerization of vinyl monomers.

Synthesis. Dialkyl peroxides are prepared by the reaction of various substrates with hydrogen peroxide, hydroperoxides, or oxygen. They also have been obtained from reactions with other organic peroxides.

α-Oxygen-Substituted Hydroperoxides and Dialkyl Peroxides

Dialkyl peroxides and hydroperoxides which have either a hydroxy, hydroperoxy, alkoxy, or alkylperoxy group on the carbon adjacent to the parent peroxide group are considered separately from the parent compounds due to their unique reactions and properties, but mainly because of their unique syntheses. Their primary preparation from aldehydes and ketones via reaction with hydrogen peroxide, alkyl hydroperoxides and peroxyacids is unique and makes it almost impossible to discuss them without referring to the parent carbonyl compound(s).

The α-oxygen-substituted hydroperoxides and dialkyl peroxides comprise a great variety as shown in Figure 1. When discussing peroxides derived from ketones and hydrogen peroxide, (1) is often referred to as a ketone peroxide monomer and (2) as a ketone peroxide dimer.

Syntheses, Physical and Chemical Properties

An example of the complex equilibrium that exists for mixtures of carbonyl compounds and hydrogen peroxide is that from aldehydes and hydrogen peroxide. Hydroxyalkyl hydroperoxides (**1**, X = OH, $R^3 = H$) and di(hydroxyalkyl) peroxides (**2**, X = Y = OH) are formed; cyclic diperoxides (**4**) are formed in some cases, e.g., from benzaldehyde with concentrated sulfuric acid. Hydroxyalkyl hydroperoxides are the principal products when equimolar amounts of aldehyde and hydrogen peroxide are used at low temperatures. Di(hydroxyalkyl) peroxides are obtained by using excess aldehyde or higher temperatures. These reactions occur without catalysts but occur at much faster rates in the presence of acids. The peroxides (**1**) and (**2**) from most straight-chain aldehydes, i.e., C_1–C_{11}, have been characterized, and a few of these and some from other aldehydes are listed in Table 4.

Starting with ketones and hydrogen peroxide in the presence of a catalytic amount of acid, mixtures of up to eight components have been identified, i.e., (**1**, X = OH, $R^3 = H$), (**1**, X = OOH, $R^3 = H$), (**2**, X = Y = OH), (**2**, X = Y = OOH), (**2**, Y = OH, Y = OOH), (**3**), (**4**), and (**5**). The ketone structure and reaction conditions, i.e., acid strength, reactant molar ratios, temperature, and time, determine which compounds form and predominate. Mixtures of several peroxide structures usually are present. Individual peroxides have been isolated from several ketones under different conditions (Table 5). The pure peroxides should be handled with extreme caution since most, especially those derived from the low molecular weight ketones, are shock- and friction-sensitive and can explode violently. Methyl ethyl ketone peroxide (MEKP) mixtures are produced commercially only as solutions containing <40 wt% MEKPs in solvents, commonly dialkyl phthalates.

Hydroxyalkyl Hydroperoxides. These compounds, represented by (**1**, X = OH, $R^3 = H$), may be isolated as discreet compounds only with certain structural restrictions, e.g., that one or both of R^1 and R^2 are hydrogen, i.e., they are derived from aldehydes, or that R^1 or R^2 contain electron-withdrawing substituents, i.e., they are derived from ketones bearing α-halogen substituents. Other hydroxyalkyl hydroperoxides may exist in equilibrium mixtures of ketone and hydrogen peroxide.

Alkoxyalkyl Hydroperoxides. These compounds (**1**, X = OR^4, R^3 = H) have been prepared by the ozonization of certain unsaturated compounds in alcohol solvents. Alkoxyalkyl hydroperoxides are more commonly called ether hydroperoxides. They form readily by the autoxidation of most ethers containing α-hydrogens, e.g., dioxane, tetrahydrofuran, diethyl ether, diisopropyl ether, di-*n*-butyl ether, and diisoamyl ether. From certain ethers, e.g., diethyl ether, the initially formed ether hydroperoxide can yield alcohol on standing, or with acid treatment form dangerously shock-sensitive and explosive polymeric peroxides.

Hydroxyalkyl Alkyl Peroxides and Hydroxyalkyl Peroxyesters. Hydroxyalkyl alkyl peroxides (**1**, X = OH, R^3 = alkyl) are reasonably stable and usually can be distilled under a vacuum; the boiling points and structures of representative compounds are listed in Table 6.

Alkoxyalkyl Alkyl Peroxides. *tert*-Butyl tetrahydropyran-2-yl peroxide (**1**, where $R^3 = tert-$butyl, $H = OR^4$, $R^1 = H$, R^2 and $R^4 = 1,4-$butanediyl, has been isolated. This is one of many examples of alkoxyalkyl alkyl peroxides which may be prepared by reaction of hydroperoxides with vinyl ethers.

1,2,4-Trioxacycloalkanes. 1,2,4-Trioxanes (**1**), X = OR^4; R^3 and R^4 = alkylene) are generally prepared by the interaction of aldehydes with zwitterionic intermediates made from reaction of singlet oxygen with olefins. They can also be prepared by catalyzed reaction of ketones or

[b] To convert kPa to mm Hg, multiply by 7.5.

aldehydes with 1,2-dioxetanes or endoperoxides, and they can be prepared directly from certain hydroperoxides.

Geminal Dihydroperoxides. These dihydroperoxides as described previously (**1**, X = OOH, R^3 = H) can be made from many different carbonyl compounds. These peroxides can also be synthesized by perhydrolysis of ketals. Low molecular weight dihydroperoxides are soluble in water and are explosive when pure. They have been reduced to the corresponding ketones with hydriodic acid or zinc and acetic acid. Hydrolysis also gives the corresponding ketones. In the presence of catalytic amounts of acids or on prolonged storage, solutions of dihydroperoxides form equilibrium amounts of hydrogen peroxide and di(hydroperoxyalkyl) peroxides and ultimately equilibrium amounts of cyclic triperoxides.

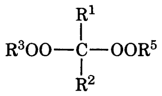
Diperoxyketals and Diperoxyacetals. Aromatic aldehydes react with alkyl hydroperoxides in the presence of strong acid catalysts such as sulfuric acid to form diperoxyacetals (**1**, X = OOR^5; R^1 = H, R^2 = Ar, $R^3 = R^5$ = alkyl). Diperoxyketals (**1**, X = OOR^5; R^1, R^2, R^3, R^5 = alkyl) are generally prepared by acid-catalyzed reaction of a ketone with two equivalents of an alkyl hydroperoxide.

Diperoxyketals are solids or colorless liquids and are soluble in common organic solvents and insoluble in water. The physical properties and structures of some diperoxyketals are listed in Table 7. In the pure state, the low molecular weight compounds can decompose violently when heated, and addition of concentrated sulfuric acid can result in flaming decompositions. There are many commercial diperoxyketals, and they are usually diluted with solvents for improved safety.

Tertiary diperoxyketals (**1**, X = OOR^5, R^1, R^2 = alkyl, R^3, R^5 = tertiary alkyl) are excellent free-radical initiators. Such diperoxyketals are stable, especially those with $R^3 = R^5$ = *tert* – butyl. Less thermally stable diperoxyketals are those derived from cyclic ketones and those with bulkier *tert*-alkyl groups, e.g., *tert*-amyl, *tert*-octyl, *tert*-cumyl. Commercial members of this group all have $R^3 = R^5$, and thermally decompose to free radicals by cleavage of only one oxygen–oxygen bond initially, usually followed by β-scission of the resulting alkoxy radicals. For acyclic diperoxyketals, β-scission produces an alkyl radical and a peroxyester. Owing to similarity of thermal stability, the peroxyester decomposes almost simultaneously.

Diperoxyketals, and many other organic peroxides, are acid-sensitive, therefore removal of all traces of the acid catalysts must be accomplished

TABLE 7. BOILING POINTS OF SOME DIPEROXYKETALS



Diperoxyketal	R^3, R^5	R^1	R^2	Bp, °C (kPa)[a]
2,2-di(t-butylperoxy)propane	t-C_4H_9	CH_3	CH_3	69–70 (2.0)
2,2-di(t-amylperoxy)propane	t-C_5H_{11}	CH_3	CH_3	68 (0.17)
2,2-di(t-butylperoxy)butane	t-C_4H_9	CH_3	C_2H_5	50 (0.27)
1,1-di(t-butylperoxy)cyclohexane	t-C_4H_9	$(CH_2)_5$		52–54 (0.02)
2,2-bis[4,4-di(t-butylperoxy)cyclohexyl]propane				117–120[b]

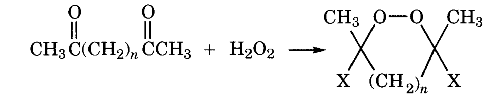
[a] To convert kPa to mm Hg, multiply by 7.5.
[b] Mp, °C.

before attempting distillations or kinetic decomposition studies. The low molecular weight diperoxyketals can decompose with explosive force and commercial formulations are available only as mineral spirits or phthalate ester solutions.

Di(hydroxyalkyl) Peroxides. The lowest molecular weight member of this group (**2**, X = Y = OH), di(hydroxymethyl) peroxide ($R^1 = R^2 =$ H) is a dangerously explosive solid. With increasing molecular weight, di(hydroxyalkyl) peroxides become liquids and eventually solids of decreasing explosive nature and water solubility. In solution, these dialkyl peroxides exist in equilibrium with other α-oxygen-substituted peroxides, carbonyl compounds, and hydrogen peroxide.

Formaldehyde reacts with di(hydroxymethyl) peroxide and phosphorus pentoxide to form di(hydroxymethoxymethyl) peroxide (**2**), where X = Y = OCH_2OH, $R^1 = R^2 =$ H.

Reaction of 1,3- and 1,4-diketones (n = 1 or 2) with hydrogen peroxide yields cyclic di(hydroxyalkyl) (X = OH) or di(hydroperoxyalkyl) (X = OOH) peroxides (**7**).



(**7**)

The di(hydroxyalkyl) peroxide (**2**) from cyclohexanone is a solid which is produced commercially. The di(hydroxyalkyl) peroxide (**2**) from 2,4-pentanedione (**7**, n = 1; X = OH) is a water-soluble solid which is also produced commercially (see Table 5). Both these peroxides are used for curing cobalt-promoted unsaturated polyester resins.

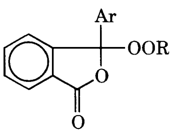
Hydroxyalkyl Hydroperoxyalkyl Peroxides. There is evidence that hydroxyalkyl hydroperoxyalkyl peroxides (**2**, X = OH, Y = OOH) exist in equilibrium with their corresponding carbonyl compounds and other α-oxygen-substituted peroxides. Thermal decomposition of hydroxyalkyl hydroperoxyalkyl peroxides produces mixtures of starting carbonyl compounds, mono and dicarboxylic acids, cyclic diperoxides, carbon dioxide, and water.

Di(hydroperoxyalkyl) Peroxides. Low molecular weight di(hydroperoxyalkyl) peroxides (**2**, X = Y = OOH) are dangerously prone to explosive decomposition when they are pure. Some have been characterized by acylation to the corresponding diperoxyesters.

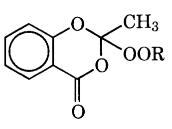
Cyclic Peroxides. Cyclic diperoxides (**4**) and triperoxides (**5**) are solids and the low molecular weight compounds are shock-sensitive and explosive. The melting points of some characteristic compounds of this type are given in Table 5.

Polymeric α-Oxygen-Substituted Peroxides. Polymeric peroxides (**3**) are formed from the following reactions: ketone and aldehydes with hydrogen peroxide, ozonization of unsaturated compounds, and dehydration of α-hydroxyalkyl hydroperoxides; consequently, a variety of polymeric peroxides of this type exist. Polymeric peroxides are generally viscous liquids or amorphous solids, are difficult to characterize, and are prone to explosive decomposition.

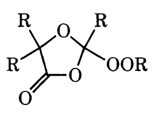
Miscellaneous α-Substituted Peroxides. 3-Aryl-3-(*tert*-alkylperoxy)-phthalides (**8**) are prepared from the corresponding 3-chlorophthalides and *tert*-alkyl hydroperoxide. 2-Methyl-2-(*tert*-alkylperoxy)-1,3-benzodioxan-4-ones (**9**) are obtained from *o*-acetylsalicyloyl chloride and *tert*-alkyl hydroperoxides. Trisubstituted 2-(*tert*-alkylperoxy)-1,3-dioxolan-4-ones (**10**) are synthesized from sterically favored α-acyloxy acid chlorides and *tert*-alkyl hydroperoxides.



(**8**)



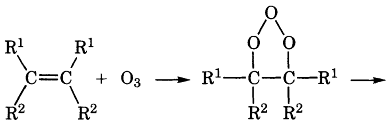
(**9**)



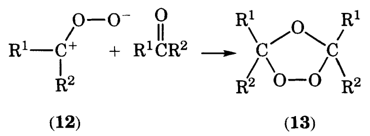
(**10**)

Ozonides and Ozonization

Unsaturated compounds undergo ozonization to initially produce highly unstable primary ozonides (**11**), i.e., 1,2,3-trioxolanes, also known as molozonides, which rapidly split into carbonyl compounds (aldehydes and ketones) and 1,3-zwitterion (**12**) intermediates. The carbonyl compound-zwitterion pair then recombines to produce a thermally stable secondary ozonide (**13**), also known as a 1,2,4-trioxolane.



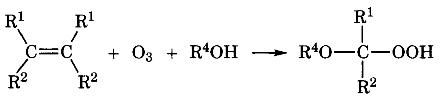
(**11**)



(**12**) (**13**)

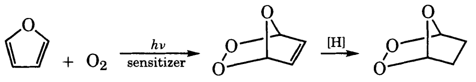
Most ozonolysis reaction products are postulated to form by the reaction of the 1,3-zwitterion with the extruded carbonyl compound in a 1,3-dipolar cycloaddition reaction to produce stable 1,2,4-trioxanes (ozonides) (**13**) as shown; with itself (dimerization) to form cyclic diperoxides (**4**); or with protic solvents, such as alcohols, carboxylic acids, etc., to form α-substituted alkyl hydroperoxides. The latter can form other peroxidic products, depending on reactants, reaction conditions, and solvent.

In the presence of alcohols, the ozonization products are alkoxyalkyl hydroperoxides (**1**, X = OR^4, R = H_3):



By-products include ozonides (**13**). Other peroxidic products including polymeric peroxides and polymeric ozonides can form, depending on reaction conditions, solvent, and olefin used. A variety of cyclic diperoxides (**4**) have been obtained by ozonolysis of olefins. Boiling point data for several 1,2,4-trioxanes are listed in Table 8.

Cyclic 1,2,4-trioxanes (**14** and **15**) have been obtained from the photosensitized oxidation of furans. These compounds are 2,3,7-trioxabicyclo [2.2.1] hept-5-ene (**14**) and 2,3,7-trioxabicyclo [2.2.1] heptane (**15**).



(**14**) (**15**)

Peroxyacids

There are two broad classes of organic peroxyacids: peroxycarboxylic acids, $R[C(O)OOH]_n$, where R is an alkyl, aralkyl, cycloalkyl, aryl,

TABLE 8. BOILING POINTS OF SOME 1,2,4-TRIOXOLANES[a]

1,2,4-Trioxolanes	Structure	Bp, °C (kPa)[b]
1,2,4-trioxolane		18 (2.13)
3,5-dimethyl-1,2,4-trioxolane		15 (2.67)
3,3-dimethyl-1,2,4-trioxolane		42–42.5 (18.67)

[a] Secondary ozonides.
[b] To convert kPa to mm Hg, multiply by 7.5.

or heterocyclic group and $n = 1$ or 2, and organoperoxysulfonic acids, $RSO_2{-}OOH$.

Three peroxyacids are produced commercially for the merchant market: peroxyacetic acid as a 40 wt % solution in acetic acid, *m*-chloroperoxybenzoic acid, and magnesium monoperoxyphthalate hexahydrate. Other peroxyacids are produced for captive use, e.g., peroxyformic acid generated *in situ*, as an epoxidizing agent.

Physical Properties. Physical properties of peroxyacids have been extensively reviewed in the literature. The melting points of some peroxycarboxylic acids are listed in order of increasing number of carbon atoms in Table 9. Aliphatic peroxyacids are characterized by sharp unpleasant odors, the intensity of which decreases with increasing chain length. They also are irritating to the skin and mucous membranes.

Chemical Properties. Organic peroxyacids are not noted for their stability and many lose active oxygen during storage at room temperature. Those that are water soluble hydrolyze slowly to the parent acid and hydrogen peroxide; however, peroxyformic acid hydrolyzes more rapidly. The longer-chain aliphatic members decompose rapidly in methanol. Stabilizers are commonly used for peroxycarboxylic acid solutions, e.g., dipicolinic acid, phytic acid, and pyro- and metaphosphates. Stability of peroxycarboxylic acids increases with increasing molecular weight. The stabilities of peroxybenzoic acids are enhanced when ring substituents are present.

Peroxycarboxylic acids and precursors to peroxycarboxylic acids are used as bleaches for removal of stains and soils from textiles. Precursors to peroxycarboxylic acids are nonperoxidic compounds possessing a reactive acyl group and a good leaving group, L. These precursors react under basic conditions with hydrogen peroxide, inorganic perborates, and inorganic percarbonates to generate peroxycarboxylic acids or salts:

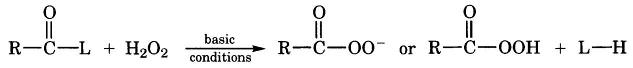

TABLE 9. PROPERTIES OF SOME ORGANIC PEROXYACIDS

Peroxyacid	Structure	Mp, °C
peroxyformic acid	HCO_3H	−18[a,b]
peroxyacetic acid	CH_3CO_3H	0[d]
peroxypropionic acid	$C_2H_5CO_3H$	−13[d]
peroxybutyric acid	n-$C_3H_7CO_3H$	−10[e]

magnesium monoperoxyphthalate hexahydrate		93

[a] 90 wt % melts at the given temperature.
[b] Bp = 50°C at 13.33 kPa[c].
[c] To convert kPa to mm Hg, multiply by 7.5.
[d] Bp = 25°C at 1.6 kPa[c] for peroxyacetic acid, and 2.67 kPa[c] for peroxypropionic acid.
[e] Bp = 26–29°C at 1.6 kPa[c].
[f] Bp = 41–43°C at 0.067 kPa[c].

Thermal decompositions of peroxycarboxylic acids and their salts can proceed by free-radical and nonradical paths. Often the decomposition products and the rate are affected by the nature of the solvent. Peroxycarboxylic acids undergo photodecomposition and radical-induced decomposition. They also are decomposed by a variety of metals, metal ions, and complexes.

Peroxycarboxylic acids are among the most powerful organic peroxide oxidizing agents. The main industrial uses of these acids are in the manufacture of epoxides, synthetic glycerol, and epoxy resins. They also have been used as disinfectants, fungicides, and bleaching agents and for shrink-proofing wool.

Synthesis. Many different methods for the preparation of peroxyacids have been described. The most widely used method is the direct, acid-catalyzed equilibrium reaction of 30–98 wt % hydrogen peroxide with carboxylic acids: The equilibrium also can be shifted to the right by removing water azeotropically and/or under a vacuum. Chelating agents may be added during processing to reduce metal-catalyzed decompositions. Sulfuric acid, methanesulfonic acid, and sulfonic acid ion-exchange resins are the most commonly used acid catalysts.

Other methods for preparing peroxycarboxylic acids include: (*1*) autoxidation of aldehydes, (*2*) reaction of acid chlorides, anhydrides, or boric-carboxylic anhydrides with hydrogen or sodium peroxide, and (*3*) basic hydrolysis or perhydrolysis of diacyl peroxides.

Organoperoxysulfonic acids and their salts have been prepared by the reaction of arenesulfonyl chlorides with calcium, silver, or sodium peroxide; treatment of metal salts of organosulfonic acids with hydrogen peroxide; hydrolysis of di(organosulfonyl) peroxides, $R^2S(O){-}OO{-}S(O)R^2$, with hydrogen peroxide; and sulfoxidation of saturated, nonaromatic hydrocarbons, e.g., cyclohexane.

Other Peroxyacids. Benzeneperoxyseleninic acid has been prepared *in situ* from benzeneseleninic acid and hydrogen peroxide and is used to epoxidize terpenic olefins and Baeyer-Villiger oxidation of cyclic ketones.

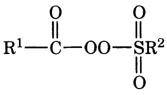
Acyl Peroxides

The acyl peroxide class is characterized by the following structures:

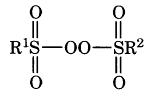
(**16**)

(**17**)

(**18**)



(**19**)



(**20**)

Acyl peroxides of structure (**16**) are known as diacyl peroxides. In this structure R^1 and R^2 are the same or different and can be alkyl, aryl, heterocyclic, imino, amino, or fluoro. Acyl peroxides of structures (**17**), (**18**), (**19**), and (**20**) are known as dialkyl peroxydicarbonates, *OO*-acyl *O*-alkyl monoperoxycarbonates, acyl organosulfonyl peroxides, and di(organosulfonyl) peroxides, respectively. R^1 and R^2 in these structures are the same or different and generally are alkyl and aryl. Many diacyl peroxides (**16**) and dialkyl peroxydicarbonates (**17**) are produced commercially and used in large volumes.

Physical Properties. Almost all liquid diacyl peroxides (**16**) and concentrated solutions of the solid compounds are unstable to normal ambient temperature storage; many must be stored well below 0°C. Most of the solid compounds are stable at ca 20°C but many are shock-sensitive. Other physical constants and properties have been reviewed. The melting points and refractive indexes of some acyl peroxides are listed in Tables 10–12.

Chemical Properties. Diacyl peroxides (**16**) decompose when heated or photolyzed (<300 mm). Although photolytic decompositions generally produce free radicals, thermal decompositions can produce nonradical and radical intermediates, depending on diacyl peroxide structure. Symmetrical aliphatic diacyl peroxides of certain structures, i.e., diacyl peroxides (**16**, $R^1 = R^2 =$ alkyl) without α-branches or with a mono-α-methyl substituent,

TABLE 10. PROPERTIES OF SOME DIACYL PEROXIDES

dioctadecanoyl peroxide	*n*-$C_{35}H_{17}$	76.5–76.9
UNSYMMETRICAL, $R^1 = CH_3$; R^2 AS GIVEN		
acetyl propionyl peroxide	C_5H_2	[d]
acetyl cyclohexyl carbonyl peroxide	cyclo-$C_{11}H_6$	42
acetyl benzoyl peroxide	C_5H_6	37–39
adipoyl bis(acetyl peroxide)	$CH_3\overset{\overset{O}{\|}}{C}OO\overset{\overset{O}{\|}}{C}(CH_2)_4—$	61–62

[a] Most of these peroxides decompose on melting, some violently.
[b] $n_D^{25} = 1.4340$.
[c] $n_D^{20} = 1.4382$.
[d] $n_D^{20} = 1.4069$.

and diaroyl peroxides (**16**, $R^1 = R^2 =$ aryl) thermally decompose almost exclusively by homolysis.

Diaroyl peroxides and diacyl peroxides without α-branches are significantly more thermally stable than those with mono- or di-α-substituents. The primary use of most commercial diacyl peroxides (**16**, $R^1 = R^2 =$ alkyl or aryl) is initiation of free-radical reactions.

Diacyl peroxides (**16**, $R^1 = R^2 =$ alkyl or aryl) also undergo radical induced decomposition either by direct radical displacement on the oxygen–oxygen bond, or by radical addition to, or abstraction from, the hydrocarbyl group adjacent to the peroxide.

Diacyl peroxide decompositions also are catalyzed by the metal ions of copper, iron, cobalt, and manganese:

$$R^1—\overset{\overset{O}{\|}}{C}—OO—\overset{\overset{O}{\|}}{C}—R^2 + Cu^+ \longrightarrow R^1—\overset{\overset{O}{\|}}{C}O\cdot + R^2—\overset{\overset{O}{\|}}{C}O^- + Cu^{2+}$$

This radical-generating reaction has been used in synthetic applications, e.g., aroyloxylation of olefins and aromatics, oxidation of alcohols to aldehydes, etc.

Hydrolysis and perhydrolysis of diacyl peroxides yields peroxycarboxylic acids. Carbanions react by displacement on oxygen.

acetyl (1-methycyclohexane)-sulfonyl peroxide		liquid
di(benzenesulfonyl) peroxide	$[C_5H_6-S(O)_2-O-]_2-$	53–54
di(*p*-toluenesulfonyl) peroxide	$[p\text{-}C_4H_6-CH_3-S(O)_2-O-]_2-$	50

[a] Most listed peroxides decompose at mp; some decompose violently.

Amines also react with diacyl peroxides by nucleophilic displacement on the oxygen–oxygen bond forming an ion pair intermediate.

$$R^1—\overset{\overset{O}{\|}}{C}—OO—\overset{\overset{O}{\|}}{C}—R^1 + :N\!\!< \longrightarrow \left[R^1—\overset{\overset{O}{\|}}{C}—O^- \quad —\overset{+}{N}—O\overset{\overset{O}{\|}}{C}—R^1 \right]$$

Dialkyl peroxydicarbonates (**17**) undergo thermolysis to form two alkoxycarbonyloxy radicals that subsequently undergo β-scission to form CO_2 and alkoxy radicals:

$$R^1O—\overset{\overset{O}{\|}}{C}—OO—\overset{\overset{O}{\|}}{C}—OR^1 \longrightarrow 2\,R^1O—\overset{\overset{O}{\|}}{C}—O\cdot \longrightarrow 2\,R^1O\cdot + 2\,CO_2$$

These low temperature peroxides are susceptible to radical-induced decompositions. This susceptibility largely accounts for the hazards associated with their production and storage. In contrast to diacyl peroxides (**16**); the true first-order decomposition rates for dialkyl peroxydicarbonates (**17**) are not affected by the nature of the R group. In free-radical scavenging

solvents, e.g., trichloroethylene, the decomposition rates of di-*n*-propyl, diisopropyl, di-*sec*-butyl, dicyclohexyl, di-2-ethylhexyl, and deheaxadecyl peroxydicarbonates are all essentially the same.

Dialkyl peroxydicarbonates are used primarily as free-radical initiators for vinyl monomer polymerizations. Dialkyl peroxydicarbonate decompositions are accelerated by certain metals, concentrated sulfuric acid, and amines. Violent decompositions can occur with neat or highly concentrated peroxides.

Acyl organosulfonyl peroxides (**19**) such as acetyl cyclohexanesulfonyl peroxide are efficient radical initiators for vinyl chloride polymerization.

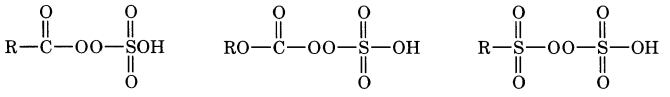
Di(arenesulfonyl) peroxides (**20,** $R^2 = R^1$ = aryl) react with aromatic solvents to form aryl arenesulfonates. These peroxides also form 1:1 adducts with styrene and form hydrobenzoin diarenesulfonates with stilbenes. Di(benzenesulfonyl) peroxide decomposes in water to phenol and sulfuric acid.

Synthesis. Symmetrical diacyl peroxides (**16,** $R^2 = R^1$ = alkyl or aryl) are prepared by the reaction of an acyl chloride or anhydride with sodium peroxide or hydrogen peroxide and a base. Unsymmetrical diacyl peroxides (**16**, $R^2 \neq R^1$ = alkyl or aryl) are prepared by the reaction of acid chlorides or anhydrides with peroxycarboxylic acids in the presence of a base. Polymeric diacyl peroxides can be prepared from the reaction of dibasic acid chlorides, e.g., succinoyl, fumaryl, sebacoyl, and terephthaloyl chlorides, with sodium or hydrogen peroxide. Cyclic diacyl peroxides can be generated from suitable dibasic acid chlorides and sodium or hydrogen peroxide, especially in dilute solutions. Symmetrical or unsymmetrical diacyl peroxides (**16,** R^1, R^2 = alkyl or aryl) can be synthesized directly from carboxylic acids and hydrogen peroxide or from peroxycarboxylic acids with dicyclohexylcarbodiimide or *N,N*-dicarbonyldiimidazole as condensing agents.

Diacyl peroxides (**16,** $R^2 = R^1$ = alkyl or aryl) have been obtained from the oxidation of carboxylic acid potassium salts by Kolbe electrolysis or by elemental fluorine.

Dialkyl peroxydicarbonates (**17**) are produced by reaction of alkyl chloroformates with sodium peroxide. *OO*-Acyl *O*-alkyl monoperoxycarbonates (**18**) are obtained from the reaction of alkyl chloroformates with peroxycarboxylic acids in the presence of a base. Symmetrical di(organosulfonyl) peroxides (**20**, R = R21) have been prepared by the reaction of organosulfonyl chlorides with sodium peroxide or hydrogen peroxide in the presence of a base. Acyl organosulfonyl peroxides (**19**) are prepared from the organosulfonyl chlorides and a metal salt of a peroxycarboxylic acid. Acetyl cyclohexanesulfonyl peroxide has been produced commercially by the sulfoxidation of cyclohexane, C_6H_{12}, in the presence of acetic anhydride.

Potassium salts of the peroxides (**21–23**) are prepared from the reaction of Caro's acid, H_2SO_5, with acyl chlorides, chloroformates, or organosulfonyl chlorides in the presence of potassium hydroxide.



(**21**) (**22**) (**23**)

Alkyl Peroxyesters

Peroxyesters include the alkyl esters of peroxycarboxylic acids; monoperoxydicarboxylic acids; diperoxycarboxylic acids; monoperoxy- (**24**) and diperoxycarbonic (**25**) acids; monoperoxy- (**26**) and diperoxyoxalic (**27**) acids; peroxycarbamic acids (**28**); peroxysulfonic acids (**29**); and peroxyphosphoric acids.

Synthesis. Peroxyesters are prepared by the reaction of alkyl hydroperoxides R′OOH, with acylating agents, e.g., acid chlorides, anhydrides, ketenes, organosulfonyl chlorides, phosgene, alkyl chloroformates, oxalyl chloride, alkyl chlorooxalates, isocyanates, carbamoyl chlorides, carboxylic acids, and esters, under appropriate reaction conditions, according to Figure 2. Reactions with acylating agents that generate hydrogen chloride are carried out in the presence of a base, e.g., pyridine or sodium hydroxide, or by using the sodium or potassium salt of the hydroperoxide.

Physical Properties. Properties of some *tert*-alkyl peroxyesters are listed in Table 13 and the properties of some *tert*-alkyl areneperoxysulfonates are given in Table 14.

Chemical Properties. Alkyl peroxyesters are hydrolyzed more readily than the analogous nonperoxidic esters and yield the original acids and hydroperoxides from which they were prepared rather than alcohols and

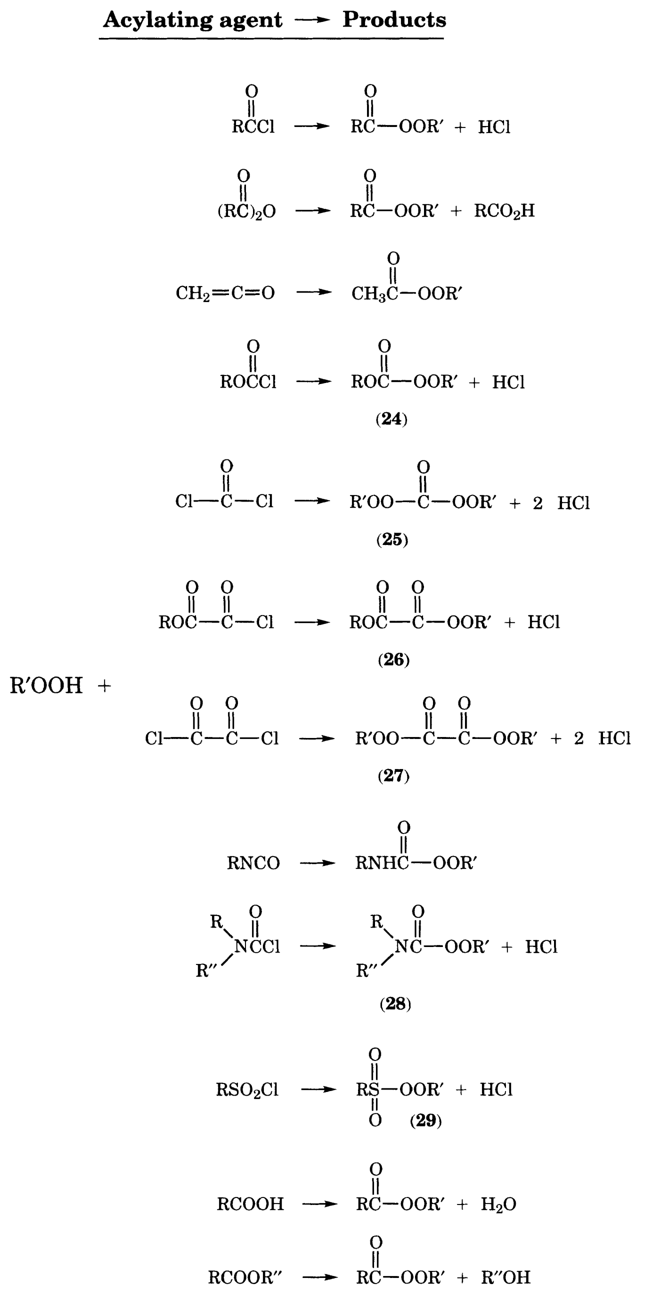


Fig. 2. Synthetic routes to alkyl peroxyesters. The acylating agent reacts with R′OOH in each case

peroxyacids. The *tert*-alkyl peroxyesters undergo homolysis, thermally and photochemically, to generate free radicals.

Primary and secondary alkyl peroxyesters thermally decompose by a nonradical process, giving almost quantitative yields of carboxylic acids and carbonyl compounds. *tert*-Alkyl peroxyesters are much less sensitive to radical-induced decompositions than diacyl peroxides. Induced decomposition is only significant in peroxyesters containing nonhindered α-hydrogens or α, β-unsaturation.

Peroxyesters decompose by an electron-transfer process catalyzed by transition metals. This reaction has been used synthetically to bond an acyloxy group to appropriate coreactive substrates.

Criegee rearrangement competes with homolysis in *tert*-alkyl peroxyesters, $RC(O){-}OOCR^1R^2R^3$, in which R is strongly electron-withdrawing and the *tert*-alkyl group, i.e., $CR^1R^2R^3$, contains a group with high migratory aptitude and ability to stabilize adjacent carbonium ions. The rearrangement converts the peroxyester to a nonperoxidic ester.

The main industrial use of *tert*-alkyl peroxyesters is in the initiation of free-radical chain reactions, primarily for vinyl monomer polymerizations.

TABLE 13. PROPERTIES OF SOME *TERT*-ALKYL PEROXYESTERS

Name	R	Mp, °C	Bp, °C (kPa)[a]
	R′ = *tert*-butyl$(CH_3)_3C-$

Manufacture and Processing

Owing to the inherent hazards of organic peroxides, they are almost never distilled or confined during manufacture. Generally, open reactors are employed that can be easily vented and deluged with water if an unanticipated exotherm occurs. The preferred materials of reactor construction are 316 stainless steel, plastic, and glass. Significant cooling capacity is required to handle reaction exotherms and to maintain temperature. Because over 100 different organic peroxides are produced commercially, organic peroxide producers manufacture many organic peroxides in the same equipment. Batch processing is generally employed when relatively small production volumes are required, whereas semicontinuous and continuous processing are employed when larger production volumes are required and when safety is a primary issue. Continuous processes are significantly safer to operate than batch processes as smaller amounts of organic peroxides are continuously in process. Besides safer continuous processing, another trend has been the use of reactants of higher purity. These process improvements have resulted in reduced environmental impact as unplanned process decompositions have been decreased and waste streams have been reduced.

Economic Aspects

Prices of commercial organic peroxides range from ca \$2.50 to >\$35/kg, depending on peroxide type, production volume, assay, nature of formulation, cost of raw materials, and degree of special processing and handling requirements.

Health and Safety Factors

Toxicology. In general, organic peroxides are characterized by a low order of acute toxicity. Most organic peroxides have some oxidizing properties and are irritants. Most of the available toxicity data on commercial organic peroxides are summarized in the literature. There is limited evidence to suggest that organic peroxides are carcinogenic.

Decomposition Hazards. The main causes of unintended decompositions of organic peroxides are heat energy from heating sources and mechanical shock, e.g., impact or friction. In addition, certain contaminants, i.e., metal salts, amines, acids, and bases, initiate or accelerate organic peroxide decompositions at temperatures at which the peroxide is normally stable. These reactions also liberate heat, thus further accelerating the decomposition. Commercial products often contain diluents that desensitize neat peroxides to these hazards. Commercial organic peroxide decompositions are low order deflagrations rather than detonations.

The organic peroxides and peroxide compositions produced commercially are those that can be manufactured, shipped, stored, and used safely. Organic peroxides can be thermally and mechanically desensitized by wetting or by dilution with suitable solvents, inert solid fillers, or insoluble

liquids (suspension of solid peroxides in liquid plasticizers or water, and emulsions of liquid peroxides in water).

Recommendations for safe handling and storage of commercial organic peroxides are available from organic peroxide manufactures.

In 1984 the United Nations (UN) Committee on the Transportation of Dangerous Goods, made up of experts from Prins Maurits Laboratory (TNO), Bundesanstalt für Materialprüfung (BAM), and the organic peroxide producers, developed a test procedure for the classification of organic peroxide compositions for transport purposes. The test procedure was accepted by most of the industrial countries of the world. The Department of Transportation (DOT) mandated that the United States peroxide industry would comply with the UN classification system by October 1993. Material Safety Data Sheets (MSDS) and the organic peroxides producers' recommendations should be followed carefully for handling and storage of organic peroxide compositions.

Uses

There are more than 100 commercially available organic peroxides in well over 300 formulations, e.g., neat liquids and solids, and pastes, powders, solutions, dispersions, and emulsions, that have utility in many commercial applications.

Excluding the peroxyacids, which are used primarily as epoxidizing and bleaching agents, approximately 90% of the commercial organic peroxides are consumed by the polymer industry.

They are used in the polymer industry as thermal sources of free radicals. They are used primarily to initiate the polymerization and copolymerization of vinyl and diene monomers.

Organic peroxides also are used as flame-retardant synergists for polystyrene, for preparing block and graft copolymers, for reactive processing, for reducing the molecular weight of polypropylene (i.e., controlled rheology or vis-breaking), for curing adhesives, for drying alkyd resin films, and for initiating cationic polymerization with cyclic ethers and maleic anhydride.

BPO is the preferred bleaching agent for flour and has been used to bleach gums, waxes, fats, and oils. It is the active ingredient in many acne medications. Diacyl peroxides have been used as burnout agents for acetate yarn, drying agents for Chinawood oils, and as free-radical sources in many organic syntheses. Di-*tert*-butyl peroxide is used as an ignition accelerator for diesel fuels and has been used in many organic syntheses either as a source of *tert*-butoxy (photo) or methyl (thermal) radicals.

PERRHENIC ACID. $HreO_4$. Exists only in solution, commercially available as aqueous syrup. Strong very stable, monobasic acid; extremely soluble in water and organic solvents.

PERRIN RULE. Ions of charge opposite to that of a diaphragm have by far the greatest effect on endosmosis. The higher their valence (or opposite sign) the greater the reduction of electroosmotic flow.

PERTHITE. An alkali feldspar comprising parallel or subparallel intergrowths. The potassium-rich phase, usually microcline, seems to be the host from which the sodium-rich phase, usually albite inclusions, exsolved. The exsolved areas typically form blebs, films, lamellae, small strings, or irregular veinlets and usually are visible to the naked eye.

PERTURBATION. 1. A small contribution to a physical quantity, such that the problem into which the quantity enters can be solved exactly or in a far simpler manner than otherwise if the perturbation is neglected. The form in which a perturbation is most frequently used in both classical and quantum mechanics is a small additional energy, called the *perturbation energy*.

2. Any departure introduced into an assumed steady state of a system. The magnitude of the departure is often assumed to be small so that product terms in the dependent variables may be neglected; the term *perturbation* is therefore sometimes used as synonymous with small perturbation. The perturbation may be concentrated at a point or in a finite volume of space; or it may be a wave (sine or cosine function); or, in the case of a rotating system, it may be symmetric about the axis of rotation.

3. In molecular spectra, perturbations cause the displacement of a band from its regular position in the band system (vibrational perturbation) or the displacement (and/or weakening) of corresponding lines in the different branches of a band (rotational perturbation). A perturbation observed in the spectrum is indicative of the presence of a perturbation (shift) of one of the energy levels involved due to interaction with another level of the same, or nearly the same, energy.

4. A much more frequent use is made of perturbation methods in quantum mechanics. The mathematical complexity of many quantum mechanical problems is such that one cannot hope to obtain exact solutions. However, good predictions can sometimes be obtained by means of perturbation theory, if one can assume that the actual system differs only slightly from a simpler system for which the problem can be solved, and the neglected difference can be dealt with as a perturbation of this simpler unperturbed system. The effect of a weak electromagnetic field on an atom, for instance, can be dealt with as a perturbation, and the transition probabilities between the energy states of the unperturbed atom can be calculated by means of perturbation theory. A weak interaction between two particles can be dealt with as a perturbation in the collision process of the two particles. The perturbation methods can be time-independent or time-dependent, according to whether the unperturbed states are described by time-independent wave functions or time-dependent ones. If the strength of a weak interaction between two systems is proportional to a constant parameter, the wave functions and energy values of the wave equation can be expanded in powers of this constant. The zero-order approximation is given by the unperturbed wave functions and energy values which are independent of this parameter. These determine the first-order approximations together with that part of the wave equation that is linear in the coupling parameter. By successive approximations one obtains expressions for second, third, and higher order perturbations in the wave function and the energy. If an unperturbed energy state is degenerate, that is, if two or more states have the same unperturbed energy, the effect of the perturbation has to be taken into account first between these degenerate states.

PERUTZ, MAX F. (1914–2002). An Austrian molecular biologist and recipient of the Nobel prize for chemistry in 1962 along with John C. Kendrew. His work was concerned with crystalline protein structure, particularly the molecular structure of hemoglobin and myoglobin. His education was in England and Austria.

PETALITE. The mineral petalite, lithium aluminum silicate ($LiAl\,Si_4O_{10}$), is monoclinic, although crystals are rare, this mineral usually occurring in cleavable, foliated masses, whence the name petalite, from the Greek meaning a *leaf.* Its hardness is 6–6.5; specific gravity 2.39–2.46. It is brittle with subconchoidal fracture; perfect basal cleavage; luster, vitreous, colorless to white or gray but may be greenish or reddish; transparent to translucent. Petalite occurs in granite pegmatites with sodium-rich feldspar, quartz, and lepidolite; has been found in Sweden; the former U.S.S.R.; on the Island of Elba; and in the United States at Bolton, Massachusetts, and Peru, Maine. It is interesting to note that lithium was first discovered in this mineral. See also **Lithium**.

PETROCHEMICALS. Chemicals derived from petroleum and, more specifically, substances or materials manufactured from a component of crude oil or natural gas. See Fig. 1. In this sense, ammonia and synthetic rubber made from natural gas components are petrochemicals. Many of these chemicals are described in separate articles in this encyclopedia. Check alphabetical index.

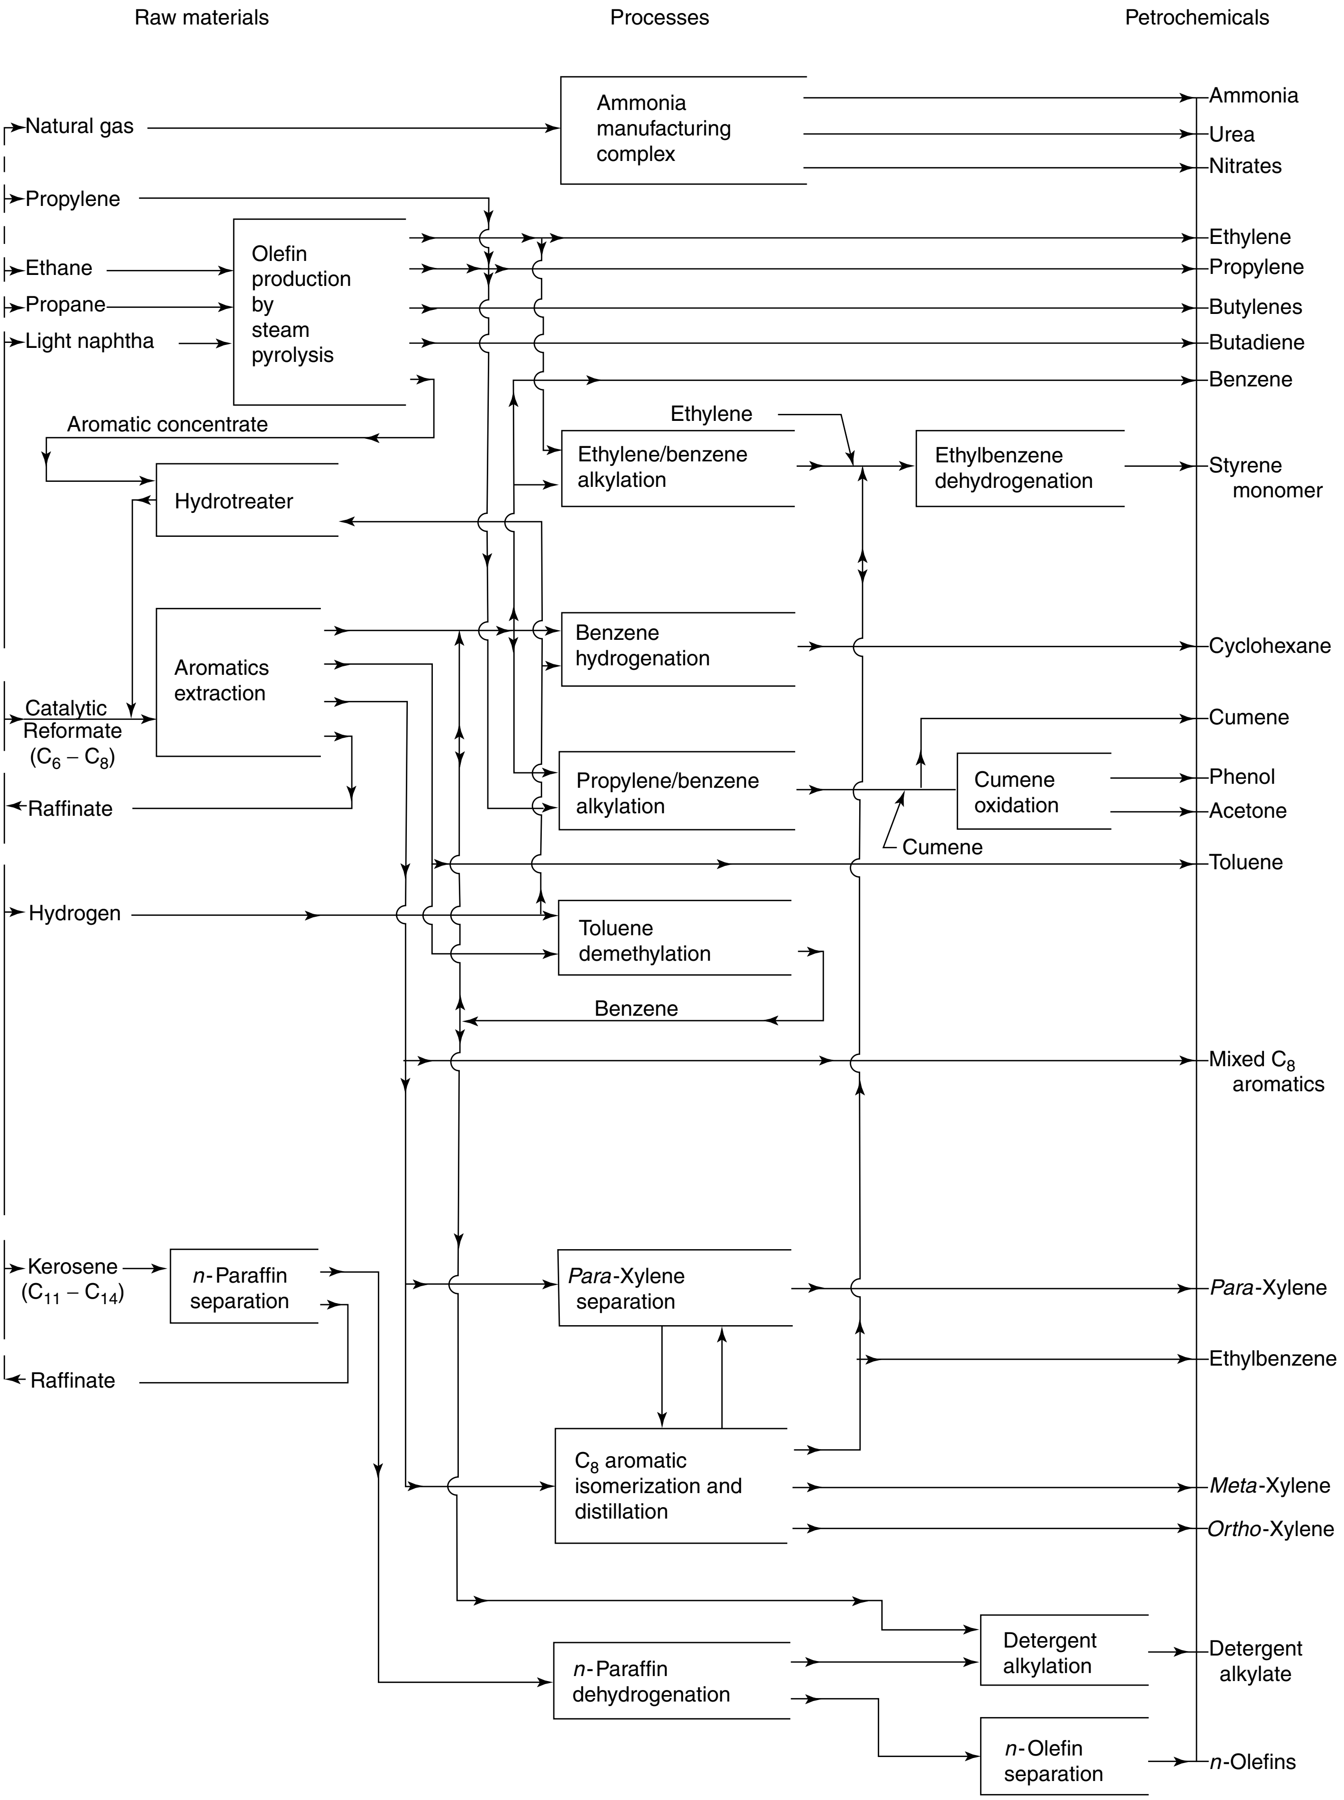

Fig. 1. Interlocking processes and flow of materials in a representative petrochemical complex. (*UOP, Inc*)

Fig. 2. Portions of a representative solvent-producing plant, using petrochemicals as raw materials

Among the most important petrochemicals manufactured are:

Acetic acid	Ethylene dichloride	Phenol
Acetone	Ethylene glycol	Polyethylene
Acrylonitrile	Ethylene oxide	Polypropylene
Benzene	Formaldehyde	Polyvinyl chloride
Cumene	Isopropyl alcohol	Styrene
Cyclohexane	Maleic anhydride	Toluene
Ethylbenzene	Methanol	Vinyl chloride
Ethylene	Phthalic anhydride	Xylenes

The chemical unit operations, such as distillation, extraction, and various separation operations, and the chemical unit processes, such as alkylation, dehydrogenation, hydrogenation, and isomerization, are essentially identical to those operations used in the manufacture of chemicals from other sources.

In order to save materials transportation costs, a petrochemical plant frequently will be located adjacent to a petroleum refinery or gas processing plant. Short pipelines can be used in place of leasing long pipelines or having to depend upon tank car shipments by rail or truck. This also contributes to the overall safety of production. A representative petrochemical plant adjacent to a refinery is shown in Fig. 2 on.

An excellent report of the petrochemical industry is prepared annually by the *Oil and Gas Journal* and *Hydrocarbon Processing* magazine.

PETROLATUM. A semisolid or liquid mixture of hydrocarbons derived by distillation of paraffin-base petroleum fractions. The solid form (mineral jelly) may be either water-white or pale yellow. Its chief uses are in mild ointments, cosmetics, softener in rubber mixtures and food processing (release agent in bakery products, dehydrated fruits and vegetables), defoaming agent (beet sugar, yeast). The liquid form (white mineral oil) is used as a laxative, textile lubricant and dispersing agent. There are three grades of both solid and liquid types with various specifications (USP, NF, and FCC).

PETROLEUM. A natural oil, ranging in color through black, brown, and green, to a light amber shade. It is often termed crude oil, and consists principally of hydrocarbons, that is, compounds of carbon and hydrogen, but varying amounts of oxygen-, nitrogen-, and sulfur-bearing compounds are almost invariably present. The term *mineral oil*, which was and is often used as a synonym for petroleum, is inadequate, for most geologists believe that it was derived from organic material resulting from reactions of organic materials such as plants and animals buried in sedimentary rocks. The more important of these geologic formations in which petroleum is found are the Tertiary period of the Cenozoic era (50% of the world's oil production comes from these rocks, including regions in California and the Gulf Coast of the United States. Russia, Venezuela, Malaysia, Iran, and Iraq); the Cretaceous period of the Mesozoic era (including the East Texas, Kuwait, and Bahrein fields); the Jurassic period of the Mesozoic era (including the Arkansas and Rocky Mountain regions of the United States, and Saudi Arabia); and the Mississippian period of the Paleozoic era (including the West Texas, Pennsylvania, and Mid-Continent regions of the United States, and the Alberta, Canada, fields).

Petroleum oils vary considerably in composition, even when closely associated geographically. In some areas of the United States, for example, crude oils near the surface may have quite a different chemical composition from those found in deeper strata. Depth alone, however, does not correlate significantly with composition.

Analysis of typical crude oils found in representative areas of the United States are given in Table 1. It may be generalized that crudes found in the eastern and midwestern sections of the United States are predominantly sweet and paraffinic; those found along the Gulf Coast usually are naphthenic; those occurring in the inland southwest are sour and naphthenic; and those found along the west coast are asphaltic. The waxy, sweet paraffinic oils found in Pennsylvania first became prominent because of the high quality of lubricating oils and greases that could be made from them. The severe stresses imposed by the bearings and close-fitting reciprocating surfaces of machinery led to the development of refining processes and the discovery of additive materials whereby many other crude oils also can be transformed into excellent lubricants. Even Pennsylvania oils require special refining and additives to meet present quality specifications.

Analyses of some crude petroleums found outside the United States are given in Table 2, which illustrates the variety of crudes existent, but is not intended to give a full representation of worldwide petroleum source compositions.

API Gravity. This parameter (API stands for American Petroleum Institute), expressed in "degrees," is mathematically related to specific gravity and can be determined with a hydrometer. The specific gravity of water (arbitrarily defined as unity) is 10.00 when expressed as degrees API. API gravity usually, although not infallibly, indicates the gasoline and kerosine contents of the crude. As an example, the Mississippi, Texas, New Mexico, and Louisiana crudes have API gravities between approximately 35 and 40; as do the Arabian, Iranian, and Colombian crudes. The gasoline content (that fraction boiling below about 400°F (204°C) of these crudes ranges from about 25% to over 35% by volume. The kerosene portions of such "light" crudes also are usually high. In contrast, Wyoming sour crude with an API gravity of 17.9 contains but 6% gasoline and about 40% asphalt. California crude has an even greater content of residuum and almost no gasoline.

Sulfur Content. The amount of sulfur in crude is important in terms of handling the crude within the refinery and the undesirable effects of sulfur in finished products. High-sulfur crudes require special materials of construction for refinery equipment because of their corrosiveness. Certain refinery processes require desulfurization of sour charge stocks prior to use as a feedstock, not only because of their corrosiveness, but also because of the effect of sulfur-bearing compounds on expensive catalysts. From the standpoint of the consumer, sulfurous gasoline has an unforgettably offensive odor unless specially sweetened and it may corrode the fuel system and engine parts, as well as pollute the atmosphere after it has been burned.

Other factors indicated in the data of Tables 1 and 2 include: **Pour Point**—defined as the lowest temperature at which the material will pour and a function of the composition of the oil in terms of waxiness and bitumen content; **Salt Content**—which is not confined to sodium chloride, but usually is interpreted in terms of NaCl. Salt is undesirable because of the tendency to obstruct fluid flow, to accumulate as an undesirable constituent of residual oils and asphalts, and a tendency of certain salt compounds to decompose when heated, causing corrosion of refining equipment; **Metals Content**—heavy metals, such as vanadium, nickel, and iron, tend to accumulate in the heavier gas oil and residuum fractions where the metals may interfere with refining operations, particularly by poisoning catalysts. The heavy metals also contribute to the formation of deposits on heated surfaces in furnaces and boiler fireboxes, leading to permanent failure of equipment, interference with heat-transfer efficiency, and increased maintenance.

Natural Gas, Oil Shales, and Tar Sands. Natural gas is not formally defined as a component of crude petroleum, although natural gas commonly exists in the same geological formations, often directly in contact with crude petroleum. However, a large percentage of natural gas wells are not associated with producing oil wells. See also **Natural Gas**.

The oils derived from oil shales are not true petroleum, although they are petroleumlike products after being subjected to specialized chemical processing. Shales are sedimentary rocks that have a relatively high content of a bituminous substance called *kerogen* and 30–60% organic matter and fixed carbon. Kerogen, although not a definite chemical compound, yields an oily substance when heated (retorted) in the absence of air. Extraction of oil shale with ordinary solvents produces no oil, and their solubility in solvents is low. This evidence supports the conclusion that the "oil" is the result of a chemical change, i.e., the thermal cracking or fragmenting (pyrolysis) of the molecules that make up kerogen. See also **Oil Shale**.

Tar sands is an expression commonly used in the petroleum industry to describe sandstone reservoirs impregnated with a very heavy viscous crude oil which cannot be produced through a well by conventional production techniques. Two other terms, *bituminous sands* and *oil sands*, are gaining favor. The heavy viscous petroleum substances impregnating the "tar sands" are called asphaltic oils. See also **Tar Sands**.

Petroleum processing and petroleum end-products are described in the article on **Petroleum Refining** immediately following this article.

Origin and Geology of Petroleum

Among the general theories for explaining the origin of petroleum, the most widely accepted is the *organic theory*, which can be quickly summarized. Over millions of years, rivers flowed to the seas, carrying large volumes of mud and sand to be spread out by currents and tides over the sea bottoms near the gradually changing shorelines. New deposits were distributed, layer upon layer, over the floors of the seas. Because of the increasing weight of these accumulations, the sea floors slowly sank, building up a thick series of mud and sand layers. High pressure and chemical forces ultimately converted these layers into sedimentary rocks of the type that often contain petroleum—the sandstones, shales, limestones, and dolomites. The organic theory further stipulates most importantly that tiny marine organisms were buried with the silt. In an airless environment and under high pressures and elevated temperatures, these carbon- and hydrogen-containing minuscule life-forms were converted over an extremely long time span into hydrocarbons. This theory, of course, requires acceptance of the concept of drastically altered shorelines, because obviously oil deposits are found in many parts of the world long distances from the present coastlines.[1]

Geologists find it particularly difficult to trace the history of a given hydrocarbon deposit, because the oil and gas may have moved as the result of numerous seismic events, again occurring over a very long time span. A past requisite for commercially exploitable hydrocarbon deposits has been prior movement and concentration of large quantities of hydrocarbons in various forms of *traps*. In contrast with oil shales and tar sands, natural gas and petroleum flow relatively easily in permeable underground structures and, consequently, tend to concentrate, greatly assisting the economic exploitation of these materials.

The movement of petroleum from the place of its origin to the traps where accumulations are found is believed to have occurred in an upward direction. This movement took place as the result of the tendency for oil and gas to rise through the ancient seawater with which the pore spaces of the sedimentary formations were filled when originally laid down. An underground porous formation or series of rocks which occur in some shape favorable to the trapping of oil and gas must also be covered or adjoined by a layer or rock that provides a covering or seal for the trap. A seal of this type, frequently called a *cap rock*, stops further upward movement of petroleum through the pore spaces.

As oil and gas gathered in the upper part of a trap, because of differences in weight of gas, oil, and salt water, these fluids also separated vertically, much in the same manner as if these materials were all present in a bottle.

[1] In a more recent, alternate theory, Thomas Gold (Cornell University) suggests that, in contrast with the organic sediments theory, the prime source of natural gas is primordial, abiotic methane rising from deep within the earth's mantle. This is discussed in further detail in the article on **Natural Gas**.

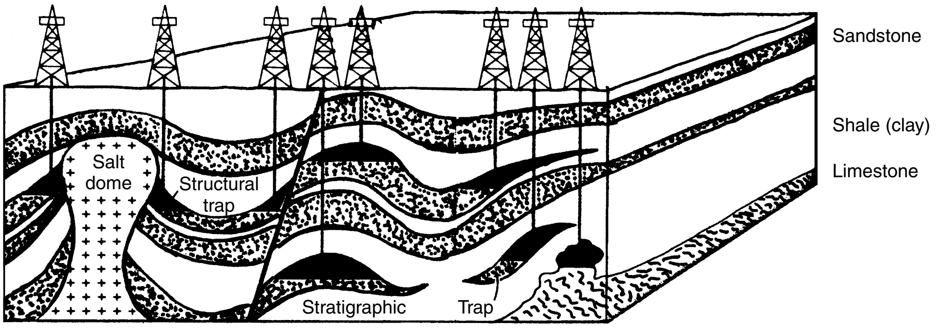

Fig. 1. Composite diagram showing different types of oil and gas accumulations (shown in solid black). *Structural traps* where petroleum deposits may have accumulated are often found along the edges of salt domes or along fault lines. *Stratigraphic traps* may exist where reservoir rock is "pinched off" by denser strata. These accumulations are the "pools" or "reservoirs" which, singly or in groups, compose an oil or gas "field." The pores of the reservoir rock contain oil or gas or both, always accompanied by briny water. The fluids tend to be layered, with gas at the top of the trap, oil in the middle, and water underneath. Most of the petroleum which ever existed has been obliterated, either by attenuation in the earth's crust, or by exposure to heat and pressure high enough to break down its chemical bonds. The accumulations that do exist have endured against long odds. Additional detail on oil and gas reservoirs will be found in Figs. 2 through 7

Thus gas, if any is present, is found in the highest parts of the trap, followed by oil (and oil with gas) below the gas, and finally salt water below the oil. Experience has indicated that the salt water seldom was completely displaced by oil or gas from the pore spaces, even within the trap. Even in the midst of oil and gas accumulation, pore spaces within the trap may contain from 10 to 50% or more of salt water. It appears that the remaining water (termed *connate water*) fills the smaller pores and also exists as a coating or film, covering the rock surfaces of the larger pore spaces; thus oil and/or gas are apparently contained in water-jacketed pore spaces. The geological structures called traps are petroleum reservoirs, i.e., they are the oil and gas fields that are explored and produced. All oil fields contain some gas, but the quantity may range widely. See also *Natural Gas*.

Types of Oil Accumulations

A composite diagram showing different types of oil and gas accumulations is given in Fig. 1.

Structural Traps. The attitude of the rocks, whether they are folded, fractured, displaced, or otherwise disturbed, is called their geologic structure. Traps that are due to geologic structure are known as *structural traps*.

A common structural trap, the *anticline*, is an upward bulge in the rock layers which forms an arch capable of holding oil under its apex. The buoyancy of oil and gas carries them upward through porous rock layers into the apex until they are trapped by an impermeable layer. Anticlinal type of folded structure is shown in Fig. 2. Reservoirs formed by folding of the rock layers or strata usually have the shapes shown in Fig. 2(a) and (b). These traps were filled by upward migration of oil and/or gas through the porous strata or beds to the location of the trap. Further movement was arrested by a combination of the forms of the structure and the seal or cap rock provided by the formation covering the structure.

Examples of domal structures are the Conroe Oil Field in Montgomery County, Texas and the Old Ocean Gas Field in Brazoria County, Texas. Another example of a reservoir formed by an anticlinal structure is the Ventura Oil Field in California.

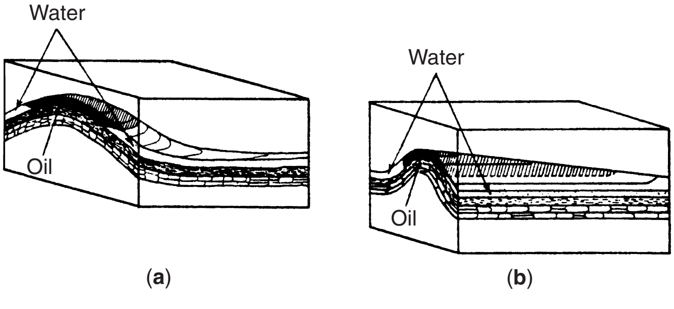

Fig. 2. Examples of anticline structural traps: (**a**) Oil accumulates in a dome-shaped structure. The dome is circular in outline. (**b**) Anticlinal trap that is long and narrow, differing from the dome configuration

Another type of structural trap is the *fault trap*. A fault is a fracture in the earth's crust along which movement has occurred such that a porous rock layer is offset by a nonporous layer. The oil moving along a porous stratum is dammed or blocked by an impermeable shale or limestone. See Fig. 3. Examples of fields of this type occur along the Mexia fault zone of East-Central Texas.

The *salt dome* is another interesting form of structural trap. This type of trap is found along the Gulf Coasts of Texas and Louisiana and in western Colorado and Utah. This type of structure resulted from the upward thrust of a great mass of salt far below the earth's surface. When a salt dome rose through a layer of oil-bearing sedimentary rock, oil may have been trapped in anticlines above the dome, or in structures similar to faults along its flanks. One famous example of a salt-dome reservoir is the Spindletop field, near Beaumont, Texas. It was "brought in" in 1901 by a 100,000-barrel-a-day gusher, giving birth to the modern petroleum industry. Another example of a salt-dome field is the Sugarland Oil Field in Fort Bend County, Texas. See Fig. 4.

Stratigraphic Traps. Petroleum geologists also seek another kind of trap, the *stratigraphic trap*, which results when a porous layer is "pinched"

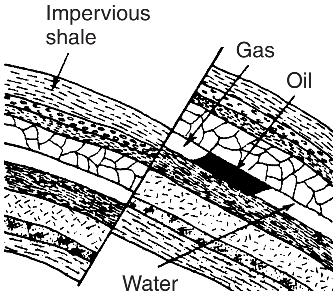

Fig. 3. Example of a fault structural trap. The oil is confined in traps like this because of the tilt of the rock layers and faulting

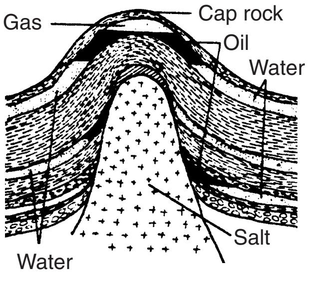

Fig. 4. Example of a salt-dome structural trap. One of the earliest and greatest reservoirs of this type was Spindletop, brought into production in 1901 and located near Beaumont, Texas

or phased out between two nonporous layers. Caught in an underground envelope of impermeable rock, the oil accumulates to form a reservoir. This type of trap may have formed from buried beaches or sandbars. The famous East Texas field is a "strat" trap. See Fig. 5. Because structural features such as anticlines and faults are often more obvious and easier for the geologist and geophysicist to detect, more fields thus far have been found in structural traps than in their stratigraphic counterparts. Stratigraphic traps are usually discovered only after exhaustive studies have been made of rock samples from outcrops and from core samples from wells drilled over large areas.

The serpentine plug, shown in Fig. 6, is an interesting type of trap, an example of which is the Hilbig Field in Bastrop County, Texas. As illustrated, a porous serpentine plug has formed a reservoir within itself by intruding into nonporous surrounding formations.

Lens-Type Traps. These form in limestone and sand. In this type of trap the reservoir is sealed in its upper regions by abrupt changes in the amount of connected pore space within a formation. A trap formed in sand is shown in Fig. 7(a). An example is the Burbank Field in Osage County, Oklahoma. This type of trap may occur in sandstones where irregular deposition of sand and shale occurred at the time the formation was laid down. In these cases, oil is confined within the porous parts of the rock by the nonporous parts of rock surrounding it. A lens-type trap formed in limestone is shown in Fig. 7(b). In limestone formations there are frequent areas of high porosity with a tendency to form traps. Examples of limestone reservoirs of this type are found in the limestone fields of West Texas.

Reef-Type Traps. These have accounted for some of the most important production in recent years. The reef is generally considered a type of stratigraphic trap. The reef was formed under the right combination of conditions by the remains of millions of small underwater animals. Building their limestone residences on top of those built by their ancestors, the tiny creatures produced columns or mounds, often reaching several hundred feet high. If eventually surrounded by impermeable rock layers, the reef could become a trap for oil and gas.

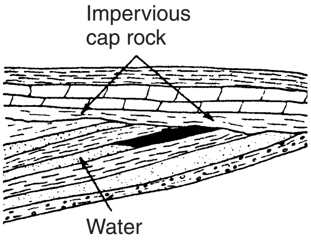

Fig. 5. Example of a stratigraphic trap. This unconformity represents the condition where upward movement of oil has been halted by the impermeable cap rock laid down across the cutoff (possibly by water or wind erosion) surfaces of the lower beds. This type of reservoir is found in the great East Texas field

Petroleum Production—Geophysics

In the petroleum industry, the word *production* is generally interpreted as the obtaining of crude oil, natural gas, and other related natural hydrocarbons, whether located in reservoirs under the land or under the oceans. Production generally does not relate to the manufacture of final end-products, such as naphtha, gasoline, diesel fuel, lubricating oils, etc. Products obtained by the processing of natural hydrocarbons are commonly referred to as *refined*. In a sense, then, petroleum production is analogous to other natural raw material mining, such as coal and metals mining.

The fundamental phases of petroleum production include: (1) the initial *exploration* required to find heretofore undiscovered oil and gas reservoirs; (2) *primary* and *secondary recovery* methods, which make use of both naturally occurring (or *primary*) reservoir energy and the application of *secondary* energy sources, such as the injection of gas or water; and (3) *enhanced oil recovery* used to increase ultimate oil production beyond that achievable with primary and secondary methods. Enhanced oil recovery (EOR) methods increase the proportion of the reservoir by improving the "sweep" efficiency, reducing the amount of residual oil in the swept zones (increasing the displacement efficiency), and reducing the viscosity of thick oils.

Petroleum Exploration

The exploration required to identify previously undiscovered oil and gas reservoirs is grossly affected by the economics and politics of the worldwide oil markets (supply and demand). The experience of one year cannot easily be extrapolated to that of subsequent years.

Although the petroleum geologist has for several years employed highly sophisticated instrumentation and computer technology, the fact remains that the geologist, in many respects, is still a *detective*, often commencing with the barest of clues and following the search hopefully to a successful conclusion. Decisions based on uncertain information are normal in petroleum exploration. How to capitalize on the creativity of the geological and geophysical scientists further complicates decision making.

Modern petroleum exploration geophysics is based on three important earth properties: (1) density, (2) magnetization; and (3) acoustic response.

Gravity Surveys. Gravitational pull is an effective way to measure the density of the strata lying far below the earth's surface. The *gravimeter* came into oil exploration use in about 1900. If there are dense rocks near the surface, a spring-loaded weight in the instrument will weigh more—obviously since denser rocks exert greater gravitational pull than those which are less dense. Usually, the denser rocks are older and their presence near or far from the surface indicates an underlying shallow or deep basement. Thus, a structural "high," such as an anticline, will often appear as a high reading on the gravimeter. Conversely, a structural "low," such as a syncline, will yield opposite effects. The low density of a salt dome will be reflected on the gravimeter as having a lesser gravity value. When using a gravity meter offshore, it is necessary to place the instrument so that it remains level, regardless of the movement of the vessel. The rise and fall of the ship and other effects of its travel must be measured by other equipment and taken into account when the gravity data are processed.

Magnetic Surveys. The natural magnetic properties of rocks can be useful in the early stages of petroleum exploration. More than three centuries ago, it was found that a freely suspended magnetic needle will move away from a level position in response to the presence of nearby iron. In 1879, this principle was applied in the first *magnetometer*, a simple device combining a magnetized needle with a compass. Both types and depths of rocks far underground affect how much and in which direction the needle will move.

Using a magnetometer, earth scientists can measure the depths at which basement rocks lie. These rocks are usually from the Precambrian period, dating back over 600 million years. They contain large amounts of magnetite, a naturally occurring iron oxide having magnetic properties. Where petroleum-bearing sedimentary rocks overlie these basement rock formations, the magnetometer can be used to indicate variations in the thickness of these sedimentary layers. This information can provide the geologist with a valuable clue as to the probability that those sediments, bent by the underlying basement rocks, may provide the right conditions for the accumulation of recoverable quantities of oil or natural gas.

It is not always necessary to place instruments on the ground to measure magnetic attraction of the subterranean rock layers. Magnetometers can also be used from aircraft flying high above the surface to determine quickly areas of general interest. Use of airborne magnetometers also eliminates the need for and the problems sometimes associated with personnel actually getting on the site.

Seismic Surveys. Gravity and magnetic measurements are considered preliminary. The principal detailing tool used is the seismograph.[2]

The type of experiment used to make a seismic survey in petroleum exploration will be determined by the type of information required, the types of rock strata anticipated, environmental considerations, the type of terrain, and, of course, the economic costs involved.

In petroleum exploration, reflection seismic surveying is the method predominantly used. The seismograph records variations in the way rocks reflect sound waves sent downward from a surface source. The reflected sound waves vary with the type, depth, density, and dip of the rocks encountered. The returning sound waves made from a series of points along the survey path can then be displayed graphically to form a seismic record for interpretation by earth scientists. These principles are diagrammed and explained in Fig. 8.

Four sources of energy may be used to generate the sound waves: (1) controlled explosives; (2) vibrators; (3) weight dropping (where heavy weights are dropped to create the waves); and (4) compressed gases (producing bursts of energy using compressed air or propane). In exploring onshore sources, controlled explosives and vibrators are most often used. In offshore work, compressed air guns are most frequently used. These sources have been shown to cause virtually no damage to marine life.

When *controlled explosives* are used, the most common method is to place carefully measured charges in shallow "shot holes" a few inches in diameter drilled from a truck-mounted drill. These charges are then detonated to produce the sound waves needed. In less accessible areas, a portable drill may be used and, in certain environmentally sensitive areas, the charges may be mounted on stakes above the ground to minimize plant disturbance.

Truck-mounted vibrators are frequently used. Metal plates, used singly or in groups, are pressed against the ground and vibrated briefly creating a frequency sweep similar to that used in radar, to send a brief acoustic signal into the ground. The vibrators cause little disturbance to the surrounding area and are often used in sensitive locations, in cities and along highways, where dynamite charges would be less acceptable. See Fig. 9.

The principles of seismic surveying are the same regardless of the type of equipment used. As the waves strike the various strata, some are reflected back to the surface, where they are picked up by sensing devices called *geophones* (on land) and *hydrophones* (offshore). See Fig. 10. These sensors convert acoustic information into electrical signals, whence the data are recorded on magnetic tape for processing at a computer center.

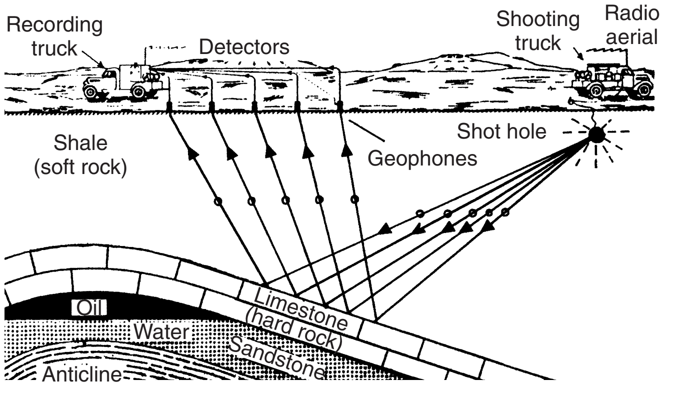

Fig. 8. Onshore seismic field operation, using the shot hole energy method. Energy from a controlled explosion is directed toward underlying rock structures and is reflected to indicate shape of formation below—in this case an anticline. Geophones placed on the ground surface by the surveying crew measure and record the reflected acoustic energy. With the survey truck safely away from the shot hole, the explosives are detonated by an assigned radio frequency from the truck

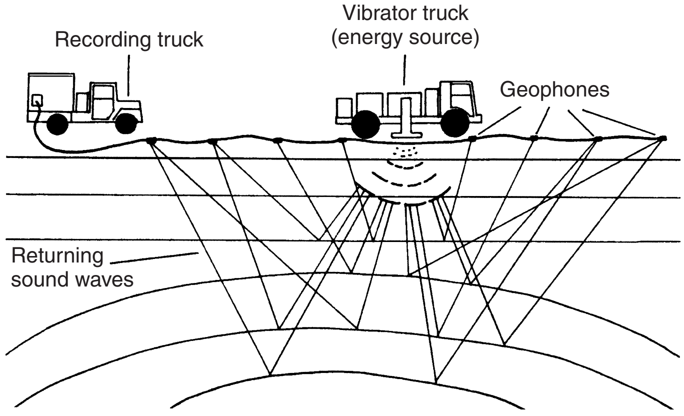

Fig. 9. Seismic survey using a truck-mounted vibrator as the energy source for creating reflected acoustic sounds. This method is used in sensitive areas near cities and along highways because disturbance to the environment is minimal. (*American Petroleum Institute*)

Seismic Data Processing. Continuing advances in technology, such as fiber optics, have enabled the capabilities of seismic surveys to be markedly increased so that, where required, a 3-dimensional picture of the rocks in the subsurface can be obtained. Advanced processing has also enabled discrete anomalies in seismic data from individual rock horizons to be analyzed. Under certain conditions, the presence of hydrocarbons can be directly detected. This analysis, sometimes referred to as "bright spot" technology, has been responsible for numerous discoveries in the Gulf of Mexico in recent years.

Raw data gathered from seismic surveys must be processed to compensate for and to remove a variety of distortions—unwanted noises created by weathered near-surface rocks, normal time delays, and echoing by rebounding acoustic waves—to provide the clearest possible image of the strata below. Computers can restore these distortions in a fraction of the time that was formerly required to adjust the data painstakingly by hand. Advanced techniques not only permit presentations in three dimensions, but also in color, and to create contour maps and models of subterranean features. However, even with the use of sophisticated tools, there remains a large measure of uncertainty. History has shown repeatedly that a prospective area rejected by one petroleum firm has been accepted by another and proved to be successful.

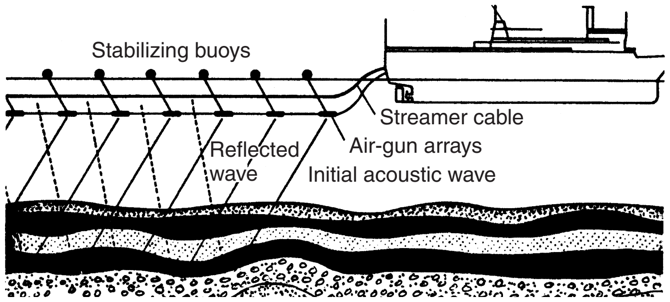

Fig. 10. In offshore exploration, vessels are specifically designed for seismic surveying. Instead of using the same equipment that is used on-shore, such as "surface shaking" machines and geophones, offshore seismic crews use chambers containing compressed gases or fluids to generate the acoustic signals and hydrophones to pick up the returning sounds. Air-gun arrays are trailed in the water behind the vessel as it plies along a predetermined survey line. The crew activates the chambers at set intervals from onboard controls connected by cables to the air guns. Other cables contain arrays of hydrophones to detect sounds that echo off the underlying strata. The vessels are kept on course through the use of radar, loran, and satellite navigation equipment. (*After Exxon*)

[2] The first "seismograph" is recorded to have been an inverted bronze urn with a pendulum inside and used by the Chinese in about 160 A.D. to announce earthquakes. Seismographs were "reinverted," so to speak, during World War I to locate heavy German artillery. In 1920, seismography for use in petroleum exploration was first demonstrated.

After thorough analysis of seismic and other exploration data, the next steps are management decision making and approval to proceed with exploratory drilling. The ultimate exploratory tool is the *drill bit*.

Exploratory Drilling

Onshore Drilling. When Col. Edwin Drake brought in the first commercial oil well in 1859, he struck oil at a depth of 59 feet, 8 inches (18.2 meters). See Fig. 11. Most early wells were less than 400 feet (122 meters) deep. Shallow oil and gas wells were fully exploited many years ago. Deep producing wells today often exceed depths of 25,000 feet (7,620 meters) and dry holes have been drilled to a depth in excess of 31,000 feet (9,449 meters). In an average year, wildcat wells reach a depth of about 6,000 feet (1,829 meters). Depth, however, is only one of the factors that makes the search for petroleum difficult in modern times. Increasingly, drilling must be done in remote places where it is costly to bring in materials and labor. For example, onshore locations, such as those found on the North Slope of Alaska, can result in drilling costs that are 10 times as high as they would be in the lower 48 states.

The Rotary Drill. This is the most commonly used method and consists of a rotary drill, a power source, a derrick and lifting and lowering devices, and a bit attached to a length ("string") of tubular high-tensile-strength steel. See Fig. 12. The drill string passes through a rotary table that turns it and thus provides the torque needed for the drilling operations. The weight applied to the formation is also a critical factor.

Shown in the upper right of this view is the *swivel* (front and side view) which permits the drill pipe to rotate while mud is pumped down to clean the hole. Shown in the lower right is a three-cone drill bit, with cutaway showing the bearings on which it rotates; and at the extreme lower right, the face of a diamond bit revealing openings through which fluids may pass. (*American Petroleum Institute; Exxon Corp.*)

During the drilling operation, a special *drilling mud* (mixture of clay, water, and chemical additives) is pumped down through the hollow drill string and bit into the borehole. The fluid is forced up the borehole and through the area between the drill string and the casing (the "annulus") to the surface. There it is cleaned and recirculated into the well. The fluid helps to cool and lubricate the bit, control the pressures within the well, provide a protective and stabilizing coating to some permeable formations, and brings the rock cuttings up the borehole to the surface. The consistency of the fluid is carefully monitored and adjusted to compensate for pressure changes within the well, as the bit penetrates the various rock strata.

Fig. 11. Colonel Edwin Drake (right) and Peter Wilson, a druggist who endorsed a $500 bank loan for Drake, confer in front of the world's first commercial oil well near Titusville, Pennsylvania. Initially, Drake rigged a large wheel powered by steam to raise and lower a cable and iron bit. Later connected to a crude drill pipe and pump, this well produced about 35 barrels a day. (*ca. 1861*)

"Spudding" is the actual start of drilling a well and is akin to the first shovel of dirt at groundbreaking. A large bit, frequently from 18 to 38 inches (46–97 cm) in diameter, is used to drill a hole to a depth of from 10 to 100 feet (3–30 meters). The hole is then lined with a conductor pipe ("casing"). The space between the casing and the drilled hole (the "borehole") is filled with cement.

Drilling is then resumed using a smaller bit and, after the borehole reaches several hundred feet (meters), the bit and drill string are hoisted out of the well and another length of pipe ("surface casing") is lowered into the borehold and cemented in place. Besides preventing the generally unconsolidated surface formation from sloughing into the hole, the casing also protects the freshwater strata ("aquifers") from being contaminated by the drilling mud.

As the drilling proceeds, additional casings of concentrically smaller diameter are lowered into the well and sealed in place until the final depth ("target zone") is reached. During the drilling, the drill bit and string must be removed from the well whenever the bit becomes dull and requires changing or cores are taken from the well. The coring process involves a special cylindrical rock bit, generally with a diamond-encrusted face and a cylinder ("core barrel") into which the core passes and is retained for recovery at the surface. These cores are analyzed to determine the type of rocks penetrated and their porosity, permeability, chemical analysis and possible hydrocarbon content. See Fig. 13.

Drilling Geometry. Deviation surveying was introduced into oil-well drilling technology in 1929. Before that time, it was generally assumed that a hole properly started as a vertical hole would remain essentially vertical. In many instances, this was not a realistic assumption because many "vertical" holes were found to be quite crooked. Crooked holes not only caused operational problems, but also resulted in false indications of depth. Since the early 1930s, drilling contracts usually have specified a maximum deviation of 3 to 5 degrees. The problem of drilling a straight hole usually is simpler with uniform materials, such as limestone, and more difficult when laminar formations of sandstone and shale are encountered. Often of even greater concern than a crooked hole is an irregular, "jagged" hole that does not have a graceful bending contour in the vertical. The presence of abrupt changes in angle interferes with the casing program and ultimately with production. Although the mechanics involved in causing nonvertical drilling are not fully understood, much has been learned through experience and great improvements in drilling have been made. For one thing, deviation results from flexibility of the drill string (drill collars), the forces acting upon the string causing it to bend. A relatively simple change to square collars, as shown in Fig. 14, has brought about marked improvement.

Of course, it is frequently desirable to utilize a controlled directional drilling technique. There are several reasons, as indicated by Fig. 15. The three most commonly patterned directional holes are shown in Fig. 16. The planned course of direction depends upon several factors, including rig capacity, hole size, mud program, types of formation, and the casing program. Meticulous surveying is required to achieve the desired results. Several types of drilling tools may be required.

Offshore Drilling. When exploration moves offshore, standard drilling equipment obviously must be supplemented by some sort of structure that provides a stable platform for operations. The structure also must be movable, given the odds against a single wildcat finding commercial quantities of petroleum.

The first offshore exploration in the 1930s in the Gulf of Mexico was conducted from rigs on barges which could be towed to drilling sites and submerged to rest on the bottom during operations. These were forerunners of the twin-hulled submersible rig, which has an upper hull housing crew quarters and working spaces and a lower hull providing the buoyancy needed to move the unit. See Fig. 17(a) on p. 2695.

The jack-up or self-elevated rig, introduced in the 1950s, is a barge with movable legs, which can be lowered to the sea floor and the barge jacked into drilling position above the water. Jack-ups are used in water depths up to about 300 feet (91 meters). See Fig. 17(b) on p. 2695.

In deeper waters, exploration is conducted from floating rigs, including submersibles and drill ships. Drill ships with conventionally shaped hulls of seagoing vessels are not so stable as semisubmersibles (semis) in rough waters, but can be moved from location to location much faster.

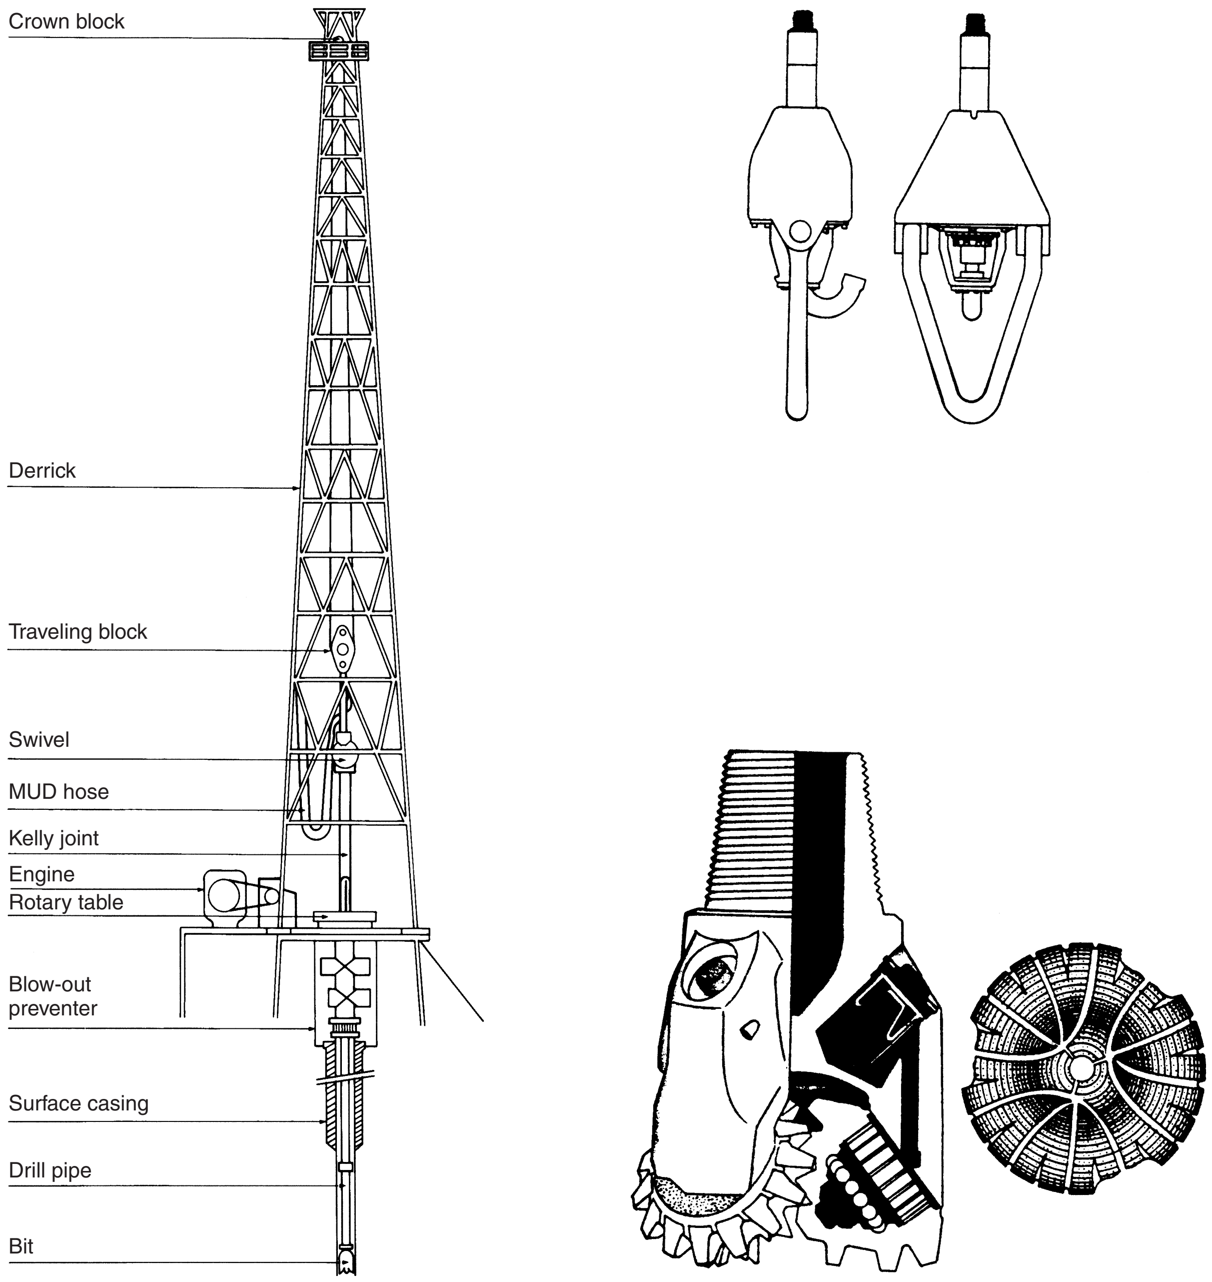

Fig. 12. A rotary rig has four systems. The *rotary system* consists of a turntable, a swivel, a square or hexagonal pipe length called a "kelly," which transmits rotary motion from the turntable to the drill pipe, and the drill "string" itself. A *circulating system* of pumps, hoses and other apparatus keeps mud circulating through the well. The *hoisting system* includes the derrick, a drawworks, hoisting blocks, and other equipment needed to lift and lower heavy pipe joints and casing. The *power system* usually consists of diesel engines and generators, set apart from the rig, which provide power for the electric motors that drive the rotary, hoisting, and pumping equipment. The elevated floor allows installation of blowout preventer beneath the platform

Fig. 13. Rock core samples cut by a diamond-faced core bit reveal underlying structure and the possible presence of hydrocarbons. (*Exxon Corp*)

A critical requirement of all floating rigs is the ability to maintain position over the wellhead while drilling proceeds. Semis and drill ships use either multiple anchors or "dynamic positioning" systems to keep on station. A dynamic positioning system uses thruster engines which, responding to signals from acoustic beacons on the sea floor, automatically make the adjustments required to maintain the rig in position. Hydraulic devices keep a constant tension on the drill string to prevent the up-and-down motion of the sea from being transmitted to the drill bit.

Semis and drill ships find limited use in arctic waters where ice covers the sea most of the year.

In offshore operations, exploration wells are almost always plugged and abandoned even when they strike petroleum. Their sole function is to find oil or gas and to delineate the reservoir. The operator uses this information to pick a location for a permanent production platform from which development wells will be drilled to recover as much petroleum as economically possible. In onshore operations, however, successful exploration wells also become producers.

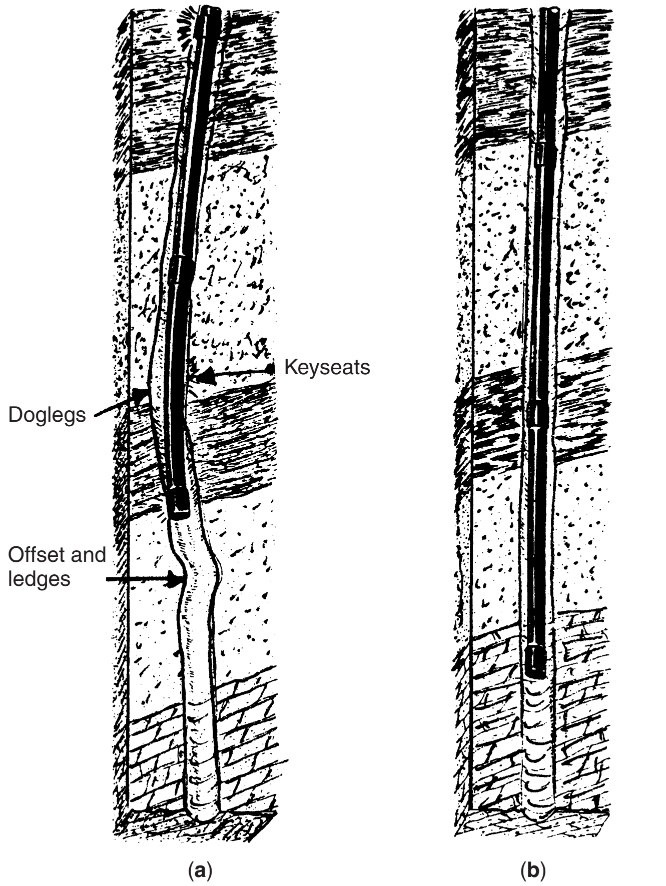

Fig. 14. Example of a crooked hole (**a**) drilled without a square collar, and a relatively straight hole (**b**) drilled with a square collar. (*Drilco*)

Measuring Well Characteristics

At selected intervals during the drilling, generally before the casing is run or when formations with hydrocarbon indications are encountered, measurements may be taken of the characteristics of the borehole and surrounding strata. Wire line logging tools are used.

In the early days of the industry, little was known about "downhole" geophysics, that is, the physical characteristics of the subsurface strata, how they might be measured, and what could be learned from such measurement. Since the Drake well, more than 3 million wells have been drilled in the United States. An estimated 27,000 fields have been found. With each new discovery, additional data become available and patterns begin to emerge. It was not until the late 1920s that technological changes were introduced that would have a lasting impact on "logging" (recording) the characteristics within the well during exploratory drilling. The first well-logging device (electrical resistivity log), invented by Conrad Schlumberger (France), was introduced into the United States. In 1934, a second development, the *spontaneous potential* (SP) *curve*, was introduced.

The *resistivity log* was lowered by cable into the borehole, with the drill bit and drill stem removed, thus enabling the recording of the electrical resistivity of the rock layers that the bit had penetrated. The record helped to identify the hydrocarbon content of the reservoir rock (since both oil and gas have different resistivities than does salt water). It was also used to correlate rock horizons between wells, which proved to be an invaluable tool in subsurface mapping.

The *SP Curve* recorded the differences in natural electrical potential between the fluids in the adjacent formations and those within the uncased borehole. This curve was soon accepted as an indicator of the porosity of the rock strata and as a means of locating the boundaries of rock beds. See Fig. 18.

Since then, a number of downhole measurements have been devised that use radioactive, acoustic, and electrical methods.

Presently, televiewers are used to look at rock features in boreholes and computers are programmed to compare, synthesize, and integrate the new range of measurements, thus providing more reliable information and definition of rock properties and formation fluids thousands of feet (meters) below the surface.

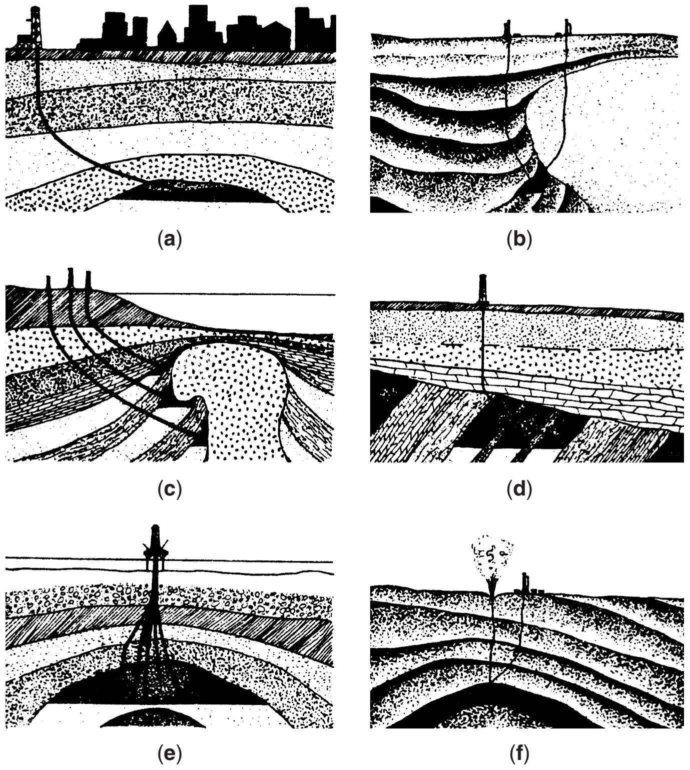

Fig. 15. Some applications for controlled directional drilling: (**a**) Reaching formations which lie below inaccessible locations, such as towns, rivers, and lakes. (**b**) Formations sometimes are found below the overhanging cap of a salt dome. A well may be drilled around this cap, or through the salt and deflected into the productive formation. (**c**) Formations below harbors or the ocean floors sometimes can be reached from rigs located on the shore. (**d**) Directional drilling into the intersection of several oil sands from a single wellbore. Obviously, a straight hole would be less effective in this type of situation, (**e**) Offshore drilling is usually most economic when several directional wells can be drilled from a single platform. As many as 20 or more wells can be drilled from a small area. (**f**) Drilling of a relief well to intersect a wild, cratered well near the source of pressure. Mud and water can be pumped in to kill the blowout. This technique, first used in 1934, helped to establish the importance of directional drilling. (*Petroleum Extension Service, The University of Texas at Austin*)

Until recently, these measurements could be taken only when the drill bit and string were removed from the borehole. However, in the mid-1980s, a new dimension was added, namely, *measurement while drilling* (MWD) instruments. These devices are mounted above the drill bit and around the drill string to provide a continuing source of data on downhole characteristics. This advancement reduces the drilling downtime previously required when measurements were taken.

Testing. Modern wire line logs will indicate with a good degree of accuracy the potential of a hydrocarbon zone. If the zone is sufficiently promising to warrant further study, a formation test will be undertaken.

Generally, a drill stem test is carried out—either in the open hole or after the hole has been cased. However, the case hole test is the most reliable.

Basically, the drill stem test involves attaching a tubing assembly to the end of the drill pipe, isolating the test zone with rubber packers, and perforating the zone. The tool is then opened so that the fluids or gas in the formation can flow up the drill pipe for metering at the surface. During this process, extensive pressure measurements are taken, which can help to indicate the extent of the reservoir and the rate at which the hydrocarbons could be recovered. Prior to describing how a well is finally completed (if the hole is not dry!), it is in order to describe the forces utilized to transfer the oil from the reservoir to the surface.

Well Drive Systems

It is convenient to classify oil and gas reservoirs in terms of the type of natural energy and forces available to produce the oil and gas. At the time

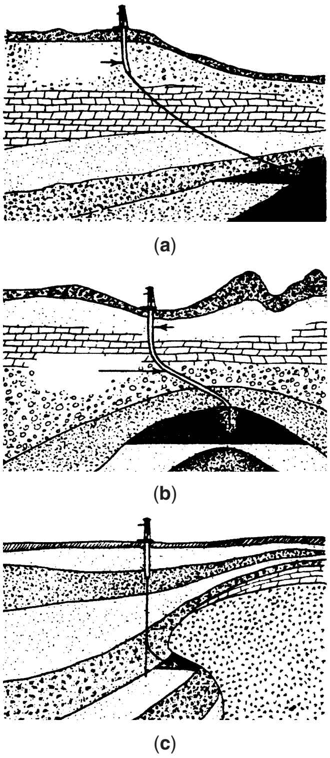

Fig. 16. Principal types of directional drilling patterns: (**a**) The most widely used directional drilling pattern is one in which the initial deflection is obtained at relatively shallow depth. Then, surface casing is set and cemented through the deviated section of hole. From that point, the angle is maintained as a straight line to the target zone. (**b**) This pattern is also initially deflected at shallow depth. Surface casing is set and cemented. Drilling continues on a straight line to a point where the hole is gradually returned to vertical. After intermediate casing is set, drilling is continued to final depth. This type hole is used when undesirable formations must be penetrated and isolated with an intermediate casing string. (**c**) In this pattern, deflection commences at a greater depth. Drift angle is maintained on a straight line to the target. This type hole may be used for exploratory drilling from a dry hole. Normally, the deflected part of this hole is not protected by casing during drilling operations. (*Petroleum Extension Service, The University of Texas at Austin*)

oil was forming and accumulating in reservoirs, pressure and energy in the gas and salt water associated with the oil were also being stored, which would later be available to assist in producing the oil and gas from the underground reservoir to the surface. Obviously, since oil cannot lift itself from reservoirs to the surface, it is largely the energy in the gas or the salt water (or both), occurring under high pressures with the oil, that furnishes the force to drive or displace the oil through and from the pores of the reservoir into the wells.

In nearly all cases, oil in an underground reservoir has dissolved in it varying quantities of gas that emerges and expands as the pressure in the reservoir is reduced. As the gas escapes from the oil and expands, it drives oil through the reservoir toward the wells and assists in lifting it to the surface. Reservoirs in which the oil is produced by dissolved gas escaping and expanding from within the oil are called *dissolved-gas-drive reservoirs*. See Fig. 19.

Often more gas exists with the oil in a reservoir than the oil can hold dissolved in it under the existing conditions of pressure and temperature in the reservoir. This extra gas, being lighter than the oil, occurs in the form of a cap of gas over the oil. This condition was previously illustrated by Figs. 3 and 4. See also Fig. 20. Such a gas cap is an important additional source of energy because, as production of oil and gas proceeds and as the reservoir pressure is lowered, the gas cap expands to help fill the pore spaces formerly occupied by the oil. Where conditions are favorable, some of the gas coming out of the oil is conserved by moving upward into the gas cap to further enlarge the gas cap. As compared with the dissolved-gas drive, the *gas-cap drive* is more effective, yielding greater recovery of oil. The gas-drive process is typically found with the discontinuous, limited, or essentially closed reservoirs of the types previously shown in Figs. 6 and 7(a). See also Fig. 20.

Where the formation containing an oil reservoir is quite uniformly porous and continuous over a large area, as compared with the size of the soil reservoir per se, very large quantities of salt water exist in surrounding parts of the same formation, often directly in contact with the oil and gas reservoir. This condition is demonstrated by previously shown Figs. 2, 3, 4, and 5. These large quantities of salt water occur under pressure and provide a large additional store of energy to assist in producing oil and gas. A situation like this is termed *water-drive reservoir* and is shown in Fig. 21. The energy supplied by the salt water comes from expansion of the water as pressure in the petroleum reservoir is reduced by production of oil and gas. Water will compress, or expand, to the extent of about one part in 2500 per 100 psi (6.8 atmospheres) change in pressure. Although this effect is slight with reference to small quantities, the phenomenon becomes of importance when changes in reservoir pressure

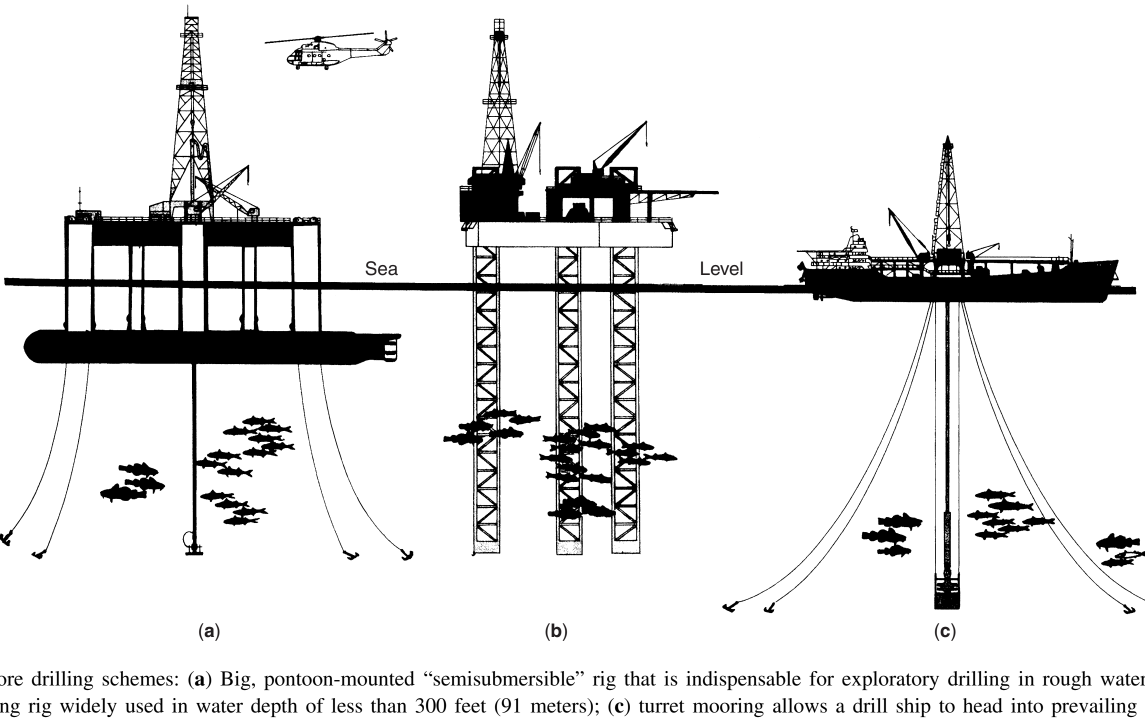

Fig. 17. Offshore drilling schemes: (**a**) Big, pontoon-mounted "semisubmersible" rig that is indispensable for exploratory drilling in rough water; (**b**) self-elevating or *jack-up* drilling rig widely used in water depth of less than 300 feet (91 meters); (**c**) turret mooring allows a drill ship to head into prevailing winds and currents while positioned over the well. Helicopters and boats are required to transport personnel to and from offshore well sites. (*Exxon Corp*)

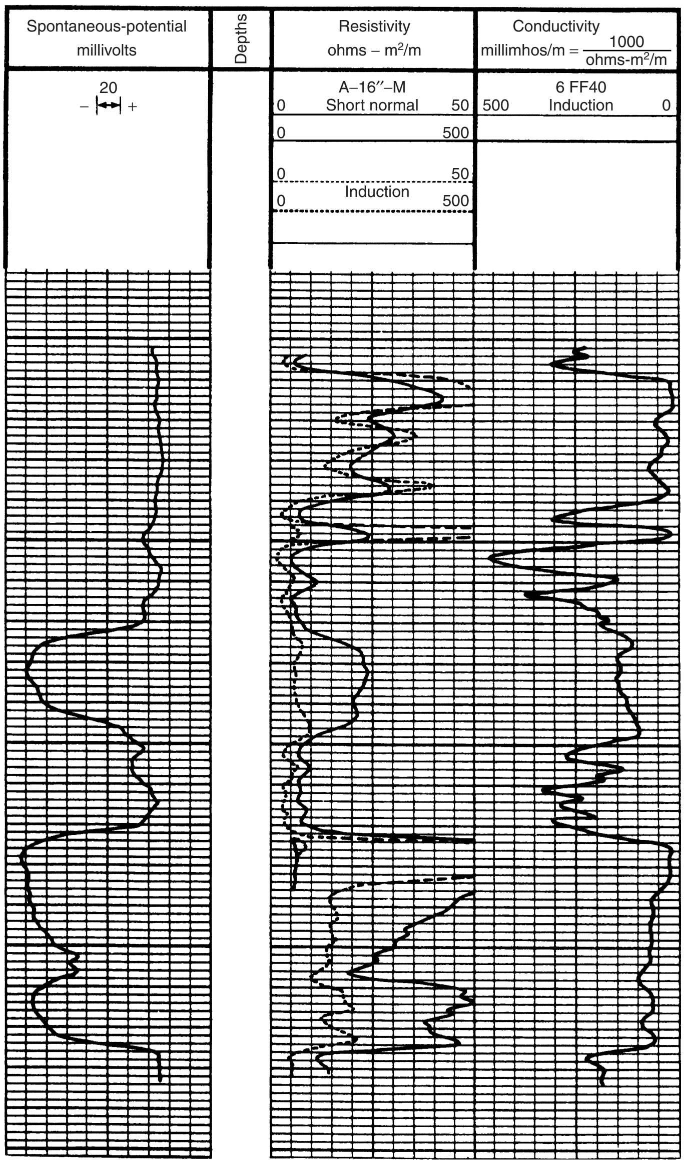

Fig. 18. Oil well logging provides valuable information on the "down-hole" characteristics of oil and gas wells. Spontaneous potential (SP), electrical resistivity/conductivity logs are frequently recorded simultaneously

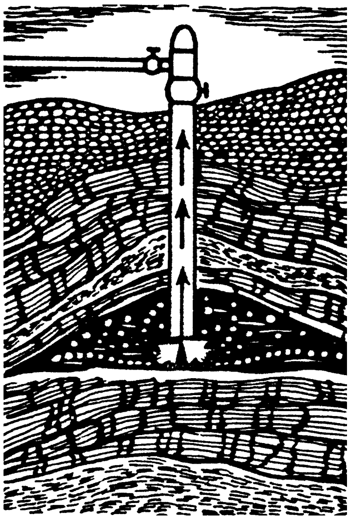

Fig. 19. Dissolved-gas drive. (*Texas Mid-Continent Oil and Gas Association*)

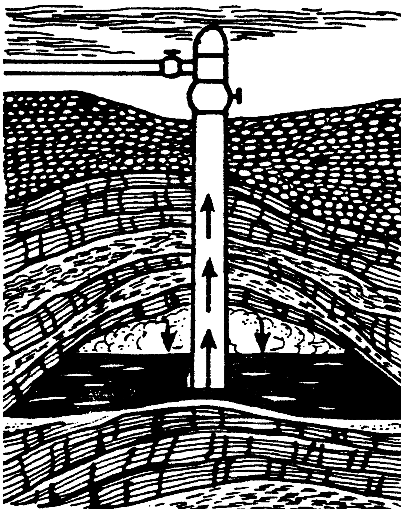

Fig. 20. Gas-cap drive. (*Texas Mid-Continent Oil and Gas Association*)

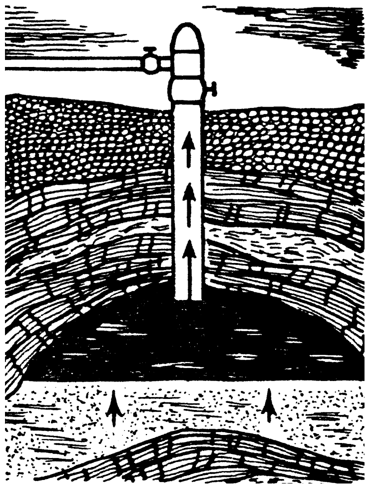

Fig. 21. Water drive. (*Texas Mid-Continent Oil and Gas Association*)

affect large volumes of salt water that are often contained in the same porous formation adjoining or surrounding a petroleum reservoir.

The expanding water moves into the regions of lowered pressure in the oil- and gas-saturated portions of the reservoir caused by production of oil and gas, and retards the decline in pressure. In this way, the expansive energy in the oil and gas is conserved. As shown in Fig. 4, the expanding water also moves and displaces the oil and gas in an upward direction out of the lower parts of the reservoir. By this natural process, the pore spaces vacated by oil and gas produced are filled with water, and oil and gas are progressively moved toward the wells.

The water drive is generally the most efficient oil-production process. Oil fields in which water drive is effective are capable of yielding recoveries ranging up to 50% of the oil originally in place, if (1) the physical nature of the reservoir rock and of the oil are conducive to the process, (2) care is exercised in completing and producing the wells, and (3) the rate of withdrawal of products is optimal.

When pressures in an oil reservoir have fallen to the point where a well will not produce by natural energy, some method of artificial lift must be used. Oil-well pumps are of three general types: (1) pumps located at the bottom of the hole run by a string of rods, (2) pumps at the bottom of the hole run by high-pressure liquids, and (3) bottom-hole centrifugal pumps. Another method involves the use of high-pressure gas to lift the oil from the reservoir.

Well Completion

Production casing must be set through which the oil and/or gas can be brought safely to the surface. The "pay zone" (productive area) is then sealed off with cement. With the production casing in place, hollow charges

are fired through it into the production formation and the drilling mud is gradually displaced, so that the hydrocarbons can flow into the well-bore and up to the surface. There, a "Christmas tree" (an assembly of valves and special connectors) is attached to the top of the production casing. This device controls the flow of oil or gas into the gathering pipelines. See Fig. 22.

Deepwater Production

Two basic types of platforms may be used in deepwater production—*fixed leg* and *compliant*. Each has its advantages and limitations. These facilities can provide all the functions required for drilling, completing, producing, and maintaining conventional wells or a combination of conventional and subsea wells.

Nearly all offshore fields have been developed with fixed-leg platforms. In 1947, for example, a fixed-leg platform weighing 1200 tons was in operation in 20 feet (6 meters) of water out of sight of land. Twenty years later, such platforms weighing in excess of 6500 tons were in use in 340 feet (104 meters) of water. See Fig. 23. To date (1986), the tallest fixed-leg platform, weighing 58,000 tons, is located in 1025 feet (312 meters) of water in the Gulf of Mexico. This platform, completed in 1979, has a total height from seabed to top of the derricks of 1265 feet (386 meters)—taller than the Empire State Building in New York City.

This type of design, known as the "steel jacket," accounts for most of the hundreds of platforms that dot the Gulf of Mexico. For larger oil fields, such as the North Sea, platforms must withstand severe environmental forces, handle large volumes of oil, gas, and water, support heavy equipment, and accommodate 200 to 300 production workers. Here, a favored type is the concrete "gravity platform," so called because its own immense weight pins it to the sea bottom and no piles are needed to secure it. Rigid platforms are impractical in waters much more than 1000 feet (305 meters) deep. An alternative for deeper water is a "compliant" structure, such as a guyed tower, a slender steel tower held in place by a radial array of anchor cables. Heavy weights attached to the cables lie on the bottom some distance away; these keep the cables taut under normal sea conditions and lift gradually in storms, to allow the tower to tilt slightly to absorb wave forces.

When a platform is not a practical way to develop an offshore field, the operator may "complete" the well using a submerged production system, in which case, the Christmas tree and other wellhead equipment are installed on the sea bottom and pipelines are connected to carry off the petroleum, either to shore, to a nearby platform, or to a vessel or storage buoy moored in the area. Divers can be used to make the necessary connections.

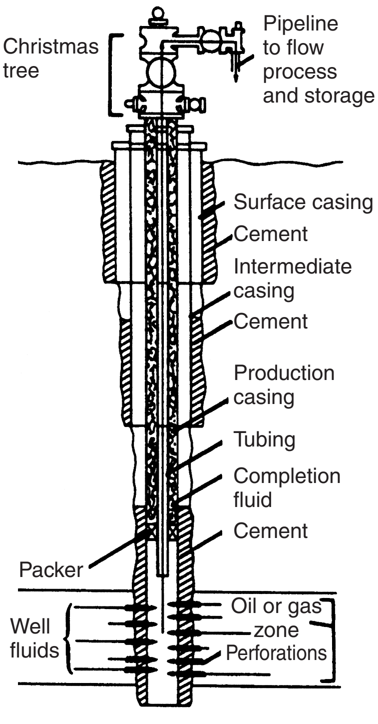

Fig. 22. Completed oil well showing the flow of oil into and up the well to the pipeline connection at the Christmas tree. (*American Petroleum Institute*)

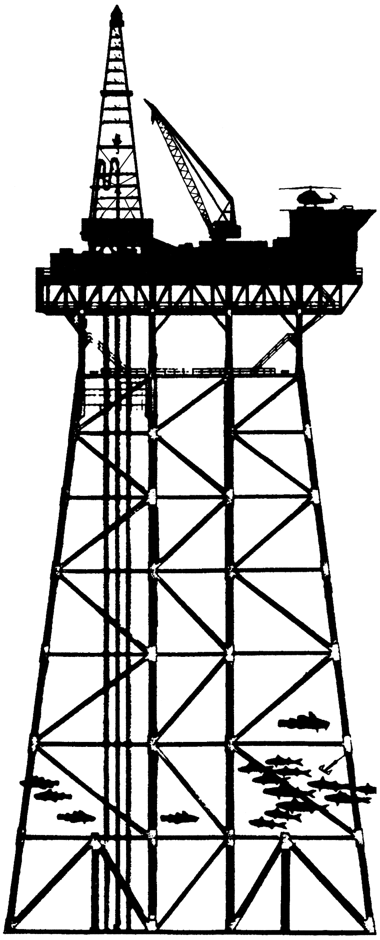

Fig. 23. Fixed-leg offshore drilling and production platform of the "steel jacket" variety. (*Exxon Corp*)

For deepwater applications, the industry is continuing to develop remote, diverless techniques for installation and maintenance of these completions.

Enhanced Oil Recovery

Enhanced oil recovery (EOR) methods increase ultimate oil production beyond that achievable with primary and secondary methods. This is accomplished by increasing the proportion of the reservoir affected. EOR methods are of three broad groups: (1) thermal, (2) miscible, and (3) chemical.

Thermally Enhanced Recovery. Because oil becomes thinner and flows more easily when it is heated, considerable effort has been devoted to the development of techniques that introduce heat into a reservoir to improve recovery of the heavier, more viscous crude oils. Hot water flooding has been tried, but it is seldom used today because it contains too little heat energy and is very slow to warm the oil and rock surrounding an injection well. More heat is needed for efficiency.

Steam contains the extra heat energy that is required and it has been widely used by the petroleum industry since the mid-1960s to stimulate the production of thick oils. Two techniques, steam stimulation and steam flooding, are currently used.

Steam stimulation or steam soaking uses a well as both injector and producer. High-pressure steam is injected directly into the production zone for several days to weeks. After this period, the reservoir area around the well is allowed to soak in the new heat energy for an additional period. During this time, most of the steam condenses to hot water. After the soak period, the well is brought back into production to recover the heated (thinner) oil and hot water near the wellbore. Because natural driving forces are relied upon to move the oil through the reservoir during the production phases, steam stimulation generally increases the *rate* of recovery rather than the *amount* of oil that ultimately may be recovered. This technique is particularly adapted to certain California fields containing heavy crude oils, as well as fields in the Orinoco oil belt of Venezuela and the Cold Lake area of Alberta, Canada.

Steam flooding is more sophisticated and difficult than steam stimulation. This technique uses separate injection and production wells to improve both *rate* and *amount* of production.

Miscible Recovery. Oil and water do not mix and they do not flow with equal facility through a porous rock. Over the years, many miscible flood processes have been tested, the most successful of which have been: (1) hydrocarbon miscible recovery; (2) carbon dioxide miscible flooding; and (3) chemically enhanced recovery.

Depending on the composition of the oil and the reservoir temperature and pressure, light hydrocarbons in liquid form, such as liquefied petroleum gas (LPG) and including propane, butane, and ethane, may be miscible with crude oil. Where conditions are right, natural gas can be used to drive a bank of injected light hydrocarbon liquids through the reservoir to form a miscible flood. The disadvantage of this method is that it involves the prolonged use of valuable hydrocarbon liquids, some of which may never be recovered. The use of natural gas alone has received consideration in special situations where high pressure, combined with low reservoir temperature, may result in miscibility.

Carbon dioxide miscible recovery is a preferred method. Carbon dioxide may not be initially miscible with crude oil, but when it is forced into an oil reservoir, some of the smaller, lighter hydrocarbon molecules in the contacted crude will vaporize and mix with the CO_2, forming a wall of enriched gas (CO_2 plus light hydrocarbons). If the temperature and pressure of the reservoir are suitable, this wall of enriched gas will mix with more of the crude, forming a "bank" of miscible solvents capable of efficiently displacing large volumes of crude oil. Carbon dioxide is found in underground deposits and can be produced through wells similar to gas wells. But its production and transportation to the oil reservoir can add significantly to the cost. A project has been proposed that would involve the construction of a long CO_2 pipeline from a Colorado CO_2 well to a large oil field in Texas. The economic feasibility of the project remains to be proved.

The use of chemicals to coax more oil out of the ground has been investigated for many years. Chemically enhanced methods are of three major types: (1) polymer flooding; (2) surfactant flooding; and (3) alkaline flooding.

Experts estimate that prudent but aggressive application of enhanced recovery technology to known reservoirs in the United States could result in the production of 20 to 30 billion barrels of oil that might otherwise be lost forever. The amount of oil that might be recovered from known oil fields worldwide is estimated to be in the range of 100 to 200 billion barrels. See Fig. 24.

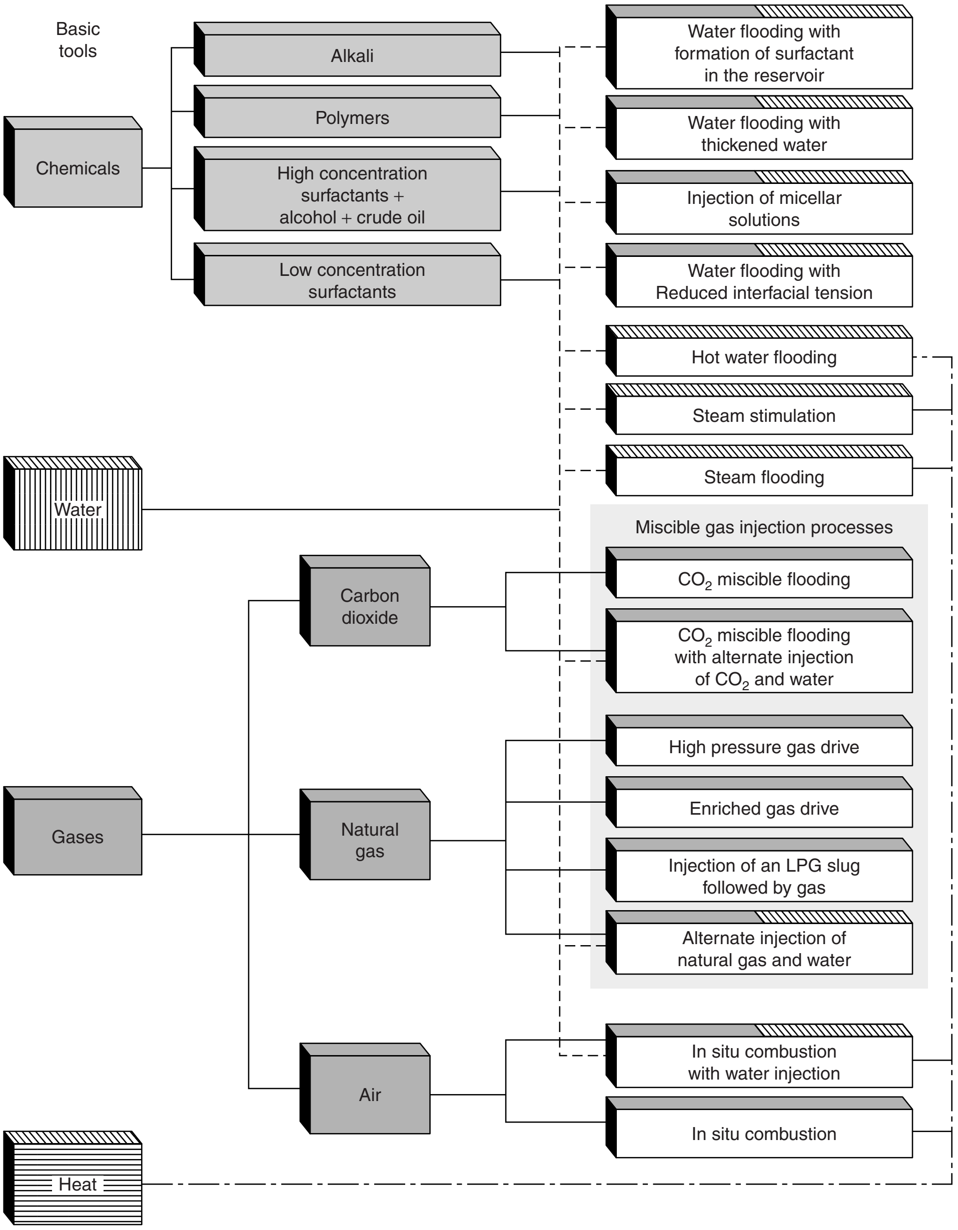

Fig. 24. Enhanced oil recovery techniques employ heat, gases, chemicals, and water—singly or in combinations—to reduce the factors that inhibit oil recovery and to augment reservoir energy. (*Exxon Corp*)

Petroleum Reserves

In 1988, the U.S. Geological Survey reduced its prior estimate of the oil and gas remaining to be discovered in the United States by 40%. As pointed out by R.A. Kerr (reference listed), "If the new estimates hold up, it would solidify a new realism in the agency's view of energy resources. In 1972, the agency claimed that there were 450 billion barrels of oil and 2100 trillion cubic feet of gas left to be found—Figures that the USGS itself soon characterized as four times too high." A revised estimate in 1981 showed 83 billion barrels and 594 trillion cubic feet left undiscovered. Even this estimate was challenged as too high by some industry experts.

The foregoing is exemplary of how assumptions of remaining oil and gas reserves are made and of the lack of confidence that *any* figures appeared to enjoy as of the 1990s. Generally, there is a consensus that, given current rates of consumption, oil reserves should be visualized as becoming exhausted in terms of decades rather than centuries!

Everyone recognizes that crude oil exists in finite amounts, but no one really knows how much of it remains in the earth. Since E.L. Drake drilled his first well in 1859, a vast industry has been established and oil became the predominant worldwide fuel. But petroleum geologists freely admit that definitive knowledge about the resource base that made this growth possible remains *elusive*. At any given time, the amount of oil available for consumption depends primarily on two factors: (1) the producibility of already discovered reserves; and (2) the production policies of governments in countries where those reserves exist. Over the long run, however, it is the amount of recoverable oil left in the ground, including those volumes yet undiscovered, that will be decisive. Estimates of the remaining petroleum resource base vary widely—in fact, too widely to record in this encyclopedia. Experts disagree about the size and producibility of individual reservoirs and about the total national and world reserves associated with already discovered fields. They are even further apart when assessing the world's undiscovered potential. This is not surprising when it is remembered that, in this current unscientific arena, the experts are making judgments—frequently educated guesses—about hydrocarbons contained in porous rocks many thousands of feet under the earth's surface. Often, they have little more to go on than the data from a few widely dispersed 8-inch-diameter holes in existing fields—and still less information in the case of fields expected to be discovered in the future. Consequently, in an attempt to be pseudoscientific, experts generally refer to three classes of reserves: (1) proved; (2) probable; and (3) potential. The chart shown in Fig. 25 represents a well-accepted approach to reserves analysis.

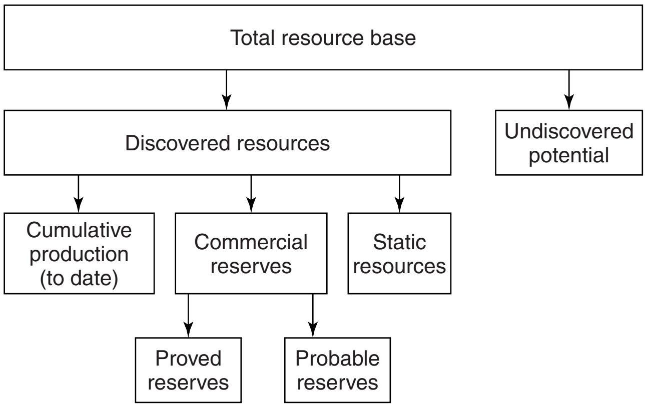

Fig. 25. Commonly used approach for handling statistics in connection with estimating oil reserves

TABLE 3. MILESTONES IN PETROLEUM EXPLORATION AND PRODUCTION TECHNOLOGY

1853	Dr. Albert Gesner manufactures kerosene from coal.
1859	Edwin Drake completes the first successful well drilled in the search for oil at Titusville, Pennsylvania, striking oil at $69\frac{1}{2}$ feet. By the start of the 20th century, crude oil and/or natural gas were being produced in 20 states; in 1984, 33 of the 50 states had some oil or gas production.
1865	First oil pipeline, 2 inches in diameter and 32,000 feet long, laid at Oil Creek, Pennsylvania, to transport oil from the field to the Oil Creek Railroad.
1883	Dr. I.C. White proposes the theory that oil and gas deposits could be found in geological anticlines.
1896	First "offshore" wells drilled from piers extending into California waters.
1899	Threllfall and Pollock devise the first gravity meter.
1901	"Spindletop" oil field is discovered on a salt dome near Beaumont, Texas; proves the value of the rotary drilling rig and popularizes the use of drilling mud.
1914	Reginal Fessenden patents the reflections seismograph.
1924	Electric well logging first used in United States; refraction seismograph graph used to discover Orchard, Texas, salt dome; first geophysical discovery using magnetic torsion-balance.
1939	First airborne magnetometer developed.
1942	Fluid formation identified using electric logging.
1954	First oil and gas lease sale in federal offshore area held; through 1984, more than 100 such sales had been held, resulting in the leasing of some 38 million acres (4 percent of the federal offshore area); and federal revenues from that leasing had exceeded $77 billion.
1968	The Prudhoe Bay, Alaska, field is discovered some 250 miles above the Arctic Circle—the largest U.S. discovery evermade—containing some 10 billion barrels of oil and 26 trillion cubic feet of natural gas.
1972	First land remote sensing satellite (Landsat) launched; information from such satellites is playing an increasingly important role in identifying from space potential deposits of oil, natural gas and other minerals.
1974	Record-depth exploratory well—a natural gas well—drilled to 31,441 feet in Oklahoma.
1979	World's tallest fixed-leg platform—1,265 feet tall and weighing 59,000 tons—installed in 1,025 feet of water in the Gulf of Mexico.
1984	Exploratory well drilled in world record water depth—6,942 feet—off the coast of New England.

PETROLEUM REFINING. Because crude oils exhibit important differences from the standpoint of processing and final end-products from one geographic resource to the next (see Tables 1 and 2 of the preceding article on **Petroleum**), very few petroleum refineries operate on exactly the same basis. The principles of the operations performed are remarkably similar, but there are basic differences in the amount of throughputs for given products. The latter varies from one geographic area to the next and with the season of the year. Modern petroleum refineries are designed with considerable built-in flexibility, so that the production of petroleum products can be customized for specific market demands. For example, the production of greater amounts of heating fuels during the fall and winter season as contrasted with larger production of gasolines and diesel fuels during summer months, when the demand is greatest. In contrast with a few decades ago, modern refineries are integrated to produce numerous products and often will also serve nearby petrochemical plants where petroleum products become starting ingredients for a vast variety of chemicals used in many industries, such as plastics, solvents, polymers, fibers, among many others.

A representative integrated petroleum refinery is shown in Fig. 1.

The major processing units fundamental to the manufacture of fuel products from crude oil include: (1) crude distillation; (2) catalytic reforming; (3) catalytic cracking; (4) catalytic hydrocracking; (5) alkylation; (6) thermal cracking; (7) hydrotreating; and (8) gas concentration. Refineries also will use numerous auxiliary processes, such as treating units to purify both liquid and gas streams, waste-management and pollution-control systems, cooling-water systems, units to recover hydrogen sulfide (or elemental sulfur) from gas streams, desalters, electric-power stations, steam-producing facilities, and provisions for storage of crude oil and products.

Petroleum refining and petrochemical production is a 24-hour, 365-day operation with a very minimum of time planned for downtime. Unless one has visited a refinery firsthand, it is very difficult to comprehend the size and complexity of the equipment used. See Figures 2, 3, and 4.

Crude Distillation. To minimize corrosion of refining equipment, a crude-oil distillation unit generally is preceded by a *desalter*, which reduces the inorganic salt content of raw crudes. Salt concentrations vary widely (from nearly zero to several hundred pounds, expressed as NaCl per

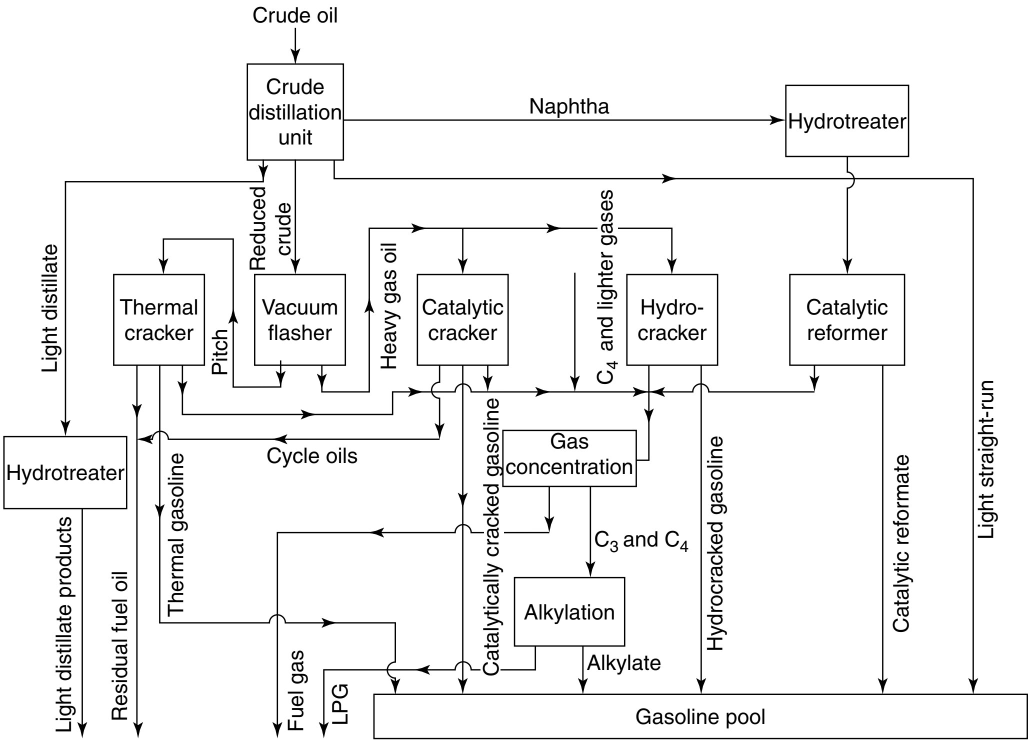

Fig. 1. Principal flow of materials in an integrated petroleum refinery for producing various fuels and raw materials for petrochemical plants

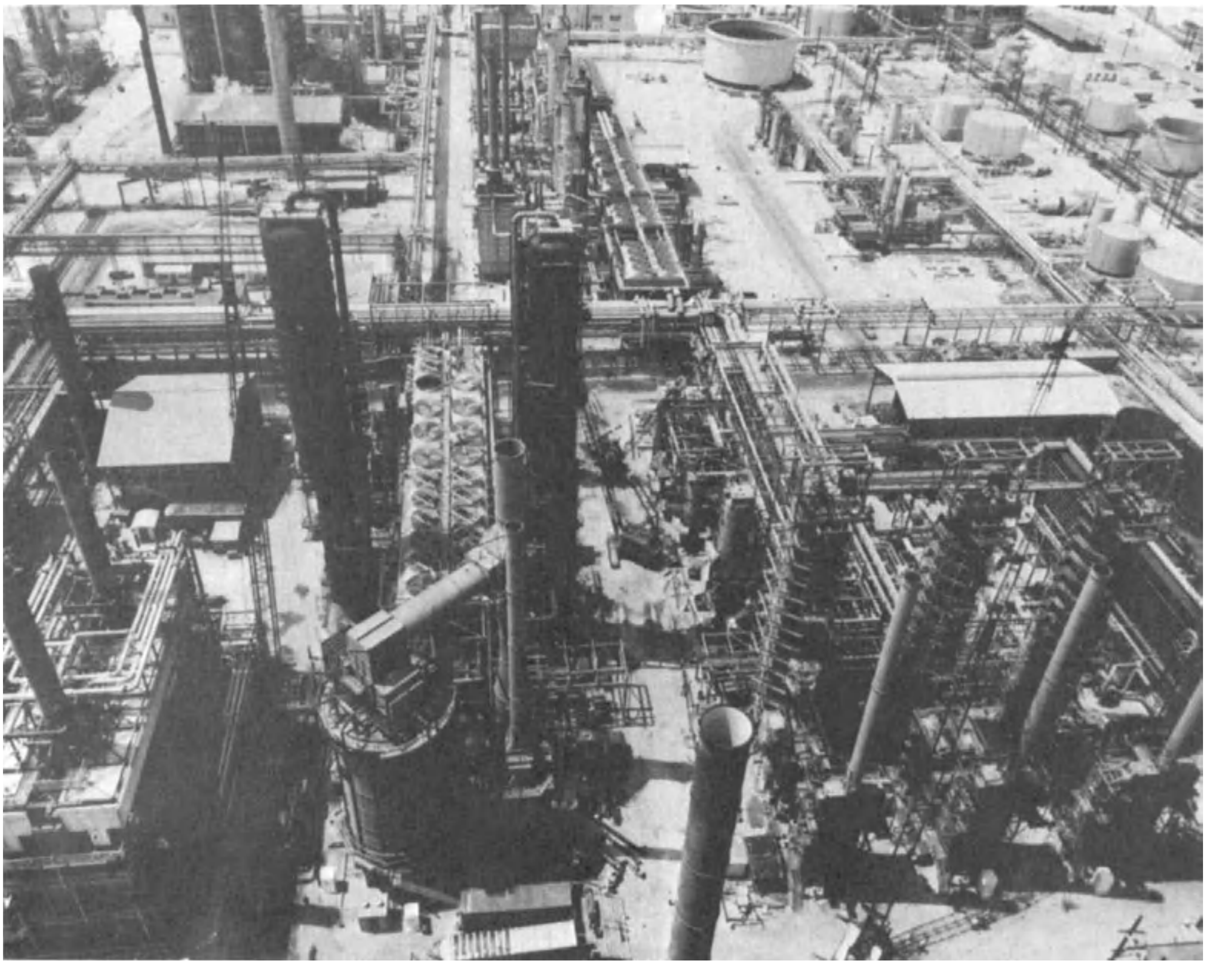

Fig. 2. Aerial view of small portion of a Texas petroleum refinery, showing the hydrocracking unit just left of center of view

1,000 barrels). The crude unit functions simply to separate the crude oil physically, by fractional distillation, into components of such boiling ranges that they can be processed by appropriately selected equipment in a long train of processing operations which follow. Although the boiling ranges of components (or fractions) vary between refineries, a typical crude distillation unit will resolve the crude into the following fractions:

By distillation at atmospheric pressure,

1. A light straight-run fraction, consisting primarily of C_5 and C_6 hydrocarbons. These also will contain any C_4 and lighter gaseous hydrocarbons that are dissolved in the crude.
2. A naphtha fraction having a nominal boiling range of 200°–400°F (93°–204°C).
3. A light distillate with boiling range of 400°–540°F (204°–343°C).

By vacuum flashing

1. Heavy gas oil, having a boiling range of 650°–1,050°F (343°–566°C).
2. A nondistillable residual pitch.

In the atmospheric-pressure distillation section of the unit, the crude oil is heated to a temperature at which it is partially vaporized and then introduced near, but at some distance above, the bottom of a distillation column. This cylindrical vessel is equipped with numerous trays through which hydrocarbon vapors can pass in an upward direction. Each tray contains a layer of liquid through which the vapors can bubble, and the liquid can flow continuously by gravity in a downward direction from one tray to the next one below. As the vapors pass upward through the succession of trays, they become lighter (lower in molecular weight and more volatile with lower boiling temperature). The liquid flowing downward becomes progressively heavier (higher in molecular weight and less volatile with higher boiling temperature). The countercurrent action results in fractional distillation or separation of hydrocarbons based upon their boiling points. A liquid can be withdrawn from any preselected tray as a net product. Thus, the lighter liquids, such as naphtha, exit from trays near the top of the column, whereas heavier liquids, such as diesel oil, exit from trays near the bottom of the column. Thus, the boiling range of the net product liquid depends upon the tray from which it is taken. The vapors containing the C_6 and lighter hydrocarbons are withdrawn from the top, while a liquid stream boiling at about 650°F (343°C) is taken from the bottom. The portion taken from the bottom is called *atmospheric residue*.

This residue is further heated and introduced into a vacuum column operated at an absolute pressure of about 50 millimeters of mercury, a vacuum maintained by the use of steam ejectors. A flash separation is made to produce heavy gas oil and nondistillable pitch.

The crude oil and atmospheric residue are heated in tubular heaters. Oil is pumped through the inside of the tubes contained in a refractory combustion chamber fired with oil or fuel gas in such manner that heat is transferred through the tube wall in part by convection from hot combustion gases and in part by radiation from the incandescent refractory surfaces.

The light straight-run gasoline contains all hydrocarbons lighter than C_7 in the crude and consists primarily of the native C_5 and C_6 families. After stabilization to remove the C_4 and lighter hydrocarbons (which are routed to a central gas-concentration unit), the stabilized C_5/C_6 blend is treated to remove odorous mercaptans and passed to the refinery gasoline pool for final product blending. The unleaded octane number (Research Method Number) is less than 70, and thus blending or further processing is required to improve its antiknock qualities. Isomerization can be used to improve octane rating, as well as the addition of lead alkyls.

Naphtha to become a suitable component for blending into finished gasoline pools must be further processed. The octane number will range from 40 to 50. Prior to introduction into a catalytic-reforming unit, most naphtha feedstocks are hydrotreated in the interest of prolonging the life of the reforming catalyst.

Fig. 3. Erection of 9.5-meter (31-foot) diameter, 263-ton vacuum tower at a petroleum refinery in Kuwait. (*The Fluor Corp*)

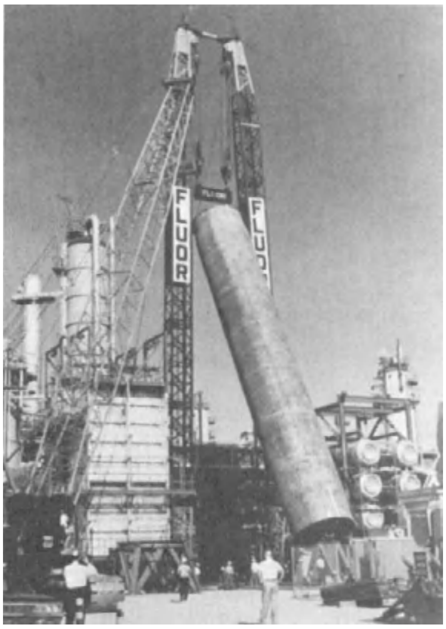

Fig. 4. Erection of a 675-ton hydrocracking reactor at Shauaiba, Kuwait, refinery, the world's first all-hydrogen refinery. (*The Fluor Corp*)

Gas oil separated from the crude by vacuum distillation, plus portions of light distillates, is the feedstock to catalytic cracking units. The main function of catalytic cracking is to convert into gasoline those fractions having boiling ranges higher than that of gasoline. Remaining uncracked distillates (cycle oils) are used as components for domestic heating fuels (generally after hydrotreating) and to blend with residual fractions to reduce their viscosity to make acceptable heavy fuel oils. In some refineries, cycle oils are hydrocracked to complete their conversion to gasoline.

The aforementioned processes are described in more detail in separate entries: **Alkylation**; **Cracking Process**; **Distillation**; and **Hydrotreating**.

Petroleum Terminology

An abridged glossary of terms used to describe petroleum products and processes would include:

Additives, Diesel Fuel—Chemicals for reducing smoke emissions and for cold weather conditioning.

Additive, Gasoline—In some instances, several functions can be combined in one chemical compound to provide "multifunctional" additives. Increasingly stringent control of automotive emissions in several countries has stimulated the development and use of "extended-range" detergents which are designed to promote peak engine performance by maintaining engine cleanliness. Some gasoline additives include:

Antiknock compounds to increase octane number.

Antioxidants to provide gasoline storage stability.

Antirust agents to prevent corrosion in gasoline-handling systems.

Detergents to control carburetor and induction system cleanliness.

Dyes to indicate kind of antiknock compounds used and to identify brand and grade of gasoline.

Viscosity index improves make lube oil more effective over a wide range of temperatures.

Alkylation—A refinery process for chemically combining isoparaffin with olefin hydrocarbons. The product, *alkylate*, has a high octane value and is blended with motor and aviation gasoline to improve the antiknock value of the fuel.

Base Oil—A refined or untreated oil used in combination with other oils and additives to produce lubricants.

Blending—The process of mixing two or more oils having different properties to obtain a final blend having the desired characteristics. This can be accomplished by off-line batch processes or by in-line operations as part of continuous-flow operations.

Bright Stock—High-viscosity, fully refined and dewaxed lubricating oils produced by the treatment of residual stocks and used to compound motor oils.

Catalytic Cracking—A refinery process that converts a high-boiling range fraction of petroleum (gas oil) to gasoline, olefin feed for alkylation, distillate, fuel oil, and fuel gas by use of a catalyst and heat.

Catalytic Reforming—A catalytic process to improve the antiknock quality of low-grade naphthas and virgin gasolines by the conversion of naphthenes (such as cyclohexane) and paraffins into higher-octane aromatics (such as benzene, toluene, and xylenes). There are approximately ten commercially licensed catalytic reforming processes, including fully regenerative and continuously regenerative designs.

Cetane Number—The cetane number (C.N.) of a fuel is the percentage by volume of normal cetane in a mixture of cetane and alpha-methylnaphthalene which matches the unknown fuel in ignition quality when compared with a standard diesel engine under specified conditions. The C.N. scale ranges from 0 to 100 C.N. for fuels equivalent in ignition quality to alpha-methylnaphthalene and cetane, respectively. For routine-testing, secondary reference fuels having cetane values of about 25 and 74 are blended in any desired proportion.

Clear Octane—The octane number of a gasoline before the addition of antiknock additives.

Cloud Point—The aniline cloud point is a measure of the paraffinicity of a fuel oil, a high value indicating a straight-run paraffinic oil and a low value indicating an aromatic, a naphthenic, or a highly cracked oil.

Coking—Distillation to dryness of a product containing complex hydrocarbons, which break down in structure during distillation, such as tar or crude petroleum. The residue is called coke.

Cracking—A process carried out in a refinery reactor in which the large molecules in the charge stock are broken up into smaller, lower-boiling, stable hydrocarbon molecules, which leave the vessel as overhead (unfinished cracked gasoline, kerosenes, and gas oils). At the same time, certain of the unstable or reactive molecules in the charge stock combine to form tar or coke bottoms. The cracking reaction may be carried out with heat and pressure (thermal cracking) or in the presence of a catalyst (catalytic cracking).

Cycle Stock—Unfinished product taken from a stage of a refinery process and recharged to the process at an earlier period in the operation.

Deasphalting—Process for removing asphalt from petroleum fractions, such as reduced crude. A common deasphalting process introduces liquid propane, in which the nonasphaltic compounds are soluble while the asphalt settles out.

Desulfurization—The removal of sulfur or sulfur-bearing compounds from a hydrocarbon by any one of a number of processes, such as hydrotreating.

Distillate—That portion of a liquid which is removed as a vapor and condensed during a distillation process. As fuel, distillates are generally within the 400° to 650°F (204° to 343°C) boiling range and include Nos. 1 and 2 fuel, diesel, and kerosene.

End Point—The temperature at which the last portion of oil has been vaporized in ASTM or Engler distillation. Also called the final boiling point.

Equilibrium Volatility of a Gasoline—The volatility of a gasoline is determined by the Reid vapor pressure and the ASTM distillation data. The Reid vapor pressure is the vapor pressure of a gasoline at 100°F (37.8°C) under specified conditions. The distillation curve of a fuel indicates the temperatures at which the various amounts of a given sample are distilled under specified test conditions. However, gasoline will completely evaporate in the presence of air at a temperature much lower than the end-point of the distillation curve. According to O.C. Bridgeman (U.S. National Bureau of Standards, Research Paper 694), the volatility of a gasoline is the temperature at which a given air-vapor mixture is formed under equilibrium conditions at a pressure of one atmosphere, when a given percentage is evaporated. According to this definition, one gasoline is more volatile than another for any given percentage evaporated if it forms the given air-vapor mixture at a lower temperature. Distillation temperature curves, for a given text sample, plot amount of sample distilled over (percentage of sample) at the time a given temperature has been reached.

Fire Point—The lowest temperature at which a fuel ignites and burns for at least 5 seconds under specified test conditions.

Flare—A device for disposing of gases by burning.

Flash Point—The lowest temperature at which a flash appears on the fuel surface when a test flame is applied under specified test conditions. This property is an approximate indication of the tendency of the fuel to vaporize.

Flue Gas Expander—A turbine used to recover energy where combustion gases are discharged under pressure to the atmosphere. The pressure reduction drives the impeller of the turbine.

Fractions—Refiner's term for the portions of oils containing a number of hydrocarbon compounds but within certain boiling ranges, separated from other portions in fractional distillation. They are distinguished from pure compounds which have specified boiling temperatures, not a range.

Fuel Oils—Any liquid or liquifiable petroleum product burned for the generation of heat in a furnace or firebox or for the generation of power in an engine. Typical fuels include clean distillate fuel for home heating and higher-viscosity residual fuels for industrial furnaces.

Gas Oil—A fraction derived in refining petroleum with a boiling range between kerosene and lubricating oil.

Heating Oils—A trade term for the group of distillate fuel oils used in heating homes and buildings as distinguished from residual fuel oils used in heating and power installations. Both are burned-fuel oils.

Heavy Ends—The highest-boiling portion of a gasoline or other petroleum oil.

Hydrocracking—The cracking of a distillate or gas oil in the presence of catalyst and hydrogen to form high-octane gasoline blending stock.

Hydrogenation—A refinery process in which hydrogen is added to the molecules of unsaturated (hydrogen-deficient) hydrocarbon fractions. It plays an important part in the manufacture of high-octane blending stocks for aviation gasoline and in the quality improvement of various petroleum products.

Hydrotreating—A treating process for the removal of sulfur and nitrogen from feedstocks by replacement with hydrogen.

Isomerization—A refining process which alters the fundamental arrangement of atoms in the molecule. Used to convert normal butane into isobutane, as alkylation process feedstock, and normal pentane and hexane into isopentane and isohexane, high-octane gasoline components.

Kinematic Viscosity—The absolute viscosity of a liquid (in centipoises) divided by its specific gravity at the temperature at which the viscosity is measured.

Knock—The sound or "ping" associated with the autoignition in the combustion chamber of an automobile engine of a portion of the fuel-air mixture ahead of the advancing flame front.

Lead Susceptibility—The increase in octane number of gasoline imparted by the addition of a specified amount of tetraethyl lead.

Low-Sulfur Crude Oil—Crude oil containing low concentrations of sulfur-bearing compounds. Crude is usually considered to be in the low-sulfur category if it contains less than 0.5% (weight) sulfur. Examples of low-sulfur crudes are offshore Louisiana, Libyan, and Nigerian crudes.

Lube Stock—Refinery term for fraction of crude petroleum suitable in terms of boiling range and viscosity to yield lubricating oils when further processed and treated.

Mercaptans—Compounds of sulfur having a strong, repulsive, garlic-like odor. A contaminant of "sour" crude oil and products.

Octane Number—The octane rating of a motor fuel is defined in terms of its knocking characteristics relative to those of blends of isooctane (2,3,4-trimethylpentane) and n-heptane, and a rating of 100 to isooctane. The octane number of an unknown fuel is numerically equal to the volume percent of isooctane in a blend with *n*-heptane which has the same knocking tendency as the unknown fuel when both the unknown and the reference blend are run in a standard single-cylinder engine operated at specified conditions. Motor Method octane numbers are measured at more severe engine conditions and are numerically lower than those determined by the milder Research Method. The difference between the two numbers is termed *sensitivity*.

Polymer—A product of polymerization of normally gaseous olefin hydrocarbons to form high-octane hydrocarbons in the gasoline boiling range. Polymerization is the process of combining two or more simple molecules of the same type, called monomers, to form a single molecule having the same elements in the same proportions as in the original molecule, but having different molecular weights. The combination of two or more dissimilar molecules is known as copolymerization—and the product is called a *copolymer*.

Pour Point—This property is defined as the lowest temperature at which the fuel will pour and is a function of the composition of the fuel. Normally, the pour point of a fuel should be at least 10 to 15 degrees below the anticipated minimum use temperature.

Presulfide—A step in the catalyst regeneration procedure which treats the catalyst with a sulfur-bearing material such as hydrogen sulfide or carbon bisulfide to convert the metallic constituents of the catalyst to the sulfide form in order to enhance its catalytic activity and stability.

Process Unit—A separate facility within a refinery, consisting of many types of equipment, such as heaters, fractionating columns, heat exchangers, vessels, and pumps, designed to accomplish a particular function within the refinery complex. For example, the crude processing unit is designed to separate the crude into several fractions, while the catalytic reforming unit is designed to convert a specific crude fraction into a usable gasoline blending stock.

Raffinate—In solvent refining, that portion of the oil that remains undissolved and is not removed by the selective solvent.

Refinery Pool—An expression for the mixture obtained if all blending stocks for a given type of product were blended together in production ratio. Usually used in reference to motor gasoline octane rating.

Refluxing—In fractional distillation, the return of part of the condensed vapor to the fractionating column to assist in making a more complete separation of the desired fractions. The material returned is called *reflux*.

Residual Fuel Oils—Topped crude petroleum or viscous residuums obtained in refinery operations. Commercial grades of burner-fuel oils Nos. 5, and 6 are residual oils and include Bunker fuels.

Riser Cracking—Applied to fluid catalytic cracking units where the mixture of feed oil and hot catalyst is continuously fed into one end of a pipe (riser) and discharges at the other end where catalyst separation is accomplished after the discharge from the pipe. There is no dense phase bed through which the oil must pass because all the cracking occurs in the inlet pipe (riser).

Road Octane—A numerical value based upon the relative antiknock performance of an automobile with a test gasoline as compared with specified reference fuels. Road octanes are determined by operating a car over a stretch of level road or on a chassis dynamometer under conditions simulating those encountered on the highway.

SAE Numbers—A classification of motor, transmission, and differential lubricants to indicate viscosities, standardized by the Society of Automotive Engineers. They do not connote quality of the lubricant.

Smoke Point—The smoking tendency of a fuel is indicated by this value, which is the maximum height of a specified type of flame in a given wick lamp that results in no visible smoke.

Solvent Extraction—The process of mixing a petroleum stock with a selected solvent, which preferentially dissolves undesired constituents, separating the resulting two layers, and recovering the solvent from the raffinate (the purified fraction) and from the extract by distillation.

Sour Crude—Crude oil which (1) is corrosive when heated, (2) evolves significant amounts of hydrogen sulfide on distillation, or (3) produces light fractions which require sweetening. Sour crudes usually, but not necessarily, have high sulfur content. Examples are most West Texas and Middle East crudes.

Specific Gravity—The specific gravity of a petroleum fuel is the ratio of the weight of a given volume of the product at 60°F to the weight of an equal volume of distilled water at the same temperature, both weights corrected for air buoyancy. The relation between API gravity scale and specific gravity is: °API = 141.5/(sp gr 60/60°F)−131.5.

Stability—In petroleum products, the resistance to chemical change. Gum stability in gasoline means resistance to gum formation while in storage. Oxidation stability in lubricating oils and other products means resistance to oxidation to form sludge or gum in use.

Sweet Crude—Crude oil that (1) is not corrosive when heated, (2) does not evolve significant amounts of hydrogen sulfide on distillation, and (3) produces light fractions which do not require sweetening. Examples are offshore Louisiana, Libyan, and Nigerian crudes.

Tricresyl Phosphate (TCP)—Colorless to yellow liquid used as a gasoline and lubricant additive and plasticizer. Formula, $PO(OC_6H_4CH_3)_3$.

Tetraethyl Lead (TEL)—A volatile lead compound which is added to motor and aviation gasoline to increase the antiknock properties of the fuel. $Pb(C_2H_5)_4$. The use of this compound has diminished in recent years because of pollution regulations.

Thermal Cracking—A refining process which decomposes, rearranges, or combines hydrocarbon molecules by the application of heat without the aid of a catalyst.

Topped Crude—A residual product remaining after the removal, by distillation or other processing means, of an appreciable quantity of the more volatile components of crude petroleum.

Unsaturates—Hydrocarbon compounds of such molecular structure that they readily pick up additional hydrogen atoms. Olefins and diolefins, which occur in cracking, are of this type.

Vacuum Distillation—Distillation under reduced pressure, which red uces the boiling temperature of the material being distilled sufficiently to prevent decomposition or cracking.

Vapor Lock—The displacement of liquid fuel in the feed line and the interruption of normal motor operation, caused by vaporization of light ends in the gasoline. Vaporization occurs when the temperature at some point in the fuel system exceeds the boiling points of the volatile light ends.

Virgin Stock—Oil processed from crude oil which contains no cracked material. Also called straight-run stock.

Visbreaking—Lowering or breaking the viscosity of residuum by cracking at relatively low temperatures.

Viscosity—This is generally expressed in terms of the time required for a given quantity of fuel to flow through a capillary tube under specified conditions. Kinematic viscosity v is viscosity divided by mass density, or $v = \mu\rho$. The unit in cgs units is called the *stoke*; a customary unit is the *centistoke* ($\frac{1}{100}$ of a stoke). The value of the kinematic viscosity in (cm^2/seconds) can be obtained from the indications in seconds t of various viscometers by:

$$\text{Saybolt Universal, when } 32 < t < 100 = 0.00226t - 1.95/t$$

$$\text{Saybolt Universal, when } t > 100 = 0.00220t - 1.35/t$$

$$\text{Saybolt Furol, when } 25 < t < 40 = 0.0224t - 1.84/t$$

$$\text{Saybolt Furol, when } t > 40 = 0.0215t - 0.50/t$$

Yield—In petroleum refining, the percentage of product or intermediate fractions based on the amount charged to the processing operation.

Zeolitic Catalyst—Since the early 1960s, modern cracking catalysts contain a silica-alumina crystalline structured material called zeolite. This zeolite is commonly called a molecular sieve. The admixture of a molecular sieve in with the base clay matrix imparts desirable cracking selectivities.

Crude Oil Pipelines

Transportation of crude to petroleum refineries is essentially a part of the refining operation. Petroleum movement can be measured in barrels, tons

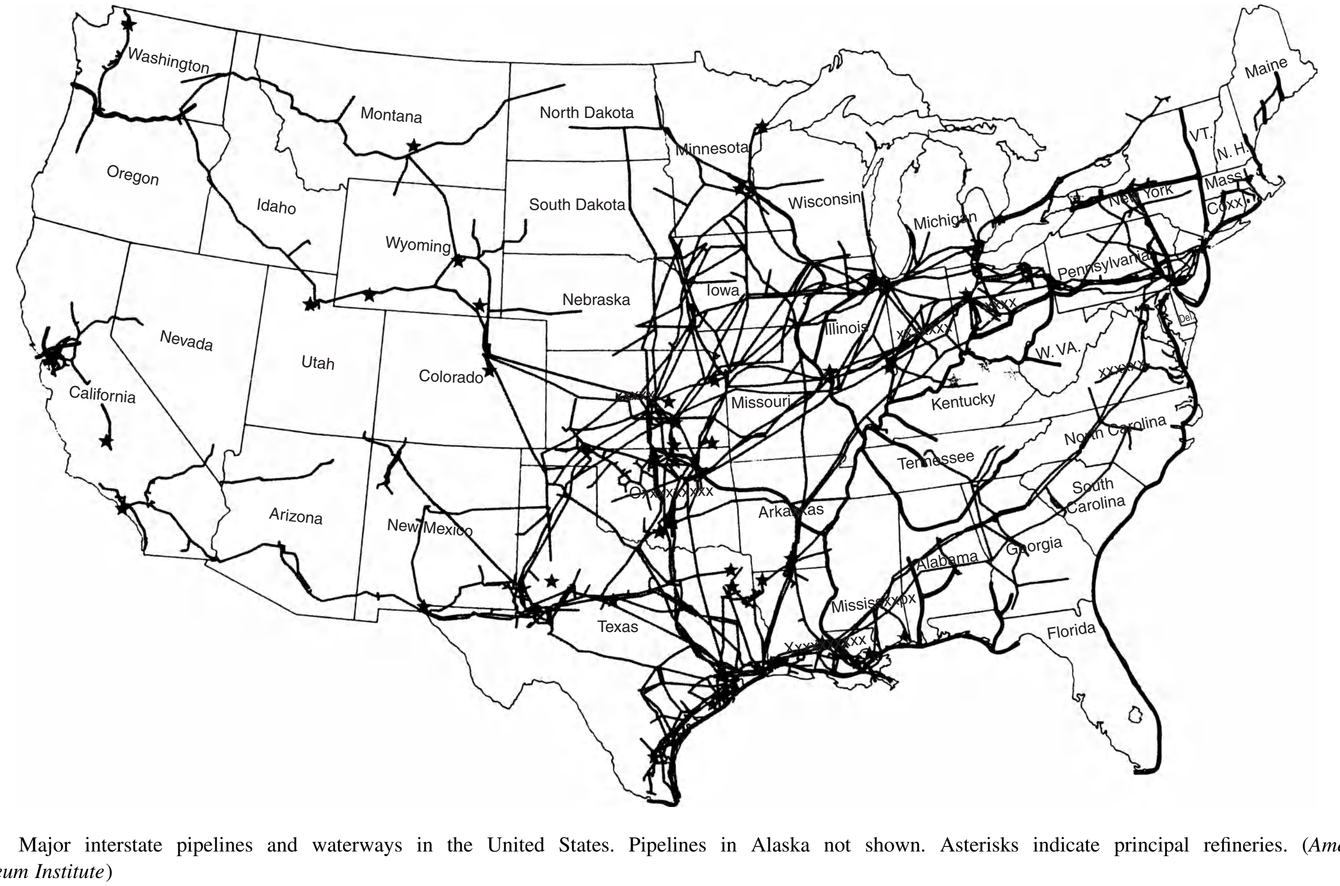

Fig. 5. Major interstate pipelines and waterways in the United States. Pipelines in Alaska not shown. Asterisks indicate principal refineries. (*American Petroleum Institute*)

TABLE 1. CHRONOLOGY OF MAJOR PETROLEUM INDUSTRY ADVANCEMENTS

Challenge	Action
1. Better gasoline quality and greater quantity needed	1. Thermal cracking processes (about 1910)
2. Need to improve odor and stability of gasoline and kerosene	2. Refining with chemical solutions and synthesis and use of oxidation inhibitors; started in late 1920s
3. Better gasoline quality and greater quality needed	3a. 19. Development of processes of dehydrogenate n-paraffins to n-olefins and alkylate benzene with them (mid-1960s) Discovery of tetraethyl lead (1921)
	b. Polymerization of light olefins to make "poly" gasoline by catalysis (mid-1930s)
	c. Catalytic cracking invented and improved (late 1930s)
4. Combat grade aviation gasoline testing above 100 octane needed for World War II	4. Alkylation of light olefins with light isoparaffins by catalysis; discovered in 1932; commercialized in early 1940s
5. More aromatic hydrocarbons needed, especially toulene for TNT; benzene, toluene, and other high-octane aromatics needed for combat grade aviation gasoline and for chemical synthesis	5a. Catalytic reforming to make toluene from petroleum naphthas (early 1940s), using non-noble metal catalyst
	b. Extractive distillation of toluene from *reformate* with phenol and other materials (early 1940s)
	c. Extraction with SO_2, suggested in 1907 to purify *kerosene*, applied to secure aromatics from reformate (early 1940s)
	d. Alkylation of propylene with benzene *using* solid H_3PO_4 catalyst to make cumene (early to mid-1940s)
6. Butadiene needed for synthetic rubber in wartime	6. *Thermal* and catalytic processing applied to petroleum distillates, "quickly" butadiene program (early 1940s)
7. More isobutane for alkylation in wartime aviation-gasoline program	7. *Isomerization* of n-butane (early 1940s)
8. Improve quality of straight-run gasoline	8. Catalytic reforming using noble-metal *catalyst* (1949)
9. Remove catalyst poisons and sulfur compounds from gasoline and naphtha	9. Catalytic hydrotreating (early 1950s)
10. Increase supplies of pure aromatic hydrocarbons and aromatic concentrates	10. Liquid-liquid solvent extraction *processes* using aqueous glycols and improved contacting means (1952)
11. Purify kerosenes and light and heavy distillates	11. *Modified* catalytic hydrotreating (mid-1950s)
12. Improve quality of light hydrocarbons used in gasoline	12. New catalytic isomerization processes using noble-metal catalysts, converting C_4, C_5, and C_6 n-paraffins to isoparaffins (mid-1950s)
13. Increase production of light fuels and gasoline; reduce production of heavy fuels	13. Development of catalytic hydrocracking processes having great flexibility (1959–1960)
14. Ethylbenzene for styrene manufacture	14. Catalytic alkylation process developed, uniting benzene directly with dilute ethylene in refinery gases (1958)
15. Separation of normal paraffins from mixtures with isoparaffins	15. Molecular sieves used as solid adsorbants (1959, but not commercialized until late 1960s)
16. Increase benzene supply and decrease toluene	16. Hydrodealkylation of toluene; produce naphthalene from alkyl naphthalenes (early 1960s)
17. Synthesize cyclohexane for nylon	17. Catalytic hydrogeneration of benzene (early 1960s)
18. Improve quality of heavy fuel oils	18. Hydrodesulfurization of heavy fuels, also by hydrocracking (mid-1960s)
19. Biodegradable synthetic detergents	19. Development of processes of dehydrogenate n-paraffins to n-olefins and alkylate benzene with them (mid-1960s)
20. Increase production of p-xylene	20. Isomerization of C_8 aromatics to p-xylene (late 1950s)
21. Improve supplies of individual pure xylene isomers	21. Adsorptive separation of p-xylene in high yield and purity, making possible separation of other isomers by precise fractionation (early 1970s)
22. Utilization of metals-containing heavy petroleum fractions	22. Development of hydroprocessing techniques to effectively convert to synthetic crude oils
23. Increase supply of liquid fuels in the face of declining petroleum reserves	23. Development of processes for producing liquid and gaseous fuels from coal, shale oil, and tar sands

Source: Universal Oil Products Company.

moved, barrel-miles, ton-miles, etc. Because oil pipelines are the most economical means of moving large volumes of petroleum overland for long distances, ton-miles (movement of one ton over one mile) is the preferred unit. About 740 billion ton-miles per year of crude oil movement by all transportation modes is required to meet the needs of the United States. About half of this quantity is moved by pipeline; water carriers account for most of the remainder. Major interstate crude oil pipelines are shown in map (Fig. 5).

As domestic crude oil is produced, pipeline gathering systems collect and move it to central locations by means of low-pressure, small-diameter pipelines. Usually, these gathering lines feed into pipeline working tanks where the oil is held until it is ready for shipment by a crude oil *trunk line*. Gathering systems include pumping stations, meters, and samplers. About 90% of the gathering lines in the United States are 6 inches (diameter) or smaller. About 34% of all oil pipeline mileage in the United States consists of gathering lines. Crude oil trunk lines, larger in diameter, receive crude oil directly from gathering systems and also from barges and tankers. Crude oil trunk lines range from 8 to 56 inches in diameter and account for 30% of total oil pipeline mileage in the nation. These trunk lines generally originate in the major oil producing areas of the nation and terminate at the main refinery complexes. The largest of these refinery complexes is in the Gulf Coast area of Texas and Louisiana. Other major complexes are located in the St. Louis-Chicago area, northern Ohio, the East and West Coasts.

Petroleum Processing Progress

Some of the major milestones achieved in petroleum processing technology are summarized in Table 1.

pH (Abrasion). The term *abrasion pH* was originated by Sevens and Carron in 1948 to designate the pH values obtained by grinding materials in water as a useful aid in the field identification of minerals. The pH value ranges from 1 for ferric sulfate minerals, such as coquimbite, konelite, and rhomboclase, to 12 for calcium-sodium carbonates, such as gaylussite, pirssonite, and shortite.

The recommended technique for determination of abrasion pH is to grind, in a nonreactive mortar, a small amount of the mineral in a few drops of water for about one minute. Usually, a pH test paper is used. Values obtained in this manner are given in the left-hand column of the accompanying table. Another method, proposed by Keller et al. in 1963 involves the grinding of 10 grams of crushed mineral in 100 milliliters of water and noting the pH of the resulting slurry electronically.

pH (Hydrogen Ion Concentration). A measure of the effective acidity or alkalinity of a solution. It is expressed as the negative logarithm of the hydrogen-ion concentration. Pure water has a hydrogen ion concentration equal to 10^{-7} moles per liter at standard conditions. The negative logarithm of this quantity is 7. Thus, pure water has a pH value of 7. The pH scale usually is considered as extending from 0 to 14. When a strong acid fully dissociates (or ionizes) in water, a 1 *N* solution of this acid will have a pH value of 0.0. Conversely, a 1 *N* base fully ionized in water will have a pH value of 14. Both hydrochloric acid and sodium hydroxide come close to meeting these stipulations. Because of the logarithmic nature of the pH scale, there is a tenfold change in hydrogen- and hydroxyl-ion concentration per unit change of pH. Thus, a slightly acidic solution having a pH of 6 will contain ten times as many active hydrogen ions as a solution of pH 7. See also **p*K***.

Effective acidity or alkalinity is stressed in pH measurement—not the total hydrogen present. Sulfuric acid and boric acid both contain significant amounts of hydrogen. Nearly all the hydrogen in sulfuric acid dissociates in the presence of sufficient water to become free hydrogen ions. On the other hand, when boric acid is added to water, it dissociates very little into free hydrogen ions. The pH of a 0.1 *N* sulfuric acid solution will be about 1.3 whereas for the same concentration, boric acid will have a pH of about 5.3. Thus, sulfuric acid is called a strong acid; boric acid a weak acid. In all materials, of course, dissociation increases with temperature, thus the same solution will have a somewhat different pH at a lower temperature than at a higher temperature. Pure water is neutral at a temperature of 25°C, having a concentration of 1×10^{-7} hydrogen ions and 1×10^{-7} hydroxyl ions and, consequently, a pH of 7. Dissociation is less at 0°C, at which temperature the hydrogen-ion concentration is 0.34×10^{-7}, or a pH of 7.47 (slightly basic rather than neutral). But, at a temperature of 100°C, dissociation is greater. The hydrogen ion concentration is 8×10^{-7} and the pH is 6.10 (or slightly acid). The pH of various substances is given in Table 1.

Buffer solutions can be added to resist changes in pH despite the addition of acid or base to the solution. This is explained under **Buffer (Chemical)**.

pH is measured in two basic ways: (1) colorimetrically, usually where high accuracy is not required and manual methods suffice; and (2) electrometrically. Color changes are based upon various organic dyes which alter their color within a relatively narrow range of pH values. Numerous dyes are required to cover the full pH range. Electrometric methods are used both in the laboratory and on-line for process control. They are continuous and easily adapted to automatic control systems. The possibility that a thin glass membrane of special composition could develop a potential in relation to hydrogen ion concentration was described as early as 1909 by the German chemist, Fritz Haber. Little progress was made until the middle-1920s. Glass electrodes are now the standard approach to electrometric pH measurement, after periods of trial with quinhydrone and antimony electrodes. The glass electrode responds in

TABLE 1. pH VALUES OF VARIOUS SUBSTANCES (AT 25°C)

Material	pH
Seawater	7.75 to 8.25
Soils	3 to 10
Plant tissues and fluids	About 5.2
Animal tissues and fluids	About 7.0 to 7.5
Blood	7.35–7.5
Urine	5.0–7.0
Milk	6.5–7.0
Gastric juice	1.7
Pancreatic juice	7.8
Intestinal juice	7.7
Internal tissue fluids:	
Minimum, below which acidosis ensues	7.0
Maximum, above which tetany ensues	7.8
Hydrochloric acid (1*N*)	0.1
Hydrochloric acid (0.1*N*)	1.08
Hydrochloric acid (0.001*N*)	3.00
Sulfuric acid (1.0*N*)	0.32
Sulfuric acid (0.1*N*)	1.17
Acetic acid (1*N*)	2.37
Lemon juice	2.0–2.2
Acid fruits	3.0–4.5
Fruit jellies	3.0–3.5
Sodium hydroxide (1*N*)	13.73
Sodium hydroxide (0.1*N*)	12.84
Ammonia (10% NH_3)	11.8
Limewater, $Ca(OH)_2$ saturated	12.4
Trisodium phosphate, 2%	11.95

a predictable fashion throughout the 0 to 14 pH range, developing 59.2 millivolts per pH unit at 25°C, values which are consistent with the classical Nernst equation. Contrary to earlier pH electrodes, the glass electrode is not influenced by oxidants or reductants in solution. With suitable temperature compensation, pH measurements can be made up to 100°C and higher. In pH measurement, a second or reference electrode is required to complete the circuit. After trials with numerous electrodes (the hydrogen electrode is the standard) for practical plant and laboratory applications, the mercury-mercurous chloride (calomel) electrode is widely used. There is also some use of the silver-silver chloride reference electrode.

pH control systems are widely used in waste control and neutralization systems, in pulp and paper manufacture, in food processing, and in the manufacture of numerous organic chemicals. pH measurement is very important in the medical field.

PHARMACEUTICALS. Pharmaceuticals are best viewed as drug-containing products in dosage forms. These forms are designed and manufactured to deliver safe and effective therapeutic responses each time administered within appropriate regimens and even after storage under well-documented conditions in scientifically designed packaging for designated time periods. Thus, pharmaceuticals are actual drug delivery systems.

Various technologies are required to produce drug products. Both federal and state laws and regulations exist in the United States to control the manufacture and distribution of pharmaceuticals. The U.S. drug distribution system is multifaceted including drug usage within the community and hospitals, under long- or short-term home health care or pharmacy practice. Individual pharmaceuticals are covered elsewhere.

In the United States, there is no national qualifying or licensing body for pharmacists. Licensure requirements are promulgated by State boards of pharmacy that administer examinations, issue internship requirements, and oversee the practice of pharmacy. The National Association of Boards of Pharmacy serves the collective needs of the state boards. This organization has no licensure authority. However, it has developed a standardized licensure examination (NABPLEX), which as of this writing is used by 48 states (see **Licensing**).

Several national organizations serve the professional needs of U.S. pharmacists. The American Pharmaceutical Association (APhA), founded in 1852, is composed of the Academy of Pharmaceutical Research and Science, Academy of Pharmaceutical Practice and Management, and the Academy of Students of Pharmacy. Other organizations include the American Society of Health-Systems Pharmacists (ASHP), National Association of Chain Drug Stores (NACDS), and National Association of Retail Druggists (NARD).

The American College of Apothecaries represents pharmacists whose practices can best be described as emphasizing prescription and related products.

The pharmaceutical industry is represented by several organizations. Examples are the Pharmaceutical Research and Manufacturers of America, the Non-Prescription Drug Manufacturers Association, and the National Pharmaceutical Council. The schools and colleges of pharmacy are organized as the American Association of Colleges of Pharmacy, representing both schools and colleges, and faculty members.

Each state has a professional pharmacy organization, some of which are affiliated with the American Pharmaceutical Association. Similarly, state organizations of hospital pharmacists exist in affiliation with the ASHP. Likewise, local or county associations exist in most instances. Each national association publishes a journal as do most state organizations. The *Federal Register* reports proposed and enacted federal regulatory occurrences several times a week. Each state has a similar publication to report its legislation and regulatory developments, e.g., *The Pennsylvania Bulletin*.

Drugs and Drug Products

The U.S. Food and Drug Administration (FDA) approved 22 new drugs and one biotech medicine during 1994. These new drug entities had an adjusted average review time of 19.7 months, from filing of the New Drug Application (NDA) at the FDA to time of approval. This was down from the 25.6 months for the 26 new entities approval in 1993. In the total drug development and approval process it takes approximately 12 years for an experimental drug to go from the lab to the medicine chest. Only about 5 in 5000 new chemical entities that enter preclinical (lab and animal studies) testing reach human clinical testing (Phase I, II, and III) and only one of the five tested clinically is approved. On average a pharmaceutical manufacturer invests ~\$360 million to get one new drug to the consumer or patient.

In the United States, through the NDA review process, pharmaceutical companies that seek FDA approval for new drug products are assessed user fees by FDA to gain faster approval, by virtue of the U.S. Prescription Drug User Fee Act of 1992. In 1962, amendments to the U.S. Federal Food, Drug and Cosmetic Act promulgated regulations concerning the requirements for premarketing approval by the FDA. This legislation established requirements of proof of both safety and therapeutic efficacy and strict control of human clinical testing, for example, which have extended the time and cost to market a new drug.

The increase in time to bring a new drug to the point of FDA approval, that the 1962 amendments generated, reduced the length of the effectiveness of the patent period. During the same period, the 1960s, availability of generic drug products began to increase significantly. The FDA at that time utilized the Abbreviated New Drug Approval (ANDA) process developed in the 1962 amendments for review and approval of generic drug products that were to be marketed after FDA approval and patent expiration of the originator new drug entity. Some legal questions, however, arose as to the use of the ANDA procedure for generic approval for both pre-1992 and post-1962 new drug approvals.

The world trade agreement, the General Agreement on Tariffs and Trade (GATT), resulted in a U.S. federal law, the Uruguay Round Agreement Act (URAA), that became effective in June 1995. Under this Act, numerous drugs are projected to gain months or even years of additional patent protection, depending on current patent expiration dates. The GATT provides new prescription drugs with 20 years of patent protection from the patent application date.

The 1962 Amendments also mandated a review of safety and therapeutic efficacy for U.S. nonprescription, i.e., over-the-counter or proprietary, products. There are an estimated 125,000–300,000 U.S. OTC products covering a variety of sizes, dosage form types, and dosage form strengths. The FDA has increased its approval rate for the switch of prescription drugs to nonprescription status in the 1990s. This procedure has gained impetus as more than 450 OTC products in 1994–1995 used ingredients and dosages only available by prescription in 1974–1975.

The principal OTC pharmaceutical products include cold remedies, vitamins and mineral preparations, antacids, analgesics, topical antibiotics, antifungals and antiseptics, and laxatives. Others include suntan products, ophthalmic solutions, hemorrhoidal products, sleep aids, and dermatological products for treatment of acne, dandruff, insect parasites, burns, dry skin, warts, and foot care products. More recent prescription-to-OTC switches have included hydrocortisone, antihistamine and decongestant products, antifungal agents, and, as of 1995, several histamine H_2-receptor antagonists.

Personnel. A large number of personnel trained in a wide range of special skills are needed for the development of a new drug. Skills include organic synthesis, medical and analytical chemistry, microbiology and immunology, biochemistry, physiology, pharmacology, toxicology, and pathology. Likewise, in the development of safe, stable, and therapeutically effective drug products various physical chemistry principles apply and specialists trained in this phase of development, pharmaceutics, assume such responsibility. These people become involved in the preformulation studies that investigate the properties of the new drug for inclusion in dosage forms, in the scale-up procedures that are needed to transfer dosage form preparation from laboratory batch sizes to manufacture batch sizes, and in the actual manufacture of the product. These specialists work closely with chemical engineers, especially during the scale-up phase.

Concepts and Processes. Contemporary dosage forms are drug delivery systems, designed and manufactured to achieve safe and effective therapeutic responses each time the forms are used as part of an appropriate regimen. Each drug product involves several interrelated concepts that must be considered in its design and manufacture. Examples include the following:

Component/concept	Requirement
drug (active ingredient)	purity, stability, accuracy in measurement
nontherapeutic ingredients (excipients)	needed for safe and effective delivery of the active ingredient
unit process/manufacturing technology	procedures needed to ensure batch-to-batch, dose-to-dose reliability of safe and effective response
packaging/labeling	designed for patient compliance and product stability
quality assurance procedures	to protect the drug product throughout its projected shelf-life
storage	to ensure stability and safety/efficacy

Attention to various physiochemical parameters of the drug moiety, such as particle size, crystalline form, and solubility, is vital to the design of a dosage form, as are its purity and accurate measurement. Nontherapeutic or excipient ingredients are selected to ensure stability (buffers, chelating agents, antioxidants, antimicrobial preservatives), and accuracy and precision of dosage (diluents, vehicles). Various types of excipients are used for specific types of dosage forms in order to permit their manufacture and desired therapeutic performances. Other excipients function as processing aids. Lubricating agents are solids used in tablet compression to lubricate the diewalls and punch faces to prevent sticking, capping, and/or excessive die-wall wear. Polymers find wide excipient use in dosage form design as viscosity-building agents in suspensions and emulsions and in the control of drug release in products prepared to achieve longer (8–12 h) than usual therapeutic periods. Various excipients are used to provide drug palatability for patients, e.g., colorants and flavoring agents.

The selection of excipient ingredients is important. These must be both chemically and physically compatible with the drug moiety and cannot negatively affect product stability or therapeutic performance, i.e., bioavailability.

The various preparation processes and technologies used in drug product manufacture also can effect product safety, stability, and performance, e.g., compression during tablet manufacture. The principal processes used in dosage form manufacture are as follows.

Dosage form types	Processes
liquid solutions	dissolution and filtration
parenterals	sterilization, lyophilization
liquid dispersion (suspensions, emulsions)	dispersion/wetting of solids, homogenization
semisolid dispersions (ointments, creams)	levigation, melting
liquid/semisolid capsules	soft gelatin encapsulation
suppositories	molding
solids (granules, capsules, tablets)	comminution, blending, granulation, compression, coating
aerosols	specialized packaging under pressure
general	heating, cooling, mixing

The therapeutically active drug can be extracted from plant or animal tissue, or be a product of fermentation, as in the case of antibiotics.

Biological characterization includes toxicological studies, dose relationships, routes of administration, identification of side effects, and absorption, distribution, metabolism, and excretion patterns. If the results are still acceptable, product formulation and dosage form are developed.

Application for discovery and product patents must be made early in the process. Appropriate labels are designed and the product is submitted to the FDA for approval to begin human testing in the form of an Investigational New Drug Application (INDA). When such approval is granted, a clinical evaluation is developed which includes general testing for human pharmacology in healthy volunteers; clinical studies for therapeutic safety and efficacy in volunteer patients who are suffering from the disease for which the drug has therapeutic promise; and drug samples are made available to select clinicians for use on large numbers of patients.

Manufacturing, analytical, and quality control procedures are established. Specifications for raw and in-process materials, as well as for final products per USP/NF and in-house standards are also determined. Process and formula validation assures that each technological procedure in manufacture accomplishes its purpose most efficiently, e.g., blending times for powdered mixtures in tableting, and that each formula ingredient is present in optimal concentrations. Thus, it serves to ensure process control, reproducibility, and content uniformity.

Stability studies are developed to assure a desirable shelf-life period. These also establish limits of acceptability for impurities and degradation compounds, when present, and determine acceptable storage conditions for raw materials and the manufactured products. Stability studies are thus important to the determination of expiration dates for drug products.

Finally, all data, including the results of the clinical investigation, are collected in a New Drug Application (NDA) and sent to the FDA. Once approved, the new drug goes into production. After manufacturing begins, the new drug products must be monitored in clinical use in the marketplace for reports of untoward reactions. This amounts to post-approval surveillance known as Phase IV. All such reports must be submitted to the FDA in a timely manner.

Bioavailability, Bioequivalence, and Pharmacokinetics. Bioavailability can be defined as the amount and rate of absorption of a drug into the body from an administered drug product. It is affected by the excipient ingredients in the product, the manufacturing technologies employed, and physical and chemical properties of the drug itself, e.g., particle size and polymorphic form. Two drug products of the same type, e.g., compressed tablets, that contain the same amount of the same drug are pharmaceutical equivalents, but may have different degrees of bioavailability. These are chemical equivalents but are not necessarily bioequivalents. For two pharmaceutically equivalent drug products to be bioequivalent, they must achieve the same plasma concentration in the same amount of time, i.e., have equivalent bioavailabilities.

Bioavailability, important to the design and preparation of drug products, can be affected adversely by the selection of excipients and/or the manufacturing processes used. Excessive pressure used in the compression of tablets, for example, could cause a tablet to pass through the gastrointestinal tract with no therapeutic effect.

Pharmacokinetics is the study of how the body affects an administered drug. It measures the kinetic relationships between the absorption, distribution, metabolism, and excretion of a drug. To be a safe and effective drug product, the drug must reach the desired site of therapeutic activity and exist there for the desired time period in the concentration needed to achieve the desired effect. Too little of the drug at such sites yields no positive effect (<MEC); too much (>MTC) leads to toxicity. For intravenous administration there is no absorption factor. Total body elimination includes both metabolic processing and excretion.

In cases of all but intravenous administration, dosage forms must make the active moiety available for absorption, i.e., for drug release. This influences the bioavailability and the drug's pharmacokinetic profile. Ideally the drug is made available to the blood for distribution and elimination at a rate equal to those processes. Through technological developments drug product design can achieve release, absorption, and elimination rates resulting in durations of activity of 8–12 hours, i.e., prolonged action/controlled release drug products.

Manufacturing

Compressed Tablets. This popular type of dosage form offers convenience, stability, accuracy and precision, and good bioavailability of active ingredients. After the best formulation has been established, compressed tablets can be manufactured at high rates of speed on advanced equipment. Tablets can be made to achieve rapid drug release or to produce delayed, repeat, or prolonged therapeutic action. Tablets are produced directly by compression of powder blends or granulations, which include a small percentage of fine, particle-sized powders.

Granulation. Granulation methods can be wet or dry. Wet granulation cannot be used for drugs that are sensitive to moisture and heat. The powered drug and diluent are blended with a dispersion of the binder

excipient, e.g., gelatin, to a consistency that can be screened to 840–1800-μm granules (10–20 mesh). These granules are dried on trays in hot-air ovens or fluid-bed dryers. Dry granulation is used when the drug is not stable under the conditions of wet granulation and when the combined powders of a formulation cannot be compressed directly.

Direct Compression. This process is relatively simple and time saving. All the ingredients are blended and then compressed into the final tablet. This is an excellent method, but encumbered by a number of problems. Not all substances can be compressed directly, necessitating a granulation step. Likewise, the flow properties of many blends of fine, particle-sized powders are not such as to ensure even filling of the die cavities of tablet presses. In addition, air entrapment can occur.

The availability of spray-dried lactose, microcrystalline cellulose, and other excipients allows for the use of granular rather than powdered phases. This eliminates some of the problems of particle segregation according to size (demixing) and even flow to the die. Direct compression eventually may be the preferred method of tablet preparation.

Tablet Press. The main components of a tablet compression machine (press) are the dies, which hold a measured volume of material to be compressed (granulation), the upper punches which exert pressure on the down stroke, and the lower punches which move upward after compaction to eject the tablets from the dies. Mechanical components deliver the necessary pressure. The granulation is fed from a hopper with a feed-frame on rotary-type presses and a feeding shoe on single-punch presses. A smooth and even flow ensures good weight and compression uniformity. Using the proper formulation, demixing in the hopper is minimized.

Compressed tablets that are composed of several layers require specially adapted presses designed with several fed hoppers. For a two-layer tablet, one granulation is first fed to a die and partially compressed into a soft tablet. The second granulation is added, and the total die components then are compressed fully. Such procedures are used when the tablet ingredients may be incompatible, which requires separate granulations. If needed, a layer of inert ingredient, e.g., lactose, is inserted between the two.

Layered tablets are also used for a prolonged or sustained therapeutic effect. In this case, one layer disintegrates and dissolves rapidly to provide the initial dosing, whereas the other is designed for controlled release.

Formulation. Compressed tablet formulations contain several types of inert, adjuvant ingredients necessary for proper preparation and therapeutic performance. Tablets designed to be swallowed need diluent, disintegrating, binding (adhesive), and lubricating inert ingredients, whereas troches or lozenges intended to be dissolved slowly in the mouth should not disintegrate quickly, need more binder, and no disintegrant. Lactose or dicalcium phosphate are common diluents, whereas starch and cellulose derivatives are used as disintegrating agents.

Glidants are needed to facilitate the flow of granulation from the hopper. Lubricants ensure the release of the compressed mass from the punch surfaces and the release/ejection of the tablet from the die. Combinations of silicas, corn starch, talc, magnesium stearate, and high molecular weight poly(ethylene glycols) are used. Most lubricants are hydrophobic and may slow down disintegration and drug dissolution.

Colors and flavors increase the elegance and acceptability of the product. Sometimes colors are used for identification.

Effervescent tablets disintegrate by virtue of the chemical reaction occurring in water between component ingredients, such as sodium bicarbonate and citric or tartaric acid, to achieve release of carbon dioxide.

Coating. Sugar or film coatings offer protection from moisture, oxygen, or light and mask unpleasant taste or appearance. Enteric coatings delay the release of active ingredients in the stomach and may prolong the onset of therapeutic activity. The latter are used for drugs that are unstable to gastric pH or enzymes, cause nausea and vomiting or irritation to the stomach, or should be present in high concentration in the intestines, e.g., preoperative sterilization of the gut or as anthelmintics. Effectiveness depends on the varying pH patterns of the gastrointestinal tract and the enzymes present for dissolution and aqueous solubility.

Enteric coating is also used for repeat-action tablets, which contain an enteric-coated core tablet and a sugar or film-coated second dose, permitting the administration of two doses simultaneously. The core dose is released several hours after the initial, outer dose.

Some tablets that provide a sustained period (up to 8–12 h) of therapy may be coated during processing. A portion is released first to bring the drug to the desired blood concentration (onset of activity), whereas a sustained-release portion maintains an effective level for a prolonged period of time (duration of activity), e.g., by coating erosion or diffusion of drug through it.

A more recent development in tablet coating involves the use of gelation as the coating material to produce geltabs. If a tablet is compressed as a capsule-shaped unit prior to gelatin coating it is called a gelcap.

Capsules. Capsules are made in two types. In hard-gelatin capsules, powders or granules are enclosed in rigid gelatin shells. Soft-gelatin capsules contain glycerol as well as gelatin and maintain plastically even when dried. Hard-gelatin capsules are made in two sections, cap and body, which are then filled, whereas soft-gelatin capsules are formed and filled in succession in one manufacturing procedure. Soft-gelatin capsules are generally filled using nonaqueous solutions, although powders can also be used. Most drug companies buy the hard-gelatin shells from external sources. These are made by dipping precisely tooled pins into controlled solutions of gelatin. A film of gelatin adheres to the pins. Upon drying, the units are trimmed to specified length, removed from the pins, and the cap and body portions are joined. Various colors can be incorporated. See also **Gelatin**.

The formulations of filled, hard-gelatin capsules are generally less complex than those of compressed tablets, and require no binders or disintegrators. Upon swallowing, the capsule shell dissolves quickly and the powder ingredients are available for dissolution. Because no initial disintegration step is needed, bioavailability of drugs in capsule formulations is generally better than that of compressed tablets. The capsules are filled by various high speed machines. Occasionally the pharmacist has to perform this procedure manually.

Prolonged Action/Controlled Release, Orally Administered Solid Dosage Forms. The therapeutic purpose of prolonged action and controlled release solid, oral drug products is to maintain safe and effective concentrations of the drug in the blood for 2–4 times longer than those times achieved using regular compressed tablets or capsules. This is accomplished by releasing one portion of the drug quickly, whereas the remaining portion is released at a rate that approaches the elimination rate. Ideally, the second portion should be released at a zero-order rate to achieve this profile. The technologies used for such controlled release only approach such a rate, but do accomplish the increased therapeutic period. These oral products mainly use diffusion-controlled or dissolution-controlled release profiles. The more recognized technologies used to achieve these methods include ion-exchange resins, coated micropellets, barrier coatings, drug embedment in either slowly eroding or plastic matrices, swelling hydrogels of various polymer resins, drug complexation, and osmotic pressure controlled tablets. Other technologies that have been attempted or tested include altered density micropellets, prodrugs, and bioadhesives. See also **Barrier Polymers**.

The best drug candidates for incorporation into prolonged action systems are uniformly absorbed throughout the gastrointestinal (GI) tract, have medium (2–8 h) biological half-lives, and are prescribed for chronic maintenance use. Drugs in large doses are difficult to formulate into such products.

Liquid Dosage Forms. Simple aqueous solutions, syrups, elixirs, and tinctures are prepared by dissolution of solutes in the appropriate solvent systems. Adjunct formulation ingredients include certified dyes, flavors, sweeteners, and antimicrobial preservatives. These solutions are filtered under pressure, often using selected filtering aid materials. The products are stored in large tanks, ready for filling into containers. Quality control analysis is then performed.

Dosage forms of naturally occurring materials having therapeutic activity are prepared by extractive processes, especially percolation and maceration. Examples of such dosage forms have included certain tinctures, syrups, fluid extracts, and powdered extracts.

Solutions for external or oral use do not require sterilization but generally contain antimicrobial preservatives. Ophthalmic solutions and parenteral solutions require sterilization.

For the preparation of suspensions and emulsions, colloid mills and homogenizers, respectively, are used. Ultrasonic mills that utilize vibrating reeds in restricted chambers to reduce the particle size of the dispersed ingredients can also be employed. See also **Colloid Systems**.

Semisolid Dosage Forms. The ingredients that constitute the base of ointments, e.g., petrolatum and waxes, are melted together, powdered drug components are added, and the mass stirred with cooling. Generally, the product then is passed through a roller mill to achieve the particle-size range desired for the dispersed solid. Pastes are ointments having relatively large, dispersed solid content, and are prepared similarly.

Creams are semisolid emulsions either water-in-oil (w/o) or oil-in-water (o/w).

Suppositories are semi-rigid, plastic dosage forms are designed to deliver a unit dose of medication to body cavities, i.e., rectum, vagina, or urethra. Depending on the base, suppositories either melt (cocoa butter) at body temperature or dissolve (poly(ethylene glycol)s, glycerogelatin) in the fluids of the cavity. They can be used for systemic therapy (rectal suppositories) or for localized treatment. Rectal suppositories are a route of administration in comatose conditions or after gastrointestinal surgery, and for pediatric patients. On a large scale, suppositories are produced by molding.

Parenteral Dosage Forms. The most commonly used forms for drug products designed and manufactured for injection through the skin include those meant for subcutaneous, intramuscular, and intravenous administration.

Intravenous aqueous injections provide an excellent means of achieving a rapid therapeutic response. Parenteral product design, e.g., vehicle and other excipient selection, as well as choice of route of administration, can prolong therapeutic activity and increase onset times. Thus, oily solutions, suspensions, or emulsions can be administered by subcutaneous or intramuscular routes to create prolonged effect, i.e., depot injection.

Several factors of design and manufacture are of great importance: sterility, absence of pyrogens and foreign particulate matter, and tonicity. The last, when adjusted to the osmotic pressure of body fluids in the case of aqueous solutions, reduces the risk of tissue irritation and pain.

Lyophilization. Lyophilization is essentially a drying technology. Some drugs and biologicals are thermolabile and/or unstable in aqueous solution. Utilization of freeze drying permits the production of granules or powders that can be reconstituted by the addition of water, buffered solution, or mixed hydrophilic solvents just prior to use, e.g., certain antibiotic suspensions.

Ophthalmic Dosage Forms. Ophthalmic preparations can be solutions, e.g., eye drops, eyewashes, ointments, or aqueous suspensions. They must be sterile and any suspended drug particles must be of a very fine particle size. Solutions must be particle free and isotonic with tears. Thus, the osmotic pressure must equal that of normal saline (0.9% sodium chloride) solution. Hypotonic solutions are adjusted to be isotonic by addition of calculated amounts of tonicity adjusters, e.g., sodium chloride, boric acid, or sodium nitrate.

Radiopharmaceuticals. Radioactive isotopes for human use in the diagnosis and treatment of disease states are called radiopharmaceuticals. Whereas the dosage form types used, e.g., solutions or injections, are traditional, special handling of these products during compounding, transport, and use is vital. Most are administered intravenously and shortly after preparation. Specialized pharmacies prepare these products overnight and transport them to hospitals for early administration by members of nuclear medicine departments.

Aerosols. Pressurized containers to deliver aerosolized drug products through appropriate systems of valves and actuators have been available since the 1950s. See also **Aerosols**. Such dosage forms are used as external applications of lotions and creams, for oral inhalation, or for treatment of the vaginal cavity, e.g., contraceptive foams. Aerosols contain two- or three-phase systems, wherein a volatile liquid or ad-mixture of liquids is sealed in a container in equilibrium with a vapor phase (propellant). Upon actuation and delivery of the product, the propellant evaporates quickly, and fine dispersion of the drug settles on the area of application. For aerosol products that need accurate dosing, metered valves are used with the valve chamber being recharged between each actuation or dose.

The popularity of aerosols has been declining. A widely used group of propellants, the fluorinated hydrocarbons, have been restricted in use since it was found that they can harm the environment by reducing the ozone layer of the upper atmosphere. See also **Pollution (Air)**; and **Ozone**.

Biotechnology and Dosage Forms. In drug development, biotechnology generally is recognized as a term that identifies those technologies that utilize living organisms in the production and/or alteration of chemical entities that have potential therapeutic activity. Besides the production of pharmacologically or biochemically active moieties, these technologies also have been used to produce food ingredients, vaccines, diagnostic testing reagents, and agricultural products. See also **Fermentation**; and **Vaccine Technology**.

Packaging. The packaging components of pharmaceutical products are vital to their safe and effective use. Besides serving the patient as a convenient unit of use, the composite package (unit container, labeling, and shipping components) must provide appropriate identification and necessary information for proper use (including warnings and cautions) and preservation of the product's chemical and physical integrity.

Labeling. Labeling, controlled by FDA regulations, includes not only the affixed labels, but also the package inserts that provide more detailed information. Trade, generic, or common name, dose, number of dose units present, and name and address of manufacturer and distributor are required. For nonprescription products, adequate directions for use are required. Prescription products must bear the phrase, "Caution: Federal law prohibits use without a prescription" on their labels.

All drug labels must include batch or lot numbers. The nature of the drug product may require special cautionary phrases, e.g., "store in cool place or refrigerator," "protect from light," and "shake well before using." In the 1990s, labels also carry the expiration date, i.e., shelf-life. This information is expected to become mandatory.

Labeling information also includes warnings as to possible side effects, e.g., drowsiness, and potential harm if used with other drugs or certain foods (drug–drug or drug–food interactions). Inserts are generally intended for use by physicians or pharmacists and give name and description of the product, mode of administration, dosage regimen, therapeutic indications and contraindications, precautions and side effects, units of supply, and literature citations. All labeling must be approved by the FDA as part of the New Drug Application.

Containers. The USPXXIII–NFXVIII lists container requirements such as well-closed, tight, or light-resistant. Most containers are light-resistant (amber) glass or plastic. The latter is break-resistant and lightweight, which reduces shipping costs and increases safety.

In hospitals and long-term care units, unit-dose packages are used more and more. This system allows better control of the dispensed drugs in institutional settings and precludes the dispensing of larger numbers of doses than needed.

Quality Control and Quality Assurance

Quality control (QC) involves the regular, daily assessment and/or analysis, according to established protocols and standards, of all ingredients, processes, and finished products. Official USP/NF monographs, for example, provide various chemical, physical, and biological tests and specifications for assurance of purity, potency, and stability of component ingredients used to prepare and package drug products. The FDA requires process validation procedures as QC constituents. The FDA also monitors QC standards through the requirements of the Current Good Manufacturing Procedures regulations.

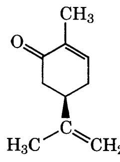
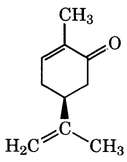
PHARMACEUTICALS, CHIRAL. Stereoisomers are compounds which have the same molecular formula but differ in the arrangement of their atoms in space. Chiral compounds are compounds which

have nonsuperimposable mirror images. Enantiomers are pairs of stereoisomers which are nonsuperimposable mirror images; they possess identical physical and chemical properties within an achiral environment. Stereoisomers other than enantiomers, i.e., diastereomers, are identified by distinct physical and chemical properties including melting points, spectral characteristics, and rates of reaction with both chiral and achiral reactants. Enantiomers, however, are only distinguished when in the presence of a homochiral environment such as polarized light, chiral solvents, chiral reagents, or chiral molecules such as biomolecules, e.g., nucleic acids, proteins, and carbohydrates. The two molecules in a pair of enantiomers rotate a plane of polarized light with equal intensities, but in opposite directions. The dextrorotatory isomer (+ or *d*) rotates the plane of polarized light clockwise; the levorotatory isomer (− or *l*) rotates the plane of polarized light counterclockwise. An equal mixture of (+) and (−)-enantiomers is a racemic mixture or racemic compound and does not rotate a plane of polarized light. Optical rotation, an intrinsic property of the substance, has no bearing on drug-macromolecule interactions. It is the absolute configuration of the homochiral compound that is important for its interaction with biomolecules.

Absorption, metabolism, and biological activities of organic compounds are influenced by molecular interactions with asymmetric biomolecules. These interactions, which involve hydrophobic, electrostatic, inductive, dipole–dipole, hydrogen bonding, van der Waals forces, steric hindrance, and inclusion complex formation give rise to enantioselective differentiation. Within a series of similar structures, substantial differences in biological effects, molecular mechanism of action, distribution, or metabolic events may be observed. For example, (*R*)-carvone (**1**) has the odor of spearmint whereas (*S*)-carvone (**2**) has the odor of caraway.



(**1**)



(**2**)

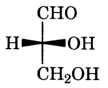
The amino acids L-leucine, L-phenylalanine, L-tyrosine, and L-tryptophan all taste bitter, whereas their D-enantiomers taste sweet. See also **Amino Acids**.

The importance of optical isomers with regard to biological effect has a long history beginning with the observations of Pasteur. The U.S. FDA requires that both enantiomers of a drug be individually tested when associated toxicities occur near the effective dose of the racemic substance. It has been suggested that the use of racemic drugs in human subjects cannot be justified until both enantiomers are tested thoroughly, both individually and in composite mixtures. Often, side effects of therapeutics are not discovered until after large-scale marketing. The distomer (therapeutically inactive enantiomer) may be at best a nontoxic impurity, but is often associated with dangerous side effects as exemplified by the thalidomide problem.

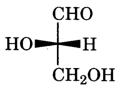
The thrust toward homochiral drugs by leading researchers and organizations such as the FDA, the rapidly expanding technology of asymmetric syntheses and chiral separations, the decreased side effects found with homochiral drugs, and the potential financial benefits are expected to ensure that the majority of chiral synthetic drugs will, in the future, be available in enantiomerically pure form. See also **Pharmaceuticals**.

Background

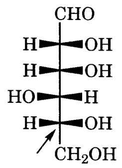
Nomenclature. Compounds which have tetrahedral atoms having four different substituents are often chiral. These tetrahedral atoms are referred to as stereocenters or stereogenic atoms; the terms asymmetric atom or asymmetric center are considered misnomers. The letters D and L are used to denote the absolute configurations of amino acids and sugars according to Fischer-Rosanoff nomenclature (See also **Sugar**). In this system, dextrorotatory glyceraldehyde (**3**) is arbitrarily assigned an absolute configuration of D. In a Fischer projection, the most highly oxidized carbon is placed on top and the last stereocenter determines the absolute configuration L or D. Examples of Fischer projections are shown for D- and L-glyceraldehyde (**4**) and D- (**5**) and L-glucose (**6**) where the arrow denotes the determining stereocenter.



(**3**)

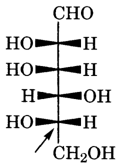


(**4**)



D-glucose [*492-62-6*]

(**5**)

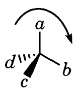


L-glucose [*921-60-8*]

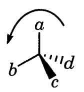
(**6**)

If the heteroatom attached to the last stereocenter projects to the right, the compound is of the D-configuration; if the heteroatom points to the left, the compound is of the L-configuration. There is no simple relationship between sign of rotation (*d* (+) or *l* (−)) and the absolute configuration D or L. However, optical activity may be related empirically to absolute configuration by observing changes in optical rotation with varying wavelength, i.e., optical rotatory dispersion (ord) and circular dichroism (cd).

Because of ambiguities involved in this nomenclature, the Cahn-Ingold-Prelog rules were introduced and are widely used to designate the absolute configuration of stereocenters. Groups attached to the stereogenic atom are assigned priorities according to the atomic number of the atom attached to the stereogenic center. Highest priority is given to the atom with the highest atomic number. The molecule is drawn such that the function of lowest priority (*d*) is directed away from the viewer:



(*R*)-enantiomer



(*S*)-enantiomer

If the observed order of priority of the remaining three functions ($a > b > c$) is in a clockwise direction, the absolute configuration is designated *R* (rectus or right); if counterclockwise, the configuration is *S* (sinister or left). Diastereomers which differ at a single stereocenter are called epimers.

Enantiomeric purity, measured as the enantiomeric excess (ee) of an isomer, is determined by the formula (% major isomer)—(% minor isomer). Thus, if a chiral drug is said to be of 50% ee, the composite mixture contains 75% of one enantiomer and 25% of the other. Enantioselectivity refers to the greater activity of one enantiomer over its mirror image. Enantiospecificity is rarely observed and implies that one enantiomer possesses 100% of the observed activity; in most cases it is more accurate to use the term highly enantioselective. The pharmacologically more active enantiomer is termed the eutomer and the less active enantiomer is referred to as the distomer.

The therapeutic efficacy of a drug is generally measured in terms of ED_{50} or ID_{50} which represent the concentration of drug which produces 50% of the maximum effect or 50% of maximum inhibition.

Role of Homochiral Molecular Building Blocks. Generally L-amino acids and D-sugars are found in biological systems.

The formation of D-amino acids in polypeptides and in monomeric form during processing of proteinaceous foods has raised considerable concern about associated nutritional and toxicity effects. Racemization of amino acids occurs under strongly basic or acidic conditions, which are conditions used in food processing. The presence of aldehydic contaminants enhances the rate of amino acid racemization through formation of stereogenically labile α-imino acids. D-Amino acids may be utilized in a nutritional manner if they are converted to L-amino acids. For the most part, D-amino acids are generally no more toxic than their L-enantiomers. Thus, foods containing proteins with high concentrations of D-amino acid residues may be useful for weight management.

Modeling of Drug-Receptor Interactions. The identification of molecular interactions between drugs and their receptor or enzyme targets and the three-dimensional spatial requirements of the macromolecular binding pocket are important for the rational design of new, more selective,

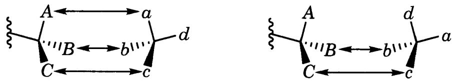
and potent pharmaceuticals. Methods used to explore such interactions include nmr spectroscopy of receptor-ligand complexes, molecular modeling, point mutation analysis, and binding assays of conformationally constrained, stereochemically defined small molecules. See also **Molecular Modeling**. X-ray crystal structure analysis of macromolecule-ligand complexes provides information concerning important molecular interactions which give rise to the observed affinity between the macromolecule and ligand. Computers are used to graphically display calculated crystal structures. Numerous computer programs have been developed and refined which are capable of determining the energy minimized structures of such complexes.

Molecular modeling techniques, although aesthetically pleasing, are far from reliable owing to the large number of associated variables.

Methods for the Preparation of Homochiral Drugs

Resolution Methods. Chiral pharmaceuticals of high enantiomeric purity may be produced by resolution methodologies, asymmetric synthesis, or the use of commercially available optically pure starting materials. Resolution refers to the separation of a racemic mixture. Classical resolutions involve the construction of a diastereomer by reaction of the racemic substrate with an enantiomerically pure compound. The two diastereomers formed possess different physical properties and may be separated by crystallization, chromatography, or distillation. A disadvantage of the use of resolutions is that the best yield obtainable is 50%, which is rarely approached. However, the yield may be improved by repeated racemization of the undesired enantiomer and subsequent resolution of the racemate. Resolutions are commonly used in industrial preparations of homochiral compounds.

Three general methods exist for the resolution of enantiomers by liquid chromatography. Conversion of the enantiomers to diastereomers and subsequent column chromatography on an achiral stationary phase with an achiral eluant represents a classical method of resolution. Diastereomeric derivatization is problematic in that conversion back to the desired enantiomers can result in partial racemization. Direct resolution of the enantiomers without derivatization is performed by use of an achiral stationary phase with a chiral mobile phase or, more commonly, by use of a chiral stationary phase and an achiral mobile phase. Ligand-exchange chromatography, using Cu^{2+} and proline, and chiral ion pair chromatography, which involves use of a chiral counterion in the mobile phase, exemplify the former method. Chromatographic resolution of enantiomers using chiral stationary phases is advantageous over the previously described methods in that no derivatization is required, there is no need to employ expensive mobile phases, and the method does not require complicated product analysis. Stationary phases include cyclodextrins, protein bonded supports, chiral polymers, and the Pirkle type. See also **Polymers**. The three-point rule for chiral recognition is used to rationalize the separation of enantiomers by use of a homochiral stationary phase and an achiral eluent. The (S)-enantiomer possesses three favorable interactions with the stationary phase and is therefore expected to traverse the column at a slower rate than its (R)-enantiomer, which maintains only two favorable interactions.



(S)-enantiomer (R)-enantiomer

Methods Employing Enantiomerically Pure Starting Materials. A large number of optically pure natural products are commercially available and relatively inexpensive. Amino acids, carbohydrates, and terpenes are some of the homochiral building blocks used routinely in enantiomeric syntheses. The stereocenter(s) in such building blocks are used as either chiral synthons (chirons) or as chiral auxiliaries. Chirons are an inexpensive source of chirality and their use in organic synthesis generally produces enantiomerically pure compounds of known absolute configuration. The commercially available polyether antibiotic monensin, which contains 17 stereocenters, is synthesized by the preparation and coupling of three fragments, each prepared from commercially available optically active starting materials.

Many notable examples of the synthesis of complex natural products from optically pure starting materials have been reported. One synthesis of considerable interest is that of taxol, a potent antitumor agent used clinically. The starting material used in the first total synthesis of taxol is produced in enantiomerically pure form from inexpensive and readily available l-camphor.

Asymmetric Induction Methodologies. Asymmetric synthesis is defined as the construction of new chiral centers within a prochiral molecule, with the condition that one optical isomer is formed to a greater extent than the other. The most common type of asymmetric induction involves the conversion of a trigonal carbon atom to a tetrahedral carbon atom by use of a reagent that is biased toward preferential attack from one side or face of the prochiral molecule. Generally, asymmetric induction involves diastereotopic transition states wherein one transition state is favored due to steric and electronic effects which govern the selective formation of one enantiomer. The primary advantage of asymmetric synthesis resides in the stereoselective production, in general, of either enantiomer of a compound; synthesis of both enantiomers is not always possible using chiral synthons or auxiliaries. Asymmetric syntheses avoid the use of inefficient resolutions, and often the reagent or catalyst is recyclable making the synthetic process both material and cost efficient. Asymmetric reduction of ketones, epoxidation of allylic alcohols, hydroboration, hydrogenation, and dihydroxylation reactions, as well as asymmetric cycloaddition reactions, allyl borations, and aldol condensations represent several classes of the numerous enantioselective reactions developed since the 1960s.

Analysis of Synthetic Homochiral Drugs

Determination of Absolute Configuration. X-irradiation of a crystal produces a diffraction pattern from which the relative spatial orientation of the atoms that make up the molecule may be determined. If the crystal is made of homochiral molecules, the absolute configuration of the compound may be deduced.

Chemical conversion of compounds to intermediates of known absolute configuration is a method routinely used to determine absolute configuration. This is necessary because x-ray analysis is not always possible; suitable crystals are required and determination of the absolute configuration of many crystalline molecules cannot be done because of poor resolution. Such poor resolution is usually a function of either molecular instability or the complex nature of the molecule.

ORD and CD also provide a basis by which the absolute configuration of a compound may be correlated with that of a known compound of similar structure by observing changes in degree of rotation with wavelength.

Determination of Enantiomeric Purity. In order to analyze the biological properties of a single enantiomer, the optical purity of the compound should be enantiomerically pure, i.e., 100% ee. Contrasting reports on the differences in pharmacological activity of single enantiomers, as well as the misinterpretation of data, are often a result of unknowingly testing enantiomerically impure material. The oldest and perhaps easiest method for determining optical purity is by measuring optical rotation and comparing the value with that reported for the enantiopure compound. There are several drawbacks to this method. The assumption must be made that the reported literature value is without error, and truly represents the optically pure compound. Numerous examples exist in which unambiguous methods, i.e., chiral gc, hplc, nmr, for determination of optical purity reveal that the previously reported values for optically pure compounds were in error. Variables such as temperature, solvent, concentration, purity of the compound, type of cell, and even differences between polarimeters employed in the measurement influence the observed degree of rotation. Therefore, polarimetry measurements for determination of optical purity deviate by at least $\pm 4\%$.

^{1}H-nmr is commonly used to determine enantiomeric purity and is reliable to above 98% ee.

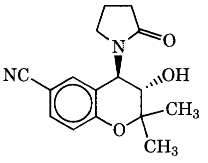
Chiral Pharmaceuticals

Enantiomeric Pairs. Enantioselective differences in absorption, metabolism, clearance, drug–macromolecule binding affinity, and other factors, which culminate in the observed enantioselective efficacy chiral drugs, are considered.

Antihypertensive Agents. Hypertension (high blood pressure) is a significant risk factor for cardiovascular diseases such as angina heart attacks, and strokes. β-Adrenoceptor (adrenergic nervous system receptors of the β-type) antagonists (β-blockers), calcium channel blockers, angiotensin-converting enzyme (ACE) inhibitors, and potassium channel activators

(KCAs) are among the numerous classes of drugs developed to control hypertension. See also **Enzyme Inhibitors**. β-Adrenoceptor antagonists exemplified by the phenoxypropanolamine derivatives propranolol and alprenolol and or the phenethanolamine drugs such as sotalol and require for activity both the ethanolamine portion and an aromatic ring. Furthermore, the correct spatial arrangement of the phenyl, ethylamine, and hydroxyl moieties is critical for β-blockade.

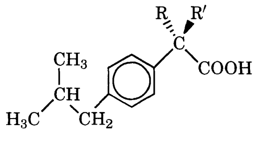
It has been demonstrated that the β_1-selectivity is due to the para-substituents of β-adrenoceptors. In contrast, (−)-erythro-isoetharine, a bronchodilator, is 80 times more selective for β_2-adrenergic receptors than for β_1-receptors. Isoetharine contains an α-alkyl substituent, thus producing four isomeric compounds. The (−)-erythro isomer is 100-fold more active than the (−)-threo isomer and has more than 500 times the activity of either of the (+)-isomers and in blocking electrically stimulated spasms. In general, introduction of α-alkyl substituents on both β-blockers and agonists provides diastereomers with increased β_2-selectivity, but often with compromised potency.



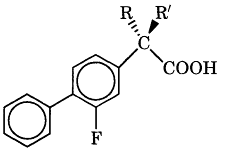
(**7**)

Cromakalim (**7**) is a potassium channel activator commonly used as an antihypertensive agent. The rationale for the design of cromakalim is based on β-blockers such as propranolol and atenolol. Conformational restriction of the propanolamine side chain as observed in the cromakalim chroman nucleus provides compounds with desired antihypertensive activity free of the side effects commonly associated with β-blockers. Enantiomerically pure cromakalim is produced by resolution of the diastereomeric (*S*)-α-methylbenzylcarbamate derivatives. X-ray crystallographic analysis of this diastereomer provides the absolute stereochemistry of cromakalim. Biological activity resides primarily in the (−)-(3*S*, 4*R*)-enantiomer. In spontaneously hypertensive rats, the (−)-(3*S*, 4*R*)-enantiomer, at dosages of 0.3 mg/kg, lowers the systolic pressure 47%, whereas the (+)-(3*R*, 4*S*)-enantiomer only decreases the systolic pressure by 14% at a dose of 3.0 mg/kg.

Nonsteroidal Antiinflammatory Drugs. Nonsteroidal antiinflammatory drugs (NSAIDs) include, among the numerous agents of this class, aspirin (acetylsalicylic acid), the arylacetic acids indomethacin and sulindac, and the arylpropionic acids, (*S*)-(**8**) and (*R*)-(**9**) ibuprofen, (*S*)-(**10**) and (*R*)-(**11**), flurbiprofen naproxen, and fenoprofen. See also **Analgesics, Antipyretics, and Antiinflammatory Agents**; and **Salicylic Acid and Related Compounds**.



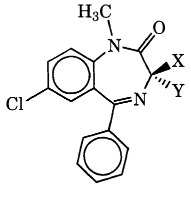
(**8**) R = CH_3; R′ = H
(**9**) R = H; R′ = CH_3



(**10**) R = CH_3; R′ = H
(**11**) R = H; R′ = CH_3

Although the arylpropionic acids contain a stereogenic center they are generally marketed as racemic mixtures. The only exception is naproxen, which is marketed as its (*S*)-enantiomer. NSAIDs produce their antiinflammatory effects by inhibiting cyclooxygenase (COX), the enzyme which catalyzes the first transformation in the biosynthetic conversion of arachidonic acid to the 20 carbon prostaglandins.

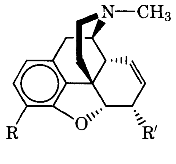
CNS Depressant Drugs. Central nervous system (CNS) depressant drugs including antianxiety agents (benzodiazepines), sedative-hypnotics, general anesthetics, and certain spasticity agents all demonstrate high degrees of enantioselective activity. Barbiturates are commonly prescribed for their sedative-hypnotic activities. In general, the (*S*)-(−)-enantiomers possess CNS depressant activities, whereas the (*R*)-(+)-isomers (*R*)-(+)-isomers often produce an excitatory effect. In humans, (*R*)-(+)-pentobarbital is found bound to human plasma proteins to a lesser extent than the (*S*)-(−)-isomer (36.6% free vs 26.5% free) and is subsequently cleared 14% faster. This increased rate of clearance is not sufficient to account for the two- to threefold greater duration of action of (*S*)-(−)-pentobarbital, and suggests that the difference in activity between the enantiomers is due to the pharmacodynamics of the more potent (*S*)-isomer. (*S*)-(+)-Hexobarbital, the eutomer, is eliminated about 2.5 times more slowly than the inactive (*R*)-(−)-isomer, a result of differences in hepatic metabolism. Diazepam (**12**), an achiral benzodiazepine, undergoes stereoselective metabolism to (*S*)-(+)-oxazepam (**13**) in the liver. (*S*)-(+)-Oxazepam produces antianxiety effects to a greater degree than the mirror image isomer (**14**).



(**12**) X, Y = H
(**13**) X = H; Y = OH
(**14**) X = OH; Y = H

Antibiotic and Antimicrobial Drugs. The antimicrobial agents flumequine and methylflumequine (S-25930) effectively eliminate a number of microbial pathogens via inhibition of the topoisomerase II enzyme of c-DNA containing bacteria. (see **Antibacterial Agents, synthetic**. The (*S*)-enantiomers of both drugs are much more potent than the (*R*)-enantiomers. The potent analogue (*S*)-(−)-ofloxacin is 8–125 times more potent than its enantiomer although it is sold only as the racemate. In humans the disposition of (*R*)- and (*S*)-enantiomers of ofloxacin is stereoselective due to differences in renal clearance rates. This difference, however, does not fully explain the large enantioselective difference in antibacterial potency. β-Lactam antibiotics. See also **Antibiotics**, such as the penicillins and cephalosporins, require the (3*S*, 5*R*, 6*R*)-configuration of the β-lactam functionality combined with a D-amine in either the 6-position (penicillins) or 7-position (cephalosporins) to produce optimal activity.

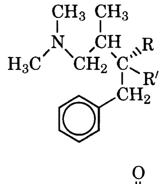
Opioid Analgesic Drugs. (5*R*, 6*S*, 9*R*, 13*S*, 14*R*)-(−)-Morphine (**15**) and its closely related relatives (−)-codeine (**16**) and (−)-heroin (**17**) are potent analgesics, while their (+)-isomers possess no analgesic effects, α-Dextropropoxyphene (DARVON) (**18**) is a marketed analgesic whereas its enantiomer, α-levopropoxyphene (NOVRAD) (**19**) is sold as an antitussive devoid of analgesic activity. These analgesics produce their biological effects via stimulation of the opioid receptor subclasses mu-, delta-, kappa-, and sigma.

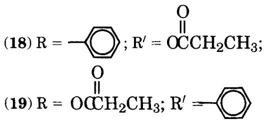


(**15**) R = R′ = OH

(**16**) R = —OCH_3; R′ = OH

(**17**) R, R′ = —OC(=O)—CH_3

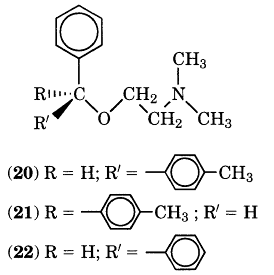


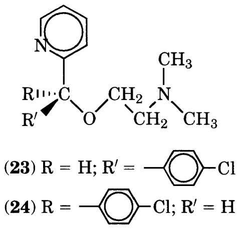


Anticoagulant Drugs. Warfarin, a potent anticoagulant, was first isolated from spoiled clover hay and identified as the agent responsible for the hemorrhagic symptoms associated with the death of livestock in the 1930s. This functionalized coumarin derivative exerts its effect via competitive inhibition of vitamin K-dependent carboxylation of blood clotting factors. Warfarin is generally administered as the racemate, even though (*S*)-warfarin is fivefold more active than (*R*)-warfarin in both rats and humans. The (*S*)-enantiomer is eliminated at a higher rate than its antipode in humans, but in rats, (*R*)-warfarin is more rapidly eliminated.

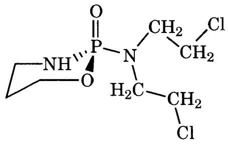
Neurotransmitters. Histamine receptors are found in at least two subtypes designated H_1 and H_2. See also **Histamine and Histamine Antagonists**. H_1-receptor antagonists produce vasoconstriction, while H_2-receptor antagonists inhibit gastric secretion. Neobenodine (**20**) and (**21**), the chiral *p*-methylphenyl analogue of benadryl (**22**), is an antihistamine marketed as the racemate. The (*R*)-(+)-isomer (**20**) is 65 times more potent than its (−)-enantiomer (**21**) when tested in guinea pig ileum. Chlorpheniramine (**23**) and (**24**) is also an enantioselective H_1-antagonist,

wherein the (S)-enantiomer (**23**) is most potent. It has been demonstrated that the more potent enantiomer of diphenhydramine and pheniramine drugs is the one in which the aryl moiety, alkylamine group, and the *p*-substituted aryl functionality occur in a clockwise orientation.

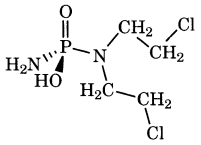




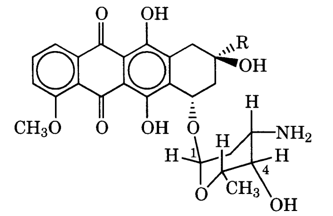
Antineoplastic Drugs. Cyclophosphamide (**25**) produces antineoplastic effects via biochemical conversion to a highly reactive phosphoramide mustard (**26**); it is chiral owing to the tetrahedral phosphorus atom. The therapeutic index of the (S)-($-$)-cyclophosphamide (**25**) is twice that of the (+)-enantiomer due to increased antitumor activity; the enantiomers are equally toxic. The effectiveness of the DNA intercalator drugs adriamycin (**27**) and daunomycin (**28**) is affected by changes in stereochemistry within the aglycon portions of these compounds. Inversion of the carbohydrate C-1 stereocenter provides compounds without activity. The carbohydrate C-4 epimer of adriamycin, epirubicin, is as potent as its parent molecule, but is significantly less toxic. (R)-3-Ethyl-3(4-pyridyl)piperidine-2,6-dione (**29**), useful in the treatment of certain breast cancers, is a 20-fold more potent aromatase inhibitor ($IC_{50} = 10\ \mu M$) than is its (S)-enantiomer.



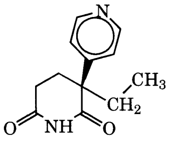
(25)



(26)



(27) R = —COCH$_3$
(28) R = —COCH$_2$OH



(29)

Peptidomimetics. Many drugs mimic natural small peptides. For example, morphine (**15**) is believed to be a natural peptidomimetic for the enkephalins. Similarly, FK-506 mimics the binding of peptidal FK-506 to the intracellular receptor, FKBP12. Numerous small endogenous peptides have been characterized which possess potent cellular signaling and homeostatic regulating activities. The regulation of glycolysis, growth, mitosis, and apoptosis, as well as the maintenance of blood pressure and the natural relief of pain, exemplify a few of the regulatory actions of peptide hormones. Exogenous control, through the use of synthetic compounds, of the activities of these regulatory elements is highly desirable as demonstrated by the use of drugs such as the ACE inhibitor captopril. The design of peptidomimetics is complicated owing to the flexibility and stereochemical complexity of such hormones. Numerous small peptides have been synthesized which possess tremendous enzyme inhibitory and receptor binding activities *in vitro*; HIV protease inhibitors are one example. Unfortunately, the use of such peptides *in vivo* generally is not successful, as peptidase enzymes rapidly degrade synthetic peptides.

Several methods are being studied to enhance the stability of peptide mimics and improve their stereochemical similarity to the endogenous peptides.

Economic Aspects

Drugs classified as either natural or semisynthetic in origin accounted for ~22% of the market share in 1991. Nearly 94% of the agents are chiral compounds and are sold as single enantiomers. Chiral synthetic drugs make up 38% of the market share and 43% of these are sold as single enantiomers, a two- to threefold increase since 1981. Achiral or symmetrical synthetic drugs make up 40% of the drug market. The vast number of marketed racemic drugs are being reinvestigated and newer pharmacological data as well as production technology are being patented.

A steady increase in the number of homochiral drugs on world markets has created an increased demand for enantiomerically pure intermediates as well as for enantioselective technologies. Many pharmaceutical companies are pursuing new financial opportunities and gaining improved bargaining positions by producing patent protected and more expensive enantiomerically pure drugs from unprotected racemic pharmaceuticals.

PHARMACODYNAMICS. Pharmacodynamics is the study of drug action primarily in terms of drug structure, site of action, and the biochemical and physiological consequences of the drug action. The availability of a drug at its site of action is determined by several processes, including absorption, metabolism, distribution, and excretion. These processes constitute the pharmacokinetic aspects of drug action. The onset, intensity, and duration of drug action are determined by these factors as well as by the availability of the drug at its receptor site(s) and the events initiated by receptor activation.

Both pharmacokinetic and pharmacodynamic processes are involved in mediating nonconstant expressions of drug action. Thus, resistance to the actions of a drug, e.g., in the development of antibiotic-resistant bacteria or of barbiturate tolerance, can arise from changes in drug metabolism and/or alterations in the receptor target site. Factors controlling drug resistance may be whole-body, cellular, or individual events. Decreased absorption, increased metabolism, or increased elimination reduce circulating drug levels and affect the whole body. Increased drug metabolism, increased concentration of an agent that antagonizes drug action, decreased affinity or concentration of a drug receptor, and depletion of an agent that mediates drug action are examples of cellular events; and genetic factors controlling metabolism, receptor alterations, and disease states are examples of individual events. Individual variation in the susceptibility to a particular drug or class of drugs also may arise from genetically based pharmacokinetic factors as well as from specific receptor-linked changes.

For a large number of drugs, including neurotransmitters, peptide and protein hormones, and their analogues and antagonists, the cell membrane is the principal locus of action. Concepts of cell membrane structure are derived from the original Davson-Danielli lipid bilayer hypothesis. More specifically, the membrane is viewed as a dynamic fluid mosaic or a matrix of fluid bilayer in which there are asymmetrically inserted proteins and glycoproteins. Phospholipids and proteins diffuse laterally and the resultant protein-protein communication is of considerable importance to the understanding of membrane-receptor function. Despite the dynamic nature of the membrane and the absence of global organization, local organization is possible through the local assembly of individual protein components and the attachment of membrane proteins to the subcellular structure of contractile proteins. However, the cell membrane is not the site of action of all drugs. A number of drugs, including steroid and thyroid hormones, exert their effects intracellularly at the level of the genetic material as well as at the plasma membrane. Other agents, including

polypeptide growth factors, exert their effects not only at the plasma membrane through tyrosine kinase receptors, but also on cell growth and differentiation at the genetic level.

Drug Discovery and Regulation

In the United States and elsewhere, the introduction of a new drug is subject to a sequence of well-defined stages of development and approval. Each stage involves either scientific testing or submission and preparation of data and analysis review (Fig. 1).

An investigational new drug (IND) application usually initiates the process for drug approval. The IND derives from the concept that a specific molecule or molecules may have a particular therapeutic benefit. Preclinical data are analyzed to determine the implications of such molecules for human pharmacology, chemical composition, manufacturing processes, and the protocols for subsequent clinical work. Clinical trials are usually carried out in at least three phases. Phase one involves a small number of individuals and is designed to find information about basic safety and response issues. In phase two studies, the drug is employed on a larger number of individuals (100–200) who suffer from the condition that the drug is designed to treat. Phase three studies involve a much larger group of patients and are designed to assess safety, efficacy, and dosage regimens in a broad range of patients across lines of age, race, and gender. Phase three studies may involve several thousand patients and be carried out at several sites.

New drug application (NDA) is the process through which the U.S. Food and Drug Administration (FDA) authorizes the marketing of a new drug. In the NDA, the data are intended to demonstrate the safety and efficacy of the drug in its intended application. After approval, the drug becomes available to the public. Subsequently, dosage amounts and forms may be modified according to experience, new indications may be added, and contraindications may be noted. All of the changes require regulatory approval. A drug in human use is subject to constant surveillance.

The Receptor Concept

Drug receptors are chemical entities which are typically, but not exclusively, small molecules that interact with cellular components, frequently at the plasma membrane level. There are many types of receptors; heat, light, immune, hormone, ion channel, toxin, and virus are but a few that can excite a cell. The receptor concept can be applied generally to signal recognition processes where a chemical or physical signal is recognized. This recognition is translated into response and the process can be seen as a flow of information.

Elucidation of the structural requirements for drug interaction at the recognition site is by the study of structure-activity relationships (SAR), in which, according to a specific biologic response, the effects of systematic molecular modification of a parent drug structure are determined. Such studies have permitted the classification of discrete classes of pharmacological receptors.

The demonstration of the existence of strictly defined SARs, which is perhaps the most important criterion of drug action at a specific receptor site, has made possible the most important pharmacologic discoveries. For example, the analgesic actions of morphine and related agents, which are indicative of specific receptors, led to the discovery of endogenous opiate peptides, i.e., the leucine and methionine enkephalins and endorphins.

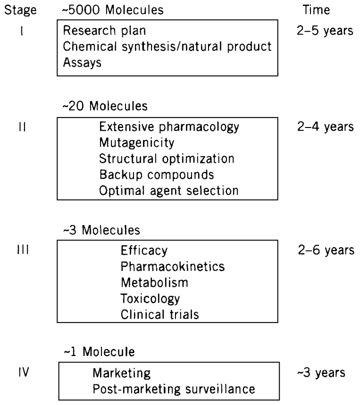

Fig. 1. Pathway for drug development

Pharmacokinetic Aspects of Drug Action

The receptor represents the locus of drug action. However, the pharmacokinetic processes of absorption (drug entry), distribution, metabolism, and excretion play principal roles in determining *in vivo* time courses and concentrations of drugs and thus modify actions initiated at receptors.

Drug Entry. Drugs enter the body by one of two routes. In enteral administration (sublingual, oral, rectal), the drug enters directly the gastrointestinal tract. In the parenteral route, the drug bypasses the gastrointestinal tract by, among others, subcutaneous (sc), intramuscular, intravascular (iv), inhalational, intraperitoneal (ip), intravaginal, and intranasal routes. Each route has a particular set of advantages and disadvantages. Patient convenience is high in the oral route; speed of action and ability to control concentrations are high in the iv route; and nonoral routes are best for unstable or insoluble drugs.

In light of the recognized importance of achieving stable, reproducible plasma concentrations of drugs, particular attention is given to pathways and devices, including sustained-release formulations, pumps, and transdermal entry processes that ensure such properties.

Drug Distribution. After administration, a drug may be distributed either generally or selectively in the body. The distribution pattern depends on many factors, including the pattern and time-course of blood flow, diffusion of drugs into tissues, binding of drugs to plasma proteins and cellular compartments, and elimination kinetics and mechanisms.

Drug Metabolism. Generally, metabolism (biotransformation) of drugs increases their water solubility as well as the rate and ease of elimination, but reduces their volume of distribution. Many drug-metabolizing pathways have arisen during evolution to deal with foreign compounds present in food materials. Although metabolism generally leads to more polar and less active compounds, there are exceptions. Metabolic pathways have also been exploited to design prodrugs, materials that are converted to active species through biotransformation.

Biotransformation reactions can be classified as phase I and phase II. In phase I reactions, drugs are converted to product by processes of functionalization, including oxidation, reduction, dealkylation, and hydrolysis. Phase II or synthetic reactions involve coupling the drug or its polar metabolite to endogenous substrates and include methylation, acetylation, and glucuronidation (Table 1).

The biotransforming pathways are subject to manipulation and modification in a variety of ways. Drug metabolism also depends on age and sex. Drug metabolism may also produce toxic materials.

Drug Elimination. Drugs are removed from their sites of action through metabolism, storage, and excretion. These processes are not necessarily independent and drugs are frequently metabolized prior to excretion. Indeed, for lipophilic drugs this is virtually a necessity. Drugs are excreted via the kidneys, biliary systems, intestines, and lungs.

TABLE 1. BIOTRANSFORMATION REACTIONS

Pathways	Reactions types	Examples
	PHASE I REACTIONS	
oxidative	aliphatic and aromatic oxidation	phenobarbital, phenytoin
	N- and *O*-dealkylation	desipramine, phenacetin
	N-oxidation	guanethidine
	oxidative deamination	amphetamine
	desulfuration	thiobarbitol
	dehalogenation	chloroform
hydrolytic	esters and amides	procaine, lidocaine
reductive	azo reduction	prontosil
	nitro reduction	chloramphenicol
nonmicrosomal oxidative	alcohol and aldehyde oxidation	ethanol
	purine oxidation	6-mercaptopurine
	oxidative deamination (monoamine oxidase)	serotonin
	PHASE II REACTIONS	
coupling	glucuronidation	acetaminophen
	acetylation	isoniazid
	glycine conjugation	salicylic acid
	sulfate conjugation	steroids, phenols
	methylation	norepinephrine

The process of reabsorption depends on the lipophilic-hydrophilic balance of the molecule. Charged and ionized molecules are reabsorbed slowly or not at all. Reabsorption of acidic and basic metabolites is pH-dependent, an important property in detoxification processes in drug poisoning. Both passive and active carrier-mediated mechanisms contribute to tubular drug reabsorption.

Clinical Pharmacokinetics. Clinical pharmacokinetics attempts to define the relationship between drug concentration and therapeutic response. The underlying assumption is that response is proportional to drug concentration at the site of action. This concentration is dependent on many factors that are frequently pharmacokinetic determinants. The most important factors are defined as clearance, bioavailability, and volume of distribution.

Clearance, *CL*, is defined by $DL = CL \cdot C_{ss}$, where *DR* represents dosing rate and C_{ss} the steady-state concentration of the drug.

Once the steady-state concentration is known, the rate of drug clearance determines how frequently the drug must be administered. Because most drug elimination systems do not achieve saturation under therapeutic dosing regimens, clearance is independent of plasma concentration of the drug.

The half-life, $t_{1/2}$, for a drug in plasma, i.e., the time it takes for the concentration of a drug to be reduced by 50%, is determined by both volume of distribution, V, and clearance: $t_{1/2} = 0.693 \cdot V/CL$. The bioavailability of a drug can be defined as the fraction of a does, F, that reaches the systemic circulation. When $F < 1$, $F \cdot DR = CL \cdot C_{ss}$.

Pharmacodynamic Aspects of Drug Action

Although the same general principles of chemical specificity apply to all ligand-macromolecular interactions, the term receptor is generally applied to those cellular macromolecules and macromolecular complexes with which ligands, physiological or synthetic, interact both to complex and to initiate a physiological response. Receptors are conveniently viewed as existing in several principal classes, i.e., G-protein-coupled receptors, ligand-gated ion channels, voltage-gated ion channels, tyrosine kinase receptors, guanylyl cyclase receptors, and steroid hormone receptors. All of these receptors form homologous classes according to structure and mechanisms of action. G-protein-coupled receptors form a homologous class of membrane proteins characterized by seven transmembrane domains and the ability to couple to guanine (G) nucleotide-binding proteins.

Ligand-gated ion channels represent a significant family of ion channels that feature as an integral component of their multimeric subunit organization a receptor site for either acetylcholine (nicotine acetylcholine receptor (AChR)), amino acids including glycine and γ-aminobutyric acid (GABA) (inhibitory transmitters), or glutamic acid (excitatory transmitter). The interaction of the ligand with the endogenous receptor site causes channel opening or closing.

An important characteristic of both classes of ion channel is that they possess multiple drug binding sites. Many of the channel-active drugs have achieved particular therapeutic importance, including, for example, the Ca^{2+} antagonists, widely used for a number of cardiovascular disorders, such as hypertension.

Structure–Activity Relationships. Until the mid-1980s, the attempted correlation of chemical structure and biological activity was the only available approach to the definition of receptor site structures. The basic assumption in the analysis of structure-activity relationships (SAR) is the existence of a definable mutual complementarity between the structure of the drug and its corresponding binding site. This application is limited when applied in empirical fashion. Many drug molecules are flexible structures and, although conformations in the solution and solid states can be determined by spectroscopic and crystallographic methods, these bear no necessary relationship to those adopted at the receptor site. The possibility of mutual conformational adaptation of both the drug and the receptor site during the binding process adds a further complication. Furthermore, there may exist multiple drug-binding modes at the receptor such that transitions in binding modes occur at some point in a structurally related series. An additional problem in the quantitative interpretation of SAR is that of the relationship between biological response and drug-receptor interaction. Despite these limitations, SARs have been of great value in providing qualitative concepts of binding site geometry, classifying receptors, furnishing evidence for the existence of new classes of receptor-specific drugs, and generating new and therapeutically effective compounds.

The simplest SARs occur in homologous series of compounds. Thus a linear relationship exists between carbon chain length and biological activity in 1-alkanol-mediated anesthesia (see **Anesthetics**). The activity can be related to the water:cell partition coefficient. For other homologous series, however, such linear relationships may not be observed; for example, in the antagonistic activity of α,ω-bistrimethylammonium alkanes at acetylcholine receptors where binding to sites of defined anionic site geometry probably is involved.

Relatively unambiguous monotonic SARs also occur where activity depends on the ionization of a particular functional group. A classic example is that of the antibacterial sulfonamides where activity is exerted by competitive inhibition of the incorporation of *p*-aminobenzoic acid into folic acid. The bell-shaped relationship is consistent with the sulfonamide acting as the anion but permeating into the cell as the neutral species.

The SAR is also determined at the level of stereochemistry of interaction. In principle, three limiting situations can apply to the stereochemistry of drug-receptor interactions: the enantiomers may not differ in activity; the species may differ quantitatively; or they may differ qualitatively.

The issue of drug stereoselectivity has become one of both developmental and regulatory significance. In principle, a racemic drug possesses only 50% of the active ingredient, and the rest may have other or interacting pharmacologic activities, which may contribute a metabolic burden or be inert. Over 50% of clinically available drugs have chiral centers and only about 10% of synthetic chiral drugs are marketed in homochiral (enantiomerically pure) form. In contrast, drugs that are naturally occurring substances, obtained from or related to naturally occurring molecules, are frequently homochiral.

There is increasing pressure to develop homochiral drugs.

Often pharmacologic agonist activity decreases and is lost with progressive structural change.

Increasing attention has been paid to the generation of quantitative structure—activity relationships in which the effects of molecular substitution on pharmacologic activity can be interpreted in terms of the physicochemical properties of the substituents. These approaches are based on the extrathermodynamic analysis of substituent effects.

Advancing technology permits increasing attention to the definition of the three-dimensional structure of the ligand in its bioactive conformation as it binds to the receptor or active site. This bioactive conformation is not necessarily the solution or the crystal structure of the ligand, which is often the most experimentally accessible structure. It is of critical importance to define the three-dimensional structure of the ligand complexed with its target. This resolution permits not only the understanding of a particular ligand–macromolecule, but also the *in vivo* design of ligand homologues that may have tighter or more selective affinities for the site.

Considerable effort must be applied to obtaining adequate quantities of the protein target and its structural solution, together with the structural solution of the complexed ligand, either by x-ray or solution nmr techniques. Alternatively, homology modeling may be possible when the structure of a homologue protein is already available. Although many examples of ligand–protein structure determinations are available, some of the most interesting targets, e.g., membranebound receptors, defy structural solution at the necessary resolution. The examination of the real structure of ligand–receptor complexes should be an increasingly important and integral part of the drug discovery process.

Quantitative Aspects of Drug–Receptor Interactions. As a general rule, pharmacological responses are graded and a defined relationship exists between the concentration of a drug and the receptor response. This usually is expressed as a concentration–response (A–R) relationship in linear or semilogarithmic coordinates and usually is referred to as a dose–response curve. The shape of these curves offers a clear analogy to processes of physical adsorption but, because of the complexity of the sequence of events between drug–receptor interaction and the response, the interpretation of dose–response curves is not simple. A quantitative understanding of drug–receptor interactions is crucial both to the nontrivial interpretation of structure–activity relationships and to the determination of the mechanisms by which drug–receptor complexes initiate pharmacological response.

Nonreceptor-Mediated Drug Action. At least one important class of drugs, the general anesthetics, has been assumed not to owe its therapeutic activities to a specific receptor process. Anesthetic potency shows an excellent linear correlation with partition coefficient and this has been extrapolated to a definition of action at a lipid site. The phospholipids of cell membranes, particularly nerve cells, have been considered as principal targets for general anesthetic action. It has been hypothesized

that anesthetics may disrupt phospholipid structure by fluidizing or expanding the cell membrane or by altering the phase relationships of the phospholipids. However, it is possible that anesthetics bind to hydrophobic sites on proteins and thus affect directly excitable cell behavior. This latter proposal is consistent both with the activity of the gaseous general anesthetics and with the activity of structurally more complex agents, e.g., 3α-hydroxy-5α-pregnane-11,20-dione, 3α-hydroxy-5-pregn-16-ene-11,20-dione, and 1,5-desmethyl-5-cyclohexenylbarbituric acid.

Although most anesthetics are achiral or are administered as racemic mixture, the anesthetic actions are stereoselective. This property can define a specific, rather than a nonspecific, site of action. Stereoselectivity is observed for such barbiturates as thiopental, pentobarbital, and secobarbital. The (*S*)-enantiomer is modestly more potent. Additionally, the volatile anesthetic isoflurane also shows stereoselectivity. The (*S*)-enantiomer is the more active. Further evidence that proteins might serve as appropriate targets for general anesthetics come from observations that anesthetics inhibit the activity of the enzyme luciferase. The potencies parallel the anesthetic activities closely.

It is likely that a principal target of the general anesthetics is neuronal ion channels of both voltage-gated and ligand-gated classes. Interactions at GABA-mediated inhibitory channels is a significant, but not exclusive, target. Thus, a general anesthetic may have specific but multiple, rather than nonspecific, sites of action.

Receptor–Effector Coupling. The informational signal initiated by drug–receptor interaction must be translated to biological response. This is activated by a variety of effector-coupling processes that lead to ionic or biochemical changes, including ion channel opening and closing; the formation of second messengers such as cyclic adenosine-3′-5′-monophosphate (cAMP) and inositol-1,4,5-triphosphate (IP_3); and protein phosphorylation through protein kinase A (cAMP-dependent) and protein kinase C (CA^{2+}-dependent), or through autophosphorylation (tyrosine kinase receptors). In these systems, it is increasingly clear that the individual components of a receptor system may be linked in multiple ways. The virtue of this organization lies in the multiple coupling processes permitted beyond a set of components.

These cascades serve as operational amplifiers of the initial ligand–receptor interaction. In each step of the process, amplification by several powers of 10 may occur so that an original signal may be multiplied several millionfold.

G-Protein Coupling. The heterotrimeric guanosine triphosphate (GTP) binding proteins, known as G-proteins, are a principal family of proteins serving to couple membrane receptors of the G-protein family to ionic and biochemical processes. The G-proteins are heterotrimers made of three families of subunits, α, β, and γ, which can interact specifically with discrete regions on G-protein-coupled receptors. This includes most receptors for neurotransmitters and polypeptide hormones (see **Neuroregulators**). G-protein-coupled receptors also embrace the odorant receptor family and the rhodopsin-linked visual cascade.

The underlying coupling mechanisms are defined by the enzymatic activity of the G-protein, that of hydrolyzing GTP, i.e., GTPase activity. In the inactive state, the heterotrimeric G-protein is liganded to the diphosphate GDP. Receptor activation reduces the affinity of the α-subunit for GDP and increases the affinity for GTP. The GTP-liganded complex then dissociates to the GTP-bound activated α-subunit and the β- and γ-subunits. These dissociated subunits then interact with the corresponding effectors. The effectors include adenylyl cyclase, phospholipase C, cGMP phosphodiesterase, some ion channels (K^+, Ca^{2+}), and receptor kinases. These signals may be excitatory or inhibitory according to the class of G-protein, some of which are listed for G-protein-linked adenylyl cyclase:

Stimulation (Gs)	Inhibition (Gi, Go)
β-adrenergic	opiate
H_2-histamine	muscarinic
dopamine	α_1-adrenergic
polypeptide hormones (glucagon, ACTH, etc)	adenosine (fat cells) A_1, prostaglandins (fat cells)
adenosine (platelets, lymphocytes) A_2	
prostaglandins (platelets)	polypeptide hormones
serotonin (5-$HT_{1\alpha}$)	somatostatin, neuropeptide Y, atriopeptin

A critical component of the G-protein effector cascade is the hydrolysis of GTP by the activated α-submit (GTPase). This provides not only a component of the amplification process of the G-protein cascade but also serves to provide further measures of drug efficacy. The coupling process also depends on the stoichiometry of receptors and G-proteins. A reduction in receptor number should diminish the efficacy of coupling and thus reduce drug efficacy.

The ability of receptors to couple to G-proteins and initiate GTPase activity may also be independent of ligand.

The principal intracellular messengers derived from activation of G-protein-coupled receptors are cAMP and IP_3. cAMP may be degraded by phosphodiesterase (PDE) or it may activate cAMP-dependent protein kinase (PKA). The activation of this enzyme involves dissociation of the inactive form. (R_2C_2) into the active form which subsequently phosphorylates specific proteins. In contrast, IP_3, one of the products of receptor-mediated phospholipase C breakdown of phosphatidylinositol (PI), acts on specific receptors in the endoplasmic reticulum to release Ca^{2+} from intracellular sources. The other product of PI turnover is a 1,2-diacylglycerol that activates protein kinase C (PKC). This is also the receptor for the tumor-promoting phorbol esters. These diacylglycerols can be cleaved by monoacyl- or diacylglycerol kinases to yield arachidonic acid, a precursor to the prostaglandins and thromboxanes.

Ion Channels. The excitable cell maintains an asymmetric distribution across both the plasma membrane, defining the extracellular and intracellular environments, as well as the intracellular membranes which define the cellular organelles. This maintained asymmetric distribution of ions serves two principal objectives. It contributes to the generation and maintenance of a potential gradient and the subsequent generation of electrical currents following appropriate stimulation. Moreover, it permits the ions themselves to serve as cellular messengers to link membrane excitation and cellular response. In some instances, the current itself may be the response, as, for example, in the electric organ of electric fishes. In most instances, however, the current serves to initiate or modulate another cellular response, including propagation of impulses in nerve fibers, and alteration of the sensitivity of membranes to other stimuli or coupling to cellular responses such as contraction and secretion. In the latter examples, a role for calcium is particularly prominent because Ca^{2+} can serve as both a current-carrying and a messenger species.

Regulation of ion channels by drugs may have excitatory or inhibitory effects according to the channels affected.

Channels may be regulated exclusively by electrical or chemical signals corresponding to purely voltage-gated or ligand-gated channels, respectively. Regardless of regulatory mechanism, ion channels may be regarded as allosteric enzymes. The function is to accelerate the transit of ions across an essentially impermeable barrier and to be responsive to a variety of heterotropic signals.

Ion channels may be regarded as pharmacological receptors frequently possessing a multiplicity of drug binding sites. These sites may be for endogenous physiological regulators or for endogenous or synthetic agents.

Tyrosine Kinase Receptors. The polypeptide growth factors control cell proliferation, differentiation, and survival. Several distinct subfamilies of receptor tyrosine kinases exist and at least nine have been characterized. These include families for epidermal growth factor, insulin and insulin-related factors, fibroblast growth factors, and neurotrophin receptors such as nerve growth factor and brain-derived neurotrophic factor. All of these receptors have kinetics that share certain fundamental signaling properties. Ligand binding to the extracellular domain activates a tyrosine kinase of the cytoplasmic domain. Subsequently, a variety of downstream signaling molecules are activated. These include phospholipase C, GTPase activating factor (GAP), *Ras*, and MAP kinases.

Guanylyl Cyclase Receptors. Cyclic GMP concentrations (cGMP) rise in response to a number of cell signals. Membrane-associated guanylyl cyclase catalyzes the conversion of guanosine triphosphate (GTP) to cGMP. This enzyme resembles in organization the tyrosine kinases having an intracellular protein kinase-like domain and a cyclase catalytic domain. The enzymes are activated by several distinct species that include atrial natriuretic peptide (ANF) and peptides related to the heart-stable enterotoxins.

In contrast, the soluble guanylyl cyclases are regulated by nitric oxide and NO-forming drugs through the Ca^{2+} calmodulin-dependent nitric oxide synthase.

Receptor Regulation and Defects. Specific recognition and the initiation of response are the accepted attributes of the drug–receptor interaction. However, target cells can alter on both short- and long-term time scales their sensitivity to drugs. Such regulation, achieved by altering the number and/or affinity of receptors, is well established for all receptor systems and can be viewed as an integral component of the drug–receptor interaction. In this view, subsequent to the formation of the drug–receptor complex with agonist, the continued existence of the drug–receptor complex may lead to one or more phases of desensitization, according to which there may occur initially transient and subsequently prolonged phases of reduced or lost sensitivity. Occupancy by antagonist, in contrast, leads to an increased number of receptors and increased drug sensitivity. This phenomenon may contribute to clinical rebound during abrupt withdrawal from drugs, including β-blockers. Additional to this homologous regulation, receptor sensitivity may be controlled through heterologous influences, whereby hormones, including thyroid and corticosteroids, regulate other receptors. These regulatory events are made possible because pharmacologic receptors, in common with other cellular components, are in dynamic balance between synthesis and degradation. This balance is sensitive to a number of influences that include agonist and antagonist presence.

There are probably several processes that contribute to the total desensitization process and these may be directed homologously (to own receptor) or heterologously (to other receptor). Additionally, the influences may be directed at the receptor itself and affect only that receptor, i.e., specific desensitization, or may affect other receptor processes as well, i.e., nonspecific desensitization.

An increasing number of diseases are known to be linked to defects in receptor structure, function, or coupling. The defects may lie at several locations: in the structure of the receptor, which may alter its ability either to bind drugs, to be inserted into the membrane, or to couple to effectors (including G-proteins); in the coupling protein; or in the presence of autoantibodies, which can proceed to activate, block, or lyse the receptors and its components.

Components of Drug Action and Responses to Drugs. The response to a drug can vary among race, gender, and age groups. It may vary according to disease state and age, and it may vary according to the time of administration. These factors may have several origins, including (*1*) compliance, the ability or desire of the subject to take a drug according to a specific regimen; (2) pharmacokinetic, disease-, age-, race-, and gender-based factors that contribute to variable absorption, distribution, metabolism, and excretion of a drug; and (*3*) pharmacodynamic, disease-, age-, race-, and gender-based factors that contribute to variable drug–receptor interactions.

PHASE DIAGRAM (Metallurgy). A graphical representation defining the phase fields of a multiphase system, such as an alloy, in a coordinate system using the temperature and the compositions of the phases as coordinates. A phase diagram may be an equilibrium diagram, but it may also sometimes show the boundaries of the phase field under nonequilibrium conditions corresponding to specific conditions of heating or cooling. See iron carbon equilibrium diagram in entry **Iron Metals, Alloys, and Steels**.

PHASE RULE. The phase rule, due to Gibbs, gives the number F of intensive variables which can be fixed arbitrary in a system in equilibrium. This number is also called the variance or the number of degrees of freedom of the system. It is given by

$$F = 2 + (C' - R) - P$$

where C' is the number of components, R, the number of independent chemical reactions, and P, the number of phases.

In terms of the number of independent components, C, Equation (1) may also be written

$$F = 2 + C - P$$

If $F = 0$ the system is invariant. We cannot fix either temperature or pressure arbitrarily. Equilibrium can only be established at isolated points. An example is the *triple point* at which pure solid, liquid and vapor are in equilibrium ($F = 2 + 1 - 3 = 0$).

If $F = 1$ the system is *monovariant*. We can, for example, fix the temperature, but the equilibrium pressure is then fixed. This is the situation for a system containing one component and two phases.

If $F = 2$ the system is *bivariant*. Within certain limits both pressure and temperature can be given arbitrarily. This is the situation for $C = 1$ and $P = 1$, or $C = 2$ and $P = 2$.

PHENACITE. The mineral phenacite is a beryllium silicate corresponding to the formula Be_2SiO_4. It is hexagonal but the crystals are usually rhombohedral in habit. It has a conchoidal fracture; is brittle, hardness, 7.5–8; specific gravity, 3; luster, vitreous; colorless to yellowish or reddish, sometimes brown; transparent to translucent. Phenacite is found in pegmatites with topaz, quartz and microcline, and occurs also in emerald-bearing mica schists of the Ural Mountains. It is found also in France, Norway, Switzerland, Africa, Brazil, and Mexico; and in the United States, in Oxford County, Maine; Carroll County, New Hampshire; and in Chaffee and El Paso Counties in Colorado. It derives its name from the Greek meaning deceiver, as it resembles quartz and topaz with which it is associated. It is sometimes spelled phenakite. It has been used as a gem.

PHENOCLAST. A textural term proposed by R.M. Field in 1916 for coarsely graded clastic sedimentary rocks in which the largest or "show" particles or fragments are referred to as phenoclasts, regardless of their shape or composition. The term implies that the larger constituents of the glomerate have been derived from prelithified rock. Rounded fragments are called pebbles or spheroclasts, which when lithified by means of matrix (sand and clay) and cement form a conglomerate. Angular fragments are called anguclasts (Field), which when lithified by means of matrix (sand and clay) and cement form a breccia.

PHENOCRYST. A textural term proposed by Iddings in 1892 for macroscopic crystals which are relatively much larger than the crystalline matrix of the igneous rock in which they occur. Rocks which have phenocrysts are called porphyritic. The term phenocryst is derived from the Greek, meaning show, and crystal.

PHENOL. 1. A class of aromatic organic compounds in which one or more hydroxy groups is attached directly to the benzene ring. Examples are phenol itself (benzophenol), the cresols, xylenols, resorcinol, naphthols. Although technically alcohols, their properties are quite distinctive.

2. Phenol (carbolic acid; phenylic acid; benzophenol; hydroxybenzene), C_6H_5OH. Phenol is a white, crystalline substance that turns pink or red if not perfectly pure, or if under influence of light; absorbs water from the air

and liquefies. It has a distinctive odor and a sharp burning taste. It is toxic by ingestion, inhalation, and skin absorption, and is a strong irritant to tissue. When in a very weak solution, phenol has a sweetish taste; specific gravity 1.07; mp 42.5–43°C; bp 182°C; flash point 77+ °C. Soluble in alcohol, water, ether, chloroform, fixed or volatile oils, and alkalies.

Most of the phenol used in the United States is made by the oxidation of cumene, yielding acetone as a byproduct. The first step in the reaction yields cumene hydroperoxide, which decomposes with dilute sulfuric acid to the primary products, plus acetophenone and phenyl dimethyl carbinol. Other processes include sulfonation, chlorination of benzene, and oxidation of benzene. The compound is purified by rectification.

Major uses of phenol include production of phenolic resins, epoxy resins, and 2,4-D (regulated in many countries); as a selective solvent for refining lubricating oils; in the manufacture of adipic acid, salicylic acid, phenophthalein, pentachlorophenol, acetophenetidine, picric acid germicidal paints, and pharmaceuticals; as well as use as a laboratory reagent. Special uses include dyes and indicators, and slimicides.

High-boiling phenols are mixtures containing predominantly meta substituted alkyl phenols. Their boiling point ranges from 238–288°C they set to a glass below −30°C. They are used in phenolic resins, as fuel-oil sludge inhibitors, as solvents and as rubber chemicals.

Phenol is regarded as a dangerous chemical. Refer to *Dangerous Properties of Industrial Materials*, 10th Edition, Sax and R.J. Lewis, Editors, Wiley, New York, 1999.

PHENOLATE PROCESS. A process for removing hydrogen sulfide from gas by the use of sodium phenolate, which reacts with the hydrogen sulfide to give sodium hydrosulfide and phenol. This can be reversed by steam heat to regenerate the sodium phenolate.

PHENOL COEFFICIENT. In determining the effectiveness of a disinfectant using phenol as a standard of comparison, the phenol coefficient is a value obtained by dividing the highest dilution of the test disinfectant by the highest dilution of phenol that sterilizes a given culture of bacteria under standard conditions of time and temperature.

See also **Disinfectant**.

PHENOL-FURFURAL RESIN. A phenolic resin that has a somewhat sharper transition than phenol-formaldehyde from the soft, thermoplastic stage to the cured, infusible state and can be fabricated by injection molding since it has little tendency to harden before curing conditions are reached.

See also **Phenolic Resins**.

PHENOLIC RESINS. These resins have been known since the 1870s when Baeyer first investigated the reactions of phenols and aldehydes. However, his findings were not commercially utilized until Dr. L. H. Baekeland disclosed his classic work in 1907. Through his use of high-pressure molding, he provided a solution to the problem of making quick-curing moldings which did not blister or crack. Contemporary with Dr. Baekeland was the work of Lebech and Aylsworth who provided the key to the application of large commercial quantities of phenolic Novolacs by suggesting the use of hexamethylenetetramine as a curing agent. Since that time, and because of their desirable price-to-property relationship, phenolic resins have enjoyed steady growth despite the encroachment into their areas of application by a few thermoplastics and other thermosetting materials.

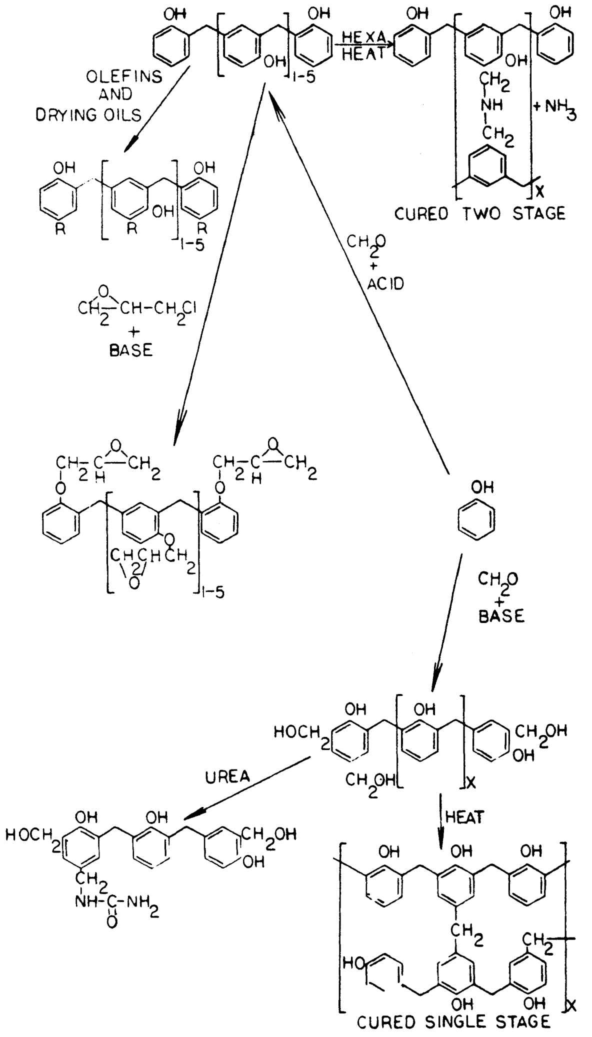
Although in the pure state phenolic resins are quite weak and brittle, they are highly regarded among the plastic materials as being capable of producing very strong physical bonds with a large variety of materials at very low concentration. Consequently, phenolics have found use in many applications as binders. In addition to the strength they impart as bonding agents in matrixes, phenolic resins also possess resistance to chemical attack by all but the most polar organic solvents. The only inorganic reagents that have a deleterious effect on them are the strongest and most oxidizing of the acids and the strongest bases.

For many years prior to the development of high-temperature thermoplastics and thermosets, such as the polyimides, polysulfones, and epoxies, phenolic molding material dominated the high temperature-resistant market. This emphasizes their ability to resist temperature degradation in the 400–500°F (204–260°C) range. Because phenolics were found to possess excellent ablative properties, it has been reported that both the American and Soviet space efforts used them in combination with certain other polymeric compounds in heat shield materials. Phenolics, like other aromatic hydrocarbon-based resins, possess excellent resistance to high-energy radiation degradation.

Unlike most thermoplastics, phenolic resins and moldings are characterized by high flexural modulus and good tensile strength while having relatively low impact resistance. In addition to their good physical strength properties, phenolic resins are used in the manufacture of many electrical devices where high dielectric breakdown strength and electrical resistance, in combination with excellent dimensional stability, are required.

Chemistry of Phenolics

Phenolic compounds are capable of chemically combining with a large number of aldehydes and other compounds to yield an almost infinite spectrum of modified polymers. However, the reaction of a phenol with an aldehyde (most commonly encountered is that between phenol and formaldehyde) leads to the formation of only two classes of phenolic resins. These are Novolacs and resols. In general, these two classes of resins may be differentiated by the fact that Novolacs are prepared with an acid catalyst and substantially less than one mole of aldehyde per mole of phenol and require the addition of a curing catalyst to become thermosetting; while resols, or single-stage resins as they are commonly called, are prepared with from 1 to 3 moles of aldehyde per mole of phenol and employ a basic condensation catalyst, and are inherently thermosetting.



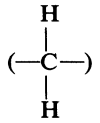
Cured single-stage and two-stage resins.

Novolacs

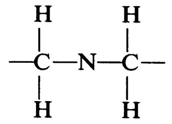
The aldehyde content of Novolac resins is insufficient to render the resin thermosetting, hence, they are true thermoplastics provided that a curing agent is not added. Novolacs may be stored indefinitely in the pulverized state at moderate temperatures even mixed with curing agent.

The final cure speed of simple Novolacs may be accurately controlled by the use of the proper condensation catalyst in the initial phase of the

reaction. Structurally, a Novolac consists of a series of phenol nuclei joined by methylene



links at the *o* and *p* positions. Only two of the three possible *o* and *p* positions on each ring within the polymeric chain are substituted with a methylene group. Only one position on each of the two terminal phenol groups is substituted with a methylene group, hence, two positions on each terminal ring and one on each internal ring is available for future reactions, including the curing reactions. When the unsubstituted positions are predominantly the para positions, very fast-curing resins result. Slower-setting resins are obtained when the unoccupied positions are the ortho positions. When hexa is used as the hardener at approximately the 10% level, the reactive sites are joined by a



linkage. One mole of ammonia is liberated for approximately every three of the above links formed.

Unaltered Novolacs and two-stage resins* find application in grinding wheel bonding, molding material, brake linings and clutch faces, foundry sand binding, premix and wood fiber bonding, thermal insulation. Modified phenolics are found in adhesives, coatings, and aerospace applications.

Resols

On the other hand, resols contain sufficient aldehyde to make them thermosetting without a curing agent. Consequently, they have only finite storage stability and care must be exercised to minimize both the length and the temperature of storage. The high aldehyde-to-phenol ratios used in the preparation of resols insure that a high percentage of the reactive *o* and *p* positions are utilized in either methylene links or are substituted by a hydroxymethyl group. It is these hydroxymethyl groups which function as crosslinking sites in the final curing reaction. In phenolformaldehyde resols, the ratio of methylene groups to hydroxymethyl groups is an important factor in determining the solubility of these resins. Low ratios insure water solubility in almost infinite proportions, while resins with high ratios can be dissolved in only low molecular weight alcohols, ketones, ethers, and esters. Solubility of resols in nonpolar solvents, such as hydrocarbons, is always very low.

In addition to acting as a crosslinking site, the hydroxymethyl group and unsubstituted *o* and *p* positions may be used as reactive sites to join numerous other compounds to the phenolic polymer. These modified resins often possess many properties normally not attributable to phenolics in the unaltered state.

Resols find application as impregnating resins, in laminating paper, cloth, glass and asbestos; as a pickup agent in grinding wheels, exterior and marine plywood, premix and granular molding material, adhesives, wood waste and particle board manufacture, and in coatings.

The final curing step of both classes of phenolics is accomplished by exposing the resin or the resin containing matrix to temperatures in the 190–450°F (88–232°C) range for an appropriate length of time to render the resin infusible. In most applications high pressure is also applied concurrently with the heating cycle to eliminate blistering, which would normally occur if the trapped gases (ammonia in the case of Novolacs, and water in the case of resols) generated in the cure were allowed to escape unrestrained.

Comparative infrared analysis of the two classes of resins in their pure state show that only resols have strong absorptions in the 1,000 and 880 cm^{-1} range. As Novolacs require a curing agent, their presence may be inferred by a strong, sharp absorption at 510 cm^{-1} which is indicative of the most common curing agent used, hexamethylenetetramine. Unfortunately, hexa also has strong absorptions at or near 1,000 and 880 cm^{-1} which makes differentiation between resols and two-stage resins, by infrared spectroscopy, possible only for the experienced. In the cured state, it is very difficult to determine the class identity of an unknown sample.

Phillip A. Waitkus
Plastics Engineering Company
Sheboygan, Wisconsin

* By convention, two-stage resins are defined as a mixture of Novolac and curing agent, which is capable of thermosetting.

PHENOLICS. These are products of the condensation reaction of phenol and formaldehyde.[1] Water is the byproduct of this reaction. Substituted phenols and higher aldehydes may be incorporated to achieve specific resin properties, e.g., flexibility, reactivity, or compatibility with elastomers and other polymers. A variety of phenolic resins can be produced by adjusting the formaldehyde:phenol molar ratio and the resinification temperature and catalyst. Single-stage (*resole*) resins are produced with an alkaline catalyst and a molar excess of formaldehyde. The reaction is carefully controlled to allow the production of low-molecular-weight, noncrosslinked resins. Single-stage resins complete the curing reaction in a heated mold with no additional catalyst. A three-dimensionally crosslinked, insoluble, and infusible polymer is formed.

Two-stage resins (*novolacs*) are produced by the acid-catalyzed reaction of phenol and a portion of the required formaldehyde. The resin product is brittle at room temperature. It can be melted, but it will not crosslink. Novolacs can only be cured by the addition of a hardener, almost always formaldehyde supplied as hexamethylene tetramine. Upon heating, the latter compound decomposes to yield ammonia and formaldehyde.

Phenolic resins are available in flake, powder, and liquid forms. A wide variety of industrial applications has been developed, including foundry molds and cores; plywood and particle board; brake and clutch linings; glass, cellulose, and foam insulation; grinding wheels and coated abrasives; adhesives and glues, rubber tackifiers; coatings; varnishes; and electrical and decorative laminates. Resole and novolac resins are combined with a variety of fillers, reinforcements, and additives to produce phenolic engineering plastics. See also **Paints and Coatings**.

Application development for phenolics has been spurred by weight and cost savings inherent in metal replacement and parts consolidation. Thermoplastics have been replaced by phenolics where creep resistance and thermal stability are required in downsized parts or applications in hostile environments.

PHILLIPSITE. The mineral phillipsite is a zeolite, a hydrous silicate of potassium, calcium, and aluminum, corresponding to formula $(K, Na_2Ca)(Al_2Si_4)O_{12} \cdot 4{-}5H_2O$. It is monoclinic, forming penetration twins, and sometimes crosses resembling orthorhombic or tetragonal forms. It also may occur in radial groups. Phillipsite is a brittle mineral; hardness, 4–4.5; specific gravity, 2.2; luster, vitreous; color, white to light red; translucent to opaque. Like other zeolites, it is found in veins and cavities in basalts, and sometimes in more acidic rocks. It is believed to be a low-temperature mineral. Phillipsite is found in Italy, especially in the lavas of Vesuvius and Monte Somma, and in the basalts of Germany, Ireland, and Australia. It has been reported from Greenland. This mineral was named in honor of the British mineralogist William Phillips.

PHLOGOPITE. The mineral phlogopite is a magnesium-bearing mica, with but little iron, corresponding essentially to the formula $K(Mg, Fe)_3(AlSi_3)O_{10}(F, OH)_2$. Fluorine is sometimes present. This mica is monoclinic like muscovite, biotite and lepidolite, forming prismatic crystals, occasionally very large, and occurring also in scales and plates. Its cleavage is basal and highly perfect with elastic laminae; hardness, 2–2.5; specific gravity, 2.76–2.90; luster, pearly to submetallic; color, yellowish-brown, green, white and colorless; transparent to translucent; may exhibit asterism, probably due to minute inclusions. Phlogopite is more nearly a characteristic of metamorphic than igneous rocks although occasionally occurring in the latter if they are rich in magnesia and with but little iron. Phlogopite is found especially in Rumania, Switzerland, Italy, Finland,

[1] Data furnished by *Occidental Chemical Corp.*

Sweden and Madagascar where it occurs in the crystalline limestones in huge crystals. In the United States it occurs in New York State at Edwards, Hammond, DeKalb, Monroe and, in New Jersey, at Franklin. In Canada it is found at many places in Ontario and Quebec.

The name phlogopite comes from the Greek word meaning like fire, referring to the copper-like reflections often observed in the reddish-brown varieties.

Phlogopite is in demand commercially by the electrical industry for use as an insulator.

PHONONS. Many of the thermal and vibrational properties of solids can be explained by considering the material to be a volume made up of a gas of particles called *phonons*. This particle description is a method of taking into account the actual motion of the atoms and molecules in the solid. Since each atom possesses energy due to its thermal environment, and since there are forces between the atoms that keep the solid together, each atom tends to oscillate about its equilibrium position. The formal mathematical development, obtained through solving the equations of motion of the array of individual atoms and molecules, indicates that the thermal energy of the solid is contained in certain combinations of particle vibrations which are equivalent to standing elastic waves in the sample and are called normal modes. Each normal mode contains a number of discreet quanta of energy $E = \hbar$ where ω is the frequency of the mode (or wave) and $\hbar$ is Planck's constant divided by 2π. Each of these quanta is called a phonon (in analogy with the light quanta or photon whose energy-frequency relationship is identical). Phonons are considered only as particles, each having an energy $E = \hbar$, a momentum q, and a velocity $v = \partial\omega/\partial q \sim \omega/q$. Analogous to the energy levels of electrons in a solid, phonons can have only certain allowed energies.

The phonon is of importance to many phenomena: electron mobility, optical absorption, electron spin resonance, electron tunneling, and superconductivity. The phonon spectrum represents a detailed picture of the forces that hold solids together. Thus, it is clear why the phonon has been and will continue to be of fundamental importance in solid-state physics.

PHOSGENE. See **Carbonyls**; **Chlorinated Organics**.

PHOSGENITE. This mineral is a chlorocarbonate of lead, $Pb_2(CO_3)Cl_3$, crystallizing in the tetragonal system, associated with other lead minerals of secondary origin, e.g., cerussite and anglesite; hardness, 2–3; specific gravity 6.133; prismatic to tabular crystals, also massive and granular, adamantine luster; color, white, gray, brown, green or pink; transparent to translucent. Some specimens show yellowish fluorescence under ultraviolet light.

Found in the United States in California, Colorado, Arizona, and New Mexico. Magnificent crystals up to 5 inches (12.5 centimeters) in diameter have been found at Monte Poni, Sicily; as fine crystals in England at Derbyshire and Matlock; and in Poland, Russia, Tasmania, Australia, and Namibia.

PHOSPHATE FERTILIZERS. See **Fertilizer**.

PHOSPHATE ROCK. A natural rock consisting largely of calcium phosphate and used as a raw material for manufacture of phosphate fertilizers, phosphoric acid, phosphorus, and animal feeds. Recovery of uranium from the manufacture of phosphoric acid and other phosphate chemicals is expected to become an important source of this metal. Phosphate rock is the primary source of superphosphate, prepared by treatment of the pulverized rock with sulfuric acid (superphosphate having 16–18% P_2O_5) or by acidifying with phosphoric acid (triple superphosphate having 40–48% P_2O_5). Nitric acid is sometimes used, i.e., nitrophosphate. Defluorinated phosphate rock is the source of phosphate used in animal feeds and feed concentrations. Important deposits are in the U.S. (Florida, North Carolina, Tennessee, California, Wyoming, Montana, Utah, and Idaho), North Africa (Morocco, Libya, and Algeria), the former U.S.S.R., and various islands in the Pacific.

See also **Fertilizer**; **Phosphoric Acid**; and **Phosphorus**.

PHOSPHATES. See **Phosphorus**.

PHOSPHATING. See **Conversion Coatings**.

PHOSPHAZENE (Phosphonitrile). A ring or chain polymer that contains alternating phosphorus and nitrogen atoms with two substituents on each phosphorus atom. Characteristic structures are cyclic trimers, cyclic tetramers, and high polymers. The substituent can be any of a wide variety of organic groups, halogen, amino, etc. Most cyclic trimers are crystalline, solids, organosoluble, and stable to weather conditions; the high polymers (polyphosphazenes) are elastomeric or thermoplastic. A copolymer of phosphazene and styrene has been investigated for use as a flame-retardant.

PHOSPHINE. See **Phosphorus**.

PHOSPHOLIPIDS. These compounds belong to a group of fatty acid compounds sometimes referred to as complex lipids. The simplest are esters of fatty acids with glycerol phosphate and are called *phosphatidic acids*. There are also phosphatidylcholines or lecithins, phosphatidylethanolamines, phosphatidylserines, and phosphatidylinositols. The latter may have one or more additional phosphate groups attached to the inositol. A similar series also exists containing an aldehyde attached to the 1-position of the glycerol, in the form of an α, β-unsaturated ether. These are commonly referred to as *plasmalogens*.

The percentage of phospholipid content of tissues varies little under normal physiological conditions, thus giving rise to the term *element constant*, in contrast to the triglycerides, which have been called the *element variable*.

Phospholipids are considered to be involved in the transport of triglycerides through the liver, especially during mobilization from adipose tissue. Conditions which could be interpreted as interfering with phosphatidylcholine formation, such as deficiency of choline or its precursors, result in a pronounced increase in liver triglycerides.

Mitochondrial phospholipids play a role in electron transport and oxidative phosphorylation, two mechanisms by which the cell accomplishes the final oxidation of the metabolites to produce energy. Phospholipids also are linked in the transport of ions, especially sodium, across membranes.

In summary, phospholipids (phosphatides) comprise a group of lipid compounds that yield, upon hydrolysis, phosphoric acid, an alcohol, fatty acid, and a nitrogenous base. They are widely distributed throughout nature.

PHOSPHOR BRONZE. See **Copper**.

PHOSPHORESCENCE. See **Luminescence**.

PHOSPHORIC ACID. [CAS: 7664-38-2]. Generally the term *phosphoric acid* refers to orthophosphoric acid, H_3PO_4. Anhydrous orthophosphoric acid is a white, crystalline solid, which melts at 42.35°C. It forms a hemihydrate, $2H_3PO_4 \cdot H_2O$, which melts at 29.32°C. Although it is possible to produce almost any desired concentration, it is common practice to supply the material as a solution containing from 75% H_3PO_4 (melting point, 17.5°C) to 85% H_3PO_4 (melting point, 21.1°C). When phosphoric acid is heated to temperatures above about 200°C, water of constitution is lost. A series of acids is formed by the dehydration, ranging from pyrophosphoric acid, $H_4P_2O_7$, to metaphosphoric acid, $(H_3PO_4)_n$. Salts of the dehydrated acids are used for the preparation of certain types of liquid fertilizers and have been used in some detergents. However, to counter the effects of "phosphate pollution," there has been a serious cutback in this latter use of the phosphates. See also **Fertilizer**.

One, two, or three of the hydrogens in phosphoric acid may be neutralized, leading to a series of products which range widely in their hydrogen ion concentration (pH): monosodium phosphate, NaH_2PO_4, with a pH of 4.0; disodium phosphate, Na_2HPO_4, with a pH of 8.3 (approximate); and trisodium phosphate, Na_3PO_4, with a pH of 12.0. Other phosphorous acids of little commercial importance are hypophosphorous acid, H_3PO_2; orthophosphorous acid, H_3PO_3; and pyrophosphorous acid, $H_4P_2O_5$.

Manufacture

The major sources of H_3PO_4 traditionally have been mineral deposits of phosphate rock. Mining operations are extensive in a number of locations, including the United States (Florida), the Mediterranean area, and Russia, among others. The major constituent of most phosphate rocks is fluorapatite, $3Ca_3(PO_4)_2 \cdot CaF_2$. The supply of high-grade phosphates,

the raw material of choice for producing high-purity phosphoric acid by the wet process, is rapidly decreasing in some areas.

Two major methods are utilized for the production of phosphoric acid from phosphate rock. The *wet process* involves the reaction of phosphate rock with sulfuric acid to produce phosphoric acid and insoluble calcium sulfates. Many of the impurities present in the phosphate rock are also solubilized and retained in the acid so produced. While they are of no serious disadvantage when the acid is to be used for fertilizer manufacture, their presence makes the product unsuitable for the preparation of phosphatic chemicals.

In the other method, the *furnace process*, phosphate rock is combined with coke and silica and reduced at high temperature in an electric furnace, followed by condensation of elemental phosphorus. Phosphoric acid is produced by burning the elemental phosphorus with air and absorbing the P_2O_5 in water. The acid produced by this method is of high purity and suitable for nearly all uses with little or no further treatment.

Basic reactions of the wet process are

$$3\ Ca_3(PO_4)_2 \cdot CaF + 10\ H_2SO_4 + 20\ H_2O$$

$$\longrightarrow 10\ CaSO_4 \cdot 2\ H_2O + 6\ H_3PO_4 + 2\ HF$$

Numerous side reactions also occur. Phosphate rock and sulfuric acid, together with recycled weak liquors, are carefully metered to a large, stirred reactor, providing retention for 4–8 hours. Conditions in the reaction are carefully controlled to maintain preselected conditions. Temperatures (77–83°C) are controlled by removing excess heat of reaction with a vacuum cooler, or by blowing air through the phosphoric acid slurry. The slurry contains precipitated gypsum and is sent to a filter. The gypsum is washed with water in several countercurrent steps, and weak liquor is returned to the reaction stage. For most uses, the acid requires further concentration, normally done in vacuum evaporators. Merchant-grade acid is generally concentrated to about 54% P_2O_5 (75% H_3PO_4). See Fig. 1.

Effluents and gypsum disposal pose problems. Fluorine is evolved at various steps in the process and scrubbers are required to reduce release to the atmosphere. Gypsum is frequently piled in diked areas or dumped into abandoned mines. Wastewater from these plants is heavily contaminated with fluorine, phosphates, sulfates, and other compounds. It is commonly impounded in large ponds, where a portion of the contaminants may precipitate or be lost by other processes. The cooled effluent from the

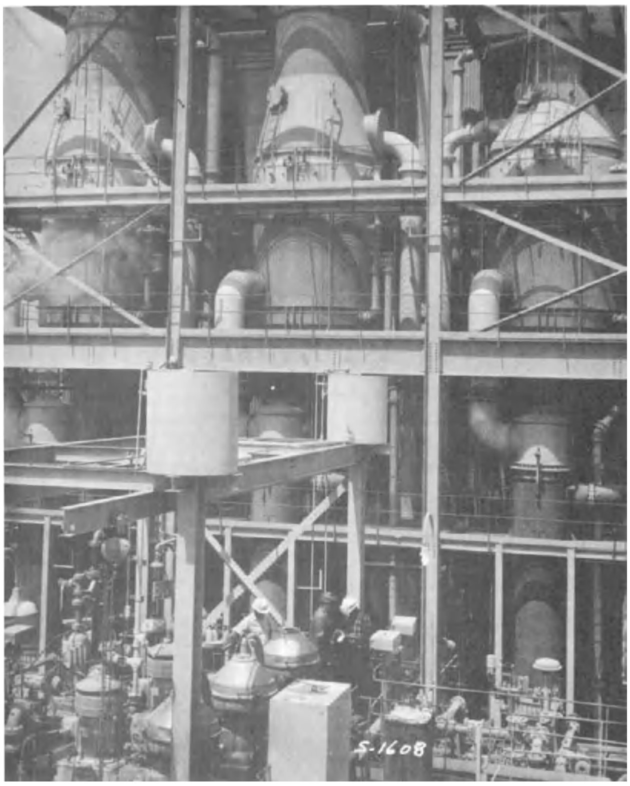

Fig. 1. View of three-stage evaporation process used for concentrating wet-process phosphoric acid. (*Swenson*)

ponds is recycled to the production unit. Any excess water must be treated with lime before it can be allowed to enter streams.

Developments of recent years include plants designed to precipitate the calcium sulfate in the form of the hemihydrate instead of gypsum. In special cases, hydrochloric acid is used instead of sulfuric acid for rock digestion, the phosphoric acid being recovered in quite pure form by solvent extraction. Solvent-extraction methods have also been developed for the purification of merchant-grade acid, which normally contains impurities amounting to 12–18% of the phosphoric acid content. Processes for recovering part of the fluorine in the phosphate rock are in commercial use.

Although more costly to operate, the electric-furnace process produces phosphoric acid of high purity. A mixture of coke, silica, and phosphate rock is formed into nodules by heating in a nodulizing kiln, and the resulting lump material is transferred to the electric furnace, where it is heated with an electric current introduced by means of graphite electrodes. The entire charge is melted, and elemental phosphorus is volatilized. The slag is tapped off intermittently while the phosphorus vapor is condensed. The phosphorus is then burned in air and the P_2O_5 is absorbed in water. Reactions are

$$2\ Ca_3(PO_4)_2 + 6\ SiO_2 + 10\ C \longrightarrow P_4 + 10\ CO + 6\ CaSiO_3$$

$$P_4 + 5\ O_2 \longrightarrow 2\ P_2O_5$$

$$P_2O_5 + 3\ H_2PO \longrightarrow 2\ H_3PO_4$$

PHOSPHORIC ACID (Fuel Cell). See **Fuel Cells**.

PHOSPHORS AND PHOSPHORESCENCE. A large variety of substances become luminescent when stimulated or excited by suitable radiation, or by emissions, such as cathode rays or beta-rays. This phenomenon is complex and exhibited in various aspects. In some cases, the light is emitted only so long as the exciting emission is maintained, in which case it is called *fluorescence*. In other cases, the luminescence persists after the excitation is removed and it is then called *phosphorescence*. It has long been known, for example, that zinc sulfide, under certain conditions, glows brightly for a time after exposure to daylight or lamplight, but the luminosity decays rapidly and disappears, usually within a few minutes. The electroluminescent phosphor of zinc sulfide-zinc selenide-copper has the property that the wavelength of the emitted radiation increases with increasing selenium content. The white luminescence of some television tubes is obtained from a combination of cadmium-zinc sulfide phosphors, one that is blue-emitting and the other yellow-emitting. Also, in some color television tubes, the blue-emitting and green-emitting phosphors are of the sulfide type, but earlier use of sulfides for the red-emitting “dots” on the tube surface were replaced by rare-earth red-emitting phosphors. One composition used is prepared by combining about 4% europium oxide and 65% yttrium oxide, with various vanadium compounds and calcining the mixture. Rare-earths also have been used in producing phosphors for high-pressure mercury-arc lamps. These phosphors increase the proportion of red light emitted by reducing the green, blue, and ultraviolet portions.

Quantitatively, phosphorescence may be defined as luminescence that is delayed by more than 10^{-8} seconds after excitation. It may be associated with transitions from a higher excited state to a lower one, the energy going into a radiationless rearrangement of the system. If the lower state is metastable, its lifetime may be considerable before it finally decays by a highly forbidden radiative transition to the ground state. In the case of zinc sulfide, the process depends upon the ionization of activator atoms, the freed electrons being trapped and only released slowly for recombination.

See also **Luminescence**.

PHOSPHORUS. [CAS: 7723-14-0]. Chemical element, symbol P, at. no. 15, at. wt. 30.9738, periodic table group 15, mp 44.1°C (α-white), bp 280°C (α-white), sp gr 1.82 (white), 2.20 (red).

Four allotropes of phosphorus are known, the hexagonal β-white, stable only below −77°C, the cubic α-white (mp 44.1°C), the violet, and the black (which is thermodynamically the most stable). The α-white form is usually taken as the standard state. The violet is obtained by continued heating at 500°C of a solution of phosphorus in lead. When α-white phosphorus is heated to 250°C in the absence of air, a red variety (mp 590°C) is obtained which is believed to consist of a mixture of the α-white and violet allotropes, although the studies of the violet component in the mixture have shown that at least four polymorphic forms of red (violet) phosphorus exist.

White phosphorus is considered to be made up largely of P_4 molecules, as is the liquid and vapor up to 800°C, where dissociation becomes appreciable. The P_4 molecule is a tetrahedron, with single covalent bonds between the P atoms, and each having an unshared pair of electrons. White phosphorus is much more reactive than red or violet.

Black phosphorus has a graphite-like structure and has a similar electrical conductivity.

There is one stable nuclide, ^{31}P. Six radioactive isotopes have been identified, ^{28}P through ^{30}P and ^{32}P through ^{34}P, all with short half-lives, measured in terms of seconds, minutes, or days. See also **Radioactivity**. In terms of terrestrial abundance, phosphorus ranks 10th with an estimated average content of igneous rocks being 0.13% phosphorus. The element ranks 19th in abundance in seawater, there being an estimated 325 tons of phosphorus per cubic mile (70 metric tons per cubic kilometer) of seawater. In terms of cosmic abundance, phosphorus is ranked 15th among the elements. The element was first identified by Hennig Brandt in Germany in 1669 during an experiment in which he was distilling urine with sand and coal. White phosphorus is very toxic.

First ionization potential 11.0 eV; second, 19.81 eV; third, 30.04 eV; fourth, 51.1 eV; fifth, 64.698 eV. Oxidation potentials $H_3PO_2 + H_2O \longrightarrow H_3PO_3 + 2H^+ + 2e^-$, 0.59 V; $P + 3H_2O \longrightarrow H_3PO_3 + 3H^+ + 3e^-$, 0.49 V; $P + 2H_2O \longrightarrow H_3PO_2 + H^+ + e^-$, 0.29 V; $H_3PO_3 + H_2O \longrightarrow H_3PO_4 + 2H^+ + 2e^-$, 0.20 V; $PH_3(g) \longrightarrow P + 3H^+ + 3e^-$, 0.04 V; $P + 2OH^- \longrightarrow H_2PO_2^- + e^-$, 1.82 V; $P + 5OH^- \longrightarrow HPO_3^{2-} + 2H_2O + 3e^-$, 1.71 V; $H_2PO_2^- + 3OH^- \longrightarrow HPO_3^{2-} + 2H_2O + 2e^-$, 1.65 V; $HPO_3^{2-} + 3OH^- \longrightarrow PO_4^{3-} + 2H_2O + 2e^-$, 1.05 V; $PH_3(g) + 3OH^- \longrightarrow P + 3H_2O + 3e^-$, 0.87 V.

Other physical characteristics of phosphorus are given under **Chemical Elements**.

Because of its reactivity, phosphorus does not occur in nature in the elemental form. Phosphate rock is the principal source of phosphorus and phosphorus compounds. Very large deposits of phosphate rock occur and are worked in the Bone Valley area of Florida, as well as deposits in Tennessee, Idaho, and South Carolina. Large deposits are mined in Northern Africa (Morocco and Tunisia). Very significant reserves have been found on several of the Pacific Islands, the reserves on Christmas Island estimated at some 30 million tons (27 million metric tons) and those on Nauru Island in excess of 100 million tons (90 million metric tons). There also are large active mining operations in the Mediterranean area as well as in the former Soviet Union. Known reserves assure a supply for several centuries. The mineral apatite, $Ca_3(PO_4)_2 \cdot CaCl_2$ or $\cdot\, CaF_2$, found in Quebec, Virginia, Brazil, and the South Pacific also contains high percentages of phosphorus, up to 20% P_2O_5. The main constituents of most phosphate rocks is fluorapatite, $3Ca_3(PO_4)_2 \cdot CaF_2$. These rocks contain 30–37% P_2O_5.

Most phosphorus raw materials are converted into phosphorus and phosphorus compounds, such as phosphoric acid, on an extremely high-tonnage basis. Percentagewise, relatively little elemental phosphorus is produced for consumption as an end product. See also **Fertilizer**. Phosphorus is important both to plant and animal nutrition. Traditionally, phosphorus compounds have been key components of cleaning compounds and detergents although there have been trends to reduce or eliminate phosphates from high-consumption items. See also **Detergents**.

Production of Elemental Phosphorus

The tricalcium phosphate in phosphate rock, mixed with coke and silica, is thermally reduced to yield P_2 vapor. The phosphorus vapors condense to a liquid and the carbon monoxide produced is returned for burning in the furnace. The process requires much heat and, in addition to the heat provided by the combustion of the coke and the heating value of the recycled carbon monoxide, an electric arc also is used. The reaction takes place in very large furnaces at a temperature of 1,300–1,500°C and at atmospheric pressure. A 70-MW furnace will produce 44,000 short tons (39,600 metric tons) of P_4 per year, equivalent to 100,000 tons (90,000 metric tons) of P_2O_5 (if converted to acid). Although there are numerous intermediate and side reactions, the overall reaction is: $Ca_3(PO_4)_2 + 5C + 3SiO_2 \longrightarrow P_2 + 5CO + 3Ca \cdot SiO_3$. Byproduct ferrophosphorus alloy and calcium silicate slag are tapped from the furnace periodically. Maximum furnace efficiency occurs when the SiO_2/CaO weight ratio is about 0.8. This ratio also assures a minimum melting-point eutectic for the melt and thus lengthens furnace life. This process was originally developed by Readman in England in 1888. The first 1,500-kW furnace in the United States was installed at Niagara Falls, N.Y. in 1896 because of the availability of low-cost energy. For many years the proximity of Tennessee brown stone (a phosphate rock) to the low-cost power of the Tennessee Valley Authority made a good economic combination. Worldwide production of phosphorus by this process is about $\frac{3}{4}$-billion short tons (0.675 billion metric tons) per year (installed capacity). In the United States, about 80% of the phosphorus produced is immediately converted to the oxide and thence to phosphoric acid. The remaining 20% has gone into alloys, organic intermediates for oil and fuel additives, pesticides, plasticizers, and pyrotechnics. In addition to use in detergents, cleaning compounds, and degreasing formulations, phosphoric acid has been consumed in the preparation of liquid fertilizers, water-treatment, pharmaceutical, and chemical products. Phosphorus-containing fertilizers, such as single superphosphate, wet-process orthophosphoric acid, triple superphosphate, ammonium phosphate, and nitrophosphates do not require elemental phosphorus (or the resulting pure P_2O_5) in their preparation, but are manufactured by directly reacting phosphate rock with requisite chemicals, such as H_2SO_4 or HNO_3. See also **Fertilizer**.

Chemistry and Compounds

Like carbon, phosphorus is covalently bound to its neighboring atoms in all of its compounds, except perhaps for some metallic phosphides. Indeed, the chemistry of carbon and that of phosphorus are somewhat similar as might be expected from the diagonal relationship of these elements in the periodic table.

Probably the major difference between carbon and phosphorus is that the former element is quite closely restricted to the use of *s*- and *p*-orbitals, because of the relatively high energy of *d*-orbitals in the case of second-period elements; whereas, phosphorus, being a third-period element, can use *d*-orbitals in bonding. For both carbon and phosphorus, the most common hybridization for σ-bonding is approximately the tetrahedral sp^3. However, in order to form π-bonds, carbon must go to lower hybrids: sp^2 and *sp*. Phosphorus, on the other hand, does not do this but can employ *d*-orbitals for π-bonding. This difference between carbon and phosphorus in sigma bond strength, and the ease with which phosphorus uses its *d*-orbitals for attachment of attacking nucleophilic groups, can be used to explain why catenation is common in carbon compounds, while at the same time phosphorus compounds containing long chains of connected phosphorus atoms have not yet been synthesized.

The known coordination numbers exhibited by phosphorus within the molecule-ions containing this element are 1, 3, 4, 5, and 6 which, to at least a first approximation, exhibit the symmetry of p, p^3, sp^3, sp^3d and sp^3d^2 hybridization, respectively. A very large number (several thousand in each case) of triply- and quadruply connected phosphorus compounds are known; but there are only a few compounds of higher coordination number in which *d*-orbitals are involved in the σ-bond base structure. These are the halogen compounds PF_5, PCl_5, PBr_5, PCl_2F_3, PBr_2F_3 and the pentaphenyl compound $(C_6H_5)_5P$, in which the phosphorus is quintuply connected to its neighboring atoms, and the PF_6^- and PCl_6^- anions, in which the phosphorus has a six-fold coordination. The singly connected phosphorus atoms appear only in compounds occurring at very high temperatures. Although singly connected phosphorus is not known under ordinary conditions, interpretation of diatomic spectra has given considerable information.

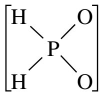
Several generalities can be stated concerning the phosphorus compounds that are stable under normal conditions:

1. In those compounds in which phosphorus shares electrons with three neighboring atoms, there are three σ-bonds, with little or no π-character, from the phosphorus.
2. In those compounds in which phosphorus shares electrons with four neighboring atoms there are four σ-bonds, with an average of about one π-bond per P atom.
3. When electrons are shared with five or six neighboring atoms, there is less than one full σ-bond for each connection between the phosphorus and a neighboring atom with apparently very little π-bonding.

These generalities are obviously dependent to a considerable extent upon the specific atoms connected to the phosphorus and, indeed, it is possible that the observed differences between the triply and quadruply connected phosphorus atoms may be attributed primarily to the individual ligands. Fluorine appears to contribute nearly as much shortening (assuming that the tabulated values for the fluorine bond length are correct) to the P–F connection in the triply connected as in the quadruply

connected phosphorus compounds. On the other hand, chlorine shows essentially no shortening, whether attached to either triply or quadruply connected phosphorus.

Phosphine. [CAS: 7803-51-2]. PH_3, and its substitution products, have a pyramidal structure. The P−H bond length is 1.42 Å, and the H−P−H angle is 93°. Hypophosphites, containing the radical

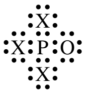


are produced by alkaline hydrolysis of white phosphorus. The barium salt yields hypophosphorous acid, H_3PO_2, upon acidification with sulfuric acid. In this acid, only one H is capable of ionization, suggesting the experimentally confirmed formula $H_2P(O)OH$. Hypophosphorous acid and its salts are reducing agents, although their reaction rates are somewhat low, which is usually explained by an equilibrium between H_3PO_2 and its hydrate form, H_5PO_3.

Phosphorus Halides. PX_3, P_2X_4 and PX_5 are formed by direct reaction of the elements, though the pure substances require special methods. Mixed halides are also known. The trihalides are covalent pyramidal compounds, the X−P−X bond angles being generally between 98° and 104°. They all undergo hydrolysis, the rate being roughly inversely proportional to the sum of the atomic numbers of the halogen atoms.

The halogen derivatives of pentavalent phosphorus may be grouped on the basis of their structure into three classes, the pentahalides, oxyhalides and related compounds, and the fluorophosphoric acids. The pentahalides (except the pentaiodide, which is unknown) are produced by reaction of the elements, or, in the case of mixed halides, by reaction of a halogen and a phosphorus trihalide in correct proportions. Their structure in the vapor state has been determined to be a trigonal bipyramid and their bonding is covalent. In the solid, however, phosphorus pentachloride, [CAS: 10026-13-8], PCl_5, is $[PCl_4^+]$ $[PCl_6^-]$ and phosphorus pentabromide, [CAS: 7789-69-7], PBr_5, is $[PBr_4^+]Br^-$. Various mixed halides are known. The five halogen atoms are not in equivalent positions. One may be ionized, with the other four forming sp^3d orbitals or there may be a transition state, to explain the nonequivalence of the exchange between the three equatorial chlorine atoms and the two apical ones in PCl_5 in carbon tetrachloride solution. The pentahalides react with excess water to yield phosphoric acid and hydrohalic acids, but with less water to form phosphorus oxyhalides instead of phosphoric acid.

Phosphorus oxyhalides have the tetrahedral structure



These compounds, particularly $POCl_3$ and $POFCl_2$, readily form complexes with metal halides. Closely analogous to the oxyhalides are the thiohalides of general formula PSX_3 and the phosphorus nitrilic halides, $(PNX_2)_n$, the chloride of the latter being obtained by partial ammonolysis of PCl_5, and existing as cyclic or polymeric structures of alternate nitrogen and phosphorus atoms.

Phosphorus Oxides and Oxyacids. The principal oxides are related to the acids which they yield when dissolved in H_2O in the following manner:

Trioxide, P_2O_3	Hypophosphorous acid, H_3PO_2
Tetroxide, P_2O_4	Phosphorous acid, H_3PO_3
Pentoxide, P_2O_5	Hypophosphoric acid, $H_4P_2O_6$
plus $3H_2O$	Orthophosphoric acid, $2H_3PO_4$
plus $2H_2O$	Pyrophosphoric acid, $H_4P_2O_7$
plus $1H_2O$	Metaphosphoric acid, $2HPO_3$

Normally when the term "phosphoric acid" is used, it is with reference to orthophosphoric acid, H_3PO_4. Anhydrous orthophosphoric acid is a white crystalline solid that melts at 42.35°C. It forms a hemihydrate, $2H_3PO_4 \cdot H_2O$, which melts at 29.32°C. Although practically any desired concentration can be produced, it is common to supply the material as a solution containing from 75% H_3PO_4 (mp −17.5°C) to 85% H_3PO_4 (mp 21.1°C). When phosphoric acid is heated to above 200°C, the water of constitution is lost. Thus, a series of acids is formed by the dehydration, ranging from pyrophosphoric acid, $H_4P_2O_7$, to metaphosphoric acid, $(HPO_3)_n$. Salts of the dehydrated acids are used for the preparation of certain kinds of liquid fertilizers and are present in numerous cleaning compounds. The dehydrated acids can form water-soluble complexes with many metals, such as calcium. One, or two, or three of the hydrogens of phosphoric acid may be neutralized. When one hydrogen is replaced with sodium, for example, the product is slightly acidic; while replacement of all three hydrogens yields a highly alkaline product. The acidity of the solutions is: NaH_2PO_4, a pH of 4.0; Na_2HPO_4, a pH of about 8.3; Na_2PO_4, a pH of 12.0. Although of interest scientifically, the other acids of phosphorus, hypophosphorous acid, H_3PO_2, orthophosphorous acid, H_3PO_3, and pyrophosphorous acid, $H_4P_2O_5$, are not important commercially.

There are two main processes for the industrial production of phosphoric acid, H_3PO_4, from phosphate rock: (1) the *wet process* which involves the reaction of phosphate rock with H_2SO_4 to yield phosphoric acid and insoluble calcium sulfates. Several of the impurities present in the rock dissolve and remain with the product acid. These are not important when the acid is used for fertilizer manufacture. However, the impurities are deleterious to the manufacture of phosphorus chemicals. For a purer product, (2) the *furnace process* is used, wherein the phosphate rock is combined with coke and silica, producing elemental phosphorus as previously described. Oxidation of the phosphorus produces P_2O_5 which, when combined with H_2O, yields H_3PO_4.

Phosphorus sesquioxide, P_4O_6, produced by controlled oxidation of white phosphorus, is hydrolyzed in the cold to produce phosphorous acid, H_3PO_3, a colorless solid (mp 73°C). Only two of its H atoms are capable of ionization, thus compounds such as M_3PO_3 do not exist. This fact leads to the formula $HP(O)(OH)_2$. Phosphorous acid is a somewhat stronger acid than phosphoric, and both it and the phosphite ion (HPO_3^{2-}) are strong reducing agents.

Hypophosphorous acid was discussed earlier in this entry.

Metaphosphorous acid, HPO_2, is produced by atmospheric combustion of PH_3, but in aqueous solution it hydrates to H_3PO_3.

Phosphorous acid is used in solution, and is usually a reducing agent. That is, in air it changes to phosphoric acid, with hot concentrated sulfuric acid it yields phosphoric acid plus SO_2, with copper sulfate it yields finely divided copper metal, with silver nitrate it yields finely divided silver metal, with permanganate after some time it yields manganous. Occasionally it is an oxidizing agent, e.g., with zinc plus dilute H_2SO_4 it yields phosphine.

Phosphorus tetroxide, P_2O_4, is obtained along with red phosphorus by heating P_4O_6 at 290°C in a closed tube. It is believed to have the formula, P_8O_{16}, and to consist of trivalent and pentavalent phosphorus. Hypophosphoric acid, $H_4P_2O_6 \cdot 2H_2O$, cannot be produced directly from the tetroxide. The acid decomposes into phosphorous and phosphoric acids on heating, and must be prepared by indirect methods, such as treatment of white phosphorus with an HNO_3 solution of $Cu(NO_3)_2$.

Phosphorus(V) oxide is the chief product of atmospheric oxidation of phosphorus, whence it is obtained as the β-allotrope, of formula P_4O_{10}. Several other allotropes are obtained by various thermal treatments of the β-form, differing in structure and physical properties. The compound hydrates rapidly to form various phosphoric acids. With an excess of H_2O, orthophosphoric acid, $(HO)_3PO$, is formed, mp 42.3°C. It is a triprotic acid, yielding $H_2PO_4^-$, HPO_4^{2-} and PO_4^{3-} ions. The other crystalline phosphoric acid, pyrophosphoric acid, is believed to have the formula $(HO)_2P(O)-O-P(O)-(OH)_2$. Its acid solution undergoes hydrolysis to the orthoacid. It is tetraprotic, yielding the ions $H_3P_2O_7^-$, $H_2P_2O_7^{2-}$, $HP_2O_7^{3-}$ and $P_2O_7^{4-}$.

Classification of Phosphates. Audrieth and Hill have proposed a classification on the basis of structure, that is, to divide them into glassy phosphates and crystalline phosphates, the latter class being subdivided into (1) linear phosphates and polyphosphates, and (2) cyclic phosphates. Three important members of class (1) are the orthophosphates, containing the PO_4^{3-} ion, the pyrophosphates, having the $P_2O_7^{4-}$ ion, and the triphosphates, having the $P_3O_{10}^{5-}$ ion. The general structural unit of the linear phosphates is the tetrahedron, containing a phosphorus atom surrounded by four oxygen atoms covalently linked to it. Such tetrahedra are linked through a common oxygen atom to form linear polyphosphates, the $P_2O_7^{4-}$ ion having two such tetrahedra, and the $P_3O_{10}^{5-}$ ion, three. Moreover, the tetrahedra may also be double linked through oxygen atoms to form cyclic structures, as in the trimetaphosphate ion, $P_3O_9^{3-}$, which has three such tetrahedra and the tetrametaphosphate ion, $P_4O_{12}^{4-}$, which has four tetrahedra. In general, heating acid salts of simpler phosphates produces polyphosphates (loss of H_2O), while alkaline hydrolysis reverses the process. The glassy phosphates, produced by fusion and rapid cooling of

metaphosphates, appear to be true glasses, containing anions with molecular weights well into the thousands.

The widely diverse functionality of phosphates makes them of exceptional importance to technologists, particularly in the food processing field. Phosphoric acid finds many direct uses as an acidulant. It has three available hydrogens which can be replaced one by one with alkali metals, forming a series of *orthophosphate salts* with pH levels ranging from moderately acid (pH = 4) to strongly alkaline (pH = 12). This wide pH range makes phosphates very useful for adjusting the pH of food and chemical systems to almost any desired level. Heating orthophosphates converts them to condensed phosphates containing two, three, or more phosphorus atoms per molecule. The *condensed phosphates*, or *polyphosphates*, have many properties that the orthophosphates do not enjoy. They are polyelectrolytes, and have dispersing or emulsifying properties. They can sequester or chelate metals, such as calcium, magnesium, iron, and copper, rendering these metals nonreactive. This functionality is useful for controlling oxidative rancidity and color formation, as both are catalyzed by metal ions.

Condensed phosphates containing two atoms of phosphorus are *pyrophosphates*. Sodium acid pyrophosphate (SAPP) is used as a leavening acid in baking, and is particularly useful because of the way it can be modified to give different rates of reaction. Pyrophosphates are good sequestrants for iron and copper, which often catalyze oxidation in fruits and vegetables. Thus, the use of a pyrophosphate effectively prevents the discoloration of such foods during preparation and storage.

Condensed phosphates containing three atoms of phosphorus are *tripolyphosphates*, the most important of which is sodium tripolyphosphate (STPP). This compound reacts with the protein in meat, fish, and poultry to prevent denaturing or loss of fluids. This property is sometimes called "moisture binding." STPP also solubilizes protein, which aids in binding diced cured meat, fish, and poultry. It also emulsifies fat to prevent separation.

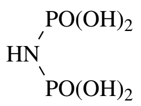
The chain length of phosphates can be increased further by melting and chilling to form a glass. Glassy sodium phosphates are generally called *sodium hexametaphosphates* (SHMP). SHMPs have excellent sequestering power toward calcium and magnesium. They are used in meat treatment as a partial replacement for STPP to improve solubility in strong pickling brine or to prevent hardness precipitation in very hard water. Considerably more information on the use of phosphates in food processing will be found in the *Foods and Food Production Encyclopedia*, D.M. Considine (editor), Van Nostrand Reinhold, New York, 1981. See also **Fertilizer**.

Peroxyphosphoric Acids. Two are known—peroxymonophosphoric acid, $HOOP(O)(OH)_2$, prepared by treatment of P_4O_{10} with hydrogen peroxide, and peroxydiphosphoric acid, $(HO)_2(O)POOP(O)(OH)_2$, prepared from metaphosphoric acid and peroxide or by electrolysis of an alkali hydrogen phosphate solution (cf. preparation of peroxydisulfuric acid). They and their salts are strong oxidants.

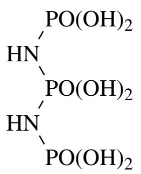
Fluorophosphoric Acids. [CAS: 13537-32-1]. H_2PO_3F, HPO_2F_2, (POF_3 is not a protic acid), "HPF_6" are obtained by replacing one or more hydroxyl groups with fluorine. They are strong fuming acids, like H_2SO_4 in most properties except its oxidizing power. Their salts are also known, extending as far as completely fluorinated MPF_6 where M is an alkali metal. The solubilities of the monofluorophosphates parallel those of the sulfates; while those of the di- and hexafluorophosphates parallel those of the perchlorates.

Upon acidification or neutralization of solutions containing phosphate anions with other anions, such as those of molybdenum and tungsten, complexes are formed which can readily be crystallized as salts, called phosphomolybdates, phosphotungstates, etc.

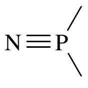
Oxygen-nitrogen Compounds of Phosphorus. These may be classified as aquo, aquo ammono, or ammono derivatives. The first group includes the various acids and oxides already discussed. The second group includes the amido phosphoric acids in which one or more of the hydroxy groups of the acid are substituted by amino groups. Thus there is amidophosphoric acid (*orthophosphoric acid* is understood when the substituted acid is not specified), amidopyrophosphoric acid, diamidophosphoric acid, and triamidophosphoric acid. The substitution of all—OH groups of phosphoric acid gives phosphoryl triamide, $OP(NH_2)_3$. Related compounds are phosphoryl amide imide, $OP(NH_2)$:NH and phosphoryl nitride $(OPN)_x$. The second group also includes imidodiphosphoric acid,



diamidotriphosphoric acid,



and still longer chain acids. Finally, many other derivatives are possible because



of the stability of the arrangement. This gives rise to the phosphonitrilic acids, $[NP(OH)_2]_x$, as well as to many ammono derivatives containing only the two elements. The latter include phosphonitrilamide, $[NP(NH_2)]_x$, phospham $[NPNH]_x$, and phosphoric nitride, $[P_3N_5]_x$. The phosphonitrilic chlorides, already discussed, are derivatives of phosphonitrilamide.

Organophosphorus Compounds. Most of the industrially important organic compounds of phosphorus commence with one of the basic inorganic phosphorus compounds, such as PCl_3, $POCl_3$, P_2S_5, and P_2O_5, reacted with an appropriate organic intermediate. Ester intermediates, such as alkyl phosphoryl chlorides, are made by the addition of primary alcohols to $POCl_3$. Triaryl phosphate plasticizers and gasoline additives, such as tricresyl phosphate (TCP), can be prepared from PCl_5 and an appropriate phenolic compound. Alkyl diaryl phosphates can be made from $POCl_3$ and corresponding phenols. A number of thiophosphate esters contain PS plus an ethyl or methyl group and a substituted aryl group and are based on $PSCl_3$ or P_2S_5. These compounds are finding use for pesticide control. Dialkyl dithiophosphates may be prepared from P_2S_5 and appropriate intermediates. They are finding application as flotation-agents, oil-additives, and insecticides. It is much more difficult to prepare organophosphorus compounds containing a C—P bond than it is to form the esters. Numerous organic phosphorus compounds are found in nearly all life processes and remain to be better understood before they can be synthesized. Classes of compounds of this type include the phosphoglycerides required for fermentation, the adenosine phosphates needed in photosynthesis and muscle activity, and the very complex phosphorus-containing groups identified in the nucleotides. Of structural interest are the catenation compounds, as illustrated below, which contain many cyclic phosphates and oxygen-linked chains. Compounds of this type include tetrachlorodiphosphine, Cl_2PPCl_2, tetraphenyldiphosphine $(C_6H_5)_2PP(C_6H_5)_2$, diphosphobenzene, $C_6H_5PPC_6H_5$, and tetramethyl hypophosphate, $(CH_3O)_2(O)PP(O)(OCH_3)_2$.

K_6  and 
Inorganic Macromolecules. After the accelerated activity in the development of new polymers that took place during the past 30 or 40 years, some researchers observed some lessening of polymer research and polymer achievements during the 1970s. Not all authorities agreed, but most agreed that the time had arrived when polymer chemistry and applications deserved evaluation both in terms of the past and the future. Synthetic polymers generally have a number of relatively negative features—flammability (derived from their organic nature); a tendency to melt, oxidize, and char at high temperatures in regular atmospheric conditions (again, a result of their organic nature); and a tendency to

become stiff and brittle at low temperatures. Many also have a tendency to soften, swell and dissolve in a number of common substances, such as gasoline, jet fuel, hot oil, and numerous other hydrocarbons. In terms of medical applications, most organic polymers tend to initiate a clotting reaction of the blood and many tend to cause toxic, irritant, and sometimes carcinogenic responses. Observers also noted that most polymer research in some way initiated with petrochemicals.

In the early 1970s, a number of investigators decided to shift emphasis and to look at a number of inorganic elements including silicon, phosphorus, sulfur, boron, and some metal atoms that might make up the backbone of a polymer. It was reasoned that the presence of some of these materials in the backbone might remedy some of the aforementioned shortcomings. It should be pointed out that as early as the 1940s, silicone, or poly(organosiloxane) polymers were developed and have proved highly satisfactory in many applications. Peters et al. (1976) reported on a new class of thermally stable polymers, which are based upon alternating siloxane and carborane units. In 1965, Allcock et al. (Pennsylvania State University) synthesized the first poly(organophosphazenes). Since that time, well over 60 new polymers have been made and presently constitute a substantial class of new elastomers. They appear to solve some of the biomedical problems previously mentioned. As pointed out by Allcock (1976), all linear, high polymeric polyphosphazenes have the general structure shown by (a), below. It is interesting to note that over a century ago researchers in Germany and Britain found that phosphorus pentachloride will react with ammonia or ammonium chloride to yield a volatile, white solid. It is now known that this product has the form of (b). Later experimentation showed that the compound would melt under strong heating to form a transparent rubbery material. Involving a ring-opening polymerization of the cyclic trimer, a poly(dichlorophosphazene), shown in (c), is formed. Mainly for the reason that the compound hydrolyzes slowly in the presence of atmospheric moisture to form a crusty mixture of ammonium phosphate and phosphoric acid, the substance was not given serious thought for many years.

Allcock and associates, during the 1960s, subjected the cyclic trimer to new procedures and, after considerable research, were successful in developing polymers that have molecular weights up to and sometimes exceeding 3 to 4 million. The investigators found that the introduction of different substituent groups had a marked effect on the properties of the polymers. See (d). The further detailed research is beyond the scope of this book, but interesting details can be found in the Allcock reference. In summarizing one of their reports, the researchers stated: "Polyphosphazenes are emerging as a new class of macromolecules that have an obvious future as technological elastomers, films, fibers, and textile treatment agents. However, they also possess almost unique attributes for use in biomedicine as reconstructive plastics or as drug-carrier molecules. Moreover, their possible value as 'pseudo-protein' model polymers is an exciting prospect."

Phosphorus Ylides. In 1979, G. Wittig received a share of the Nobel Prize for Chemistry in recognition of his development of the use of phosphorus-containing compounds as important reagents used in organic synthesis. According to the selection committee, Wittig's most important achievement was "the discovery of the rearrangement reaction that bears his name. In the Wittig reaction an organic phosphorus compound with a formal double bond between phosphorus and carbon is reacted with a carbonyl compound. The oxygen of the carbonyl compound is exchanged for carbon, the product being an olefin. This method of making olefins has opened up new possibilities, not the least of which is the synthesis of biologically active substances containing carbon-to-carbon double bonds. For example, vitamin A is synthesized industrially using the Wittig reaction." As early as 1919, some 30 years prior to Wittig's work, the first phosphorus ylide was described by Staudinger. This was diphenylmethylenetriphenylphosphorane, formed by pyrolysis of a phosphazine precursor. During that period, Staudinger conceived the possibility of olefin synthesis by condensation of this ylide with a carbonyl compound and visualized a four-membered phosphorus-oxygen heterocyclic (oxaphosphetane) as the intermediate. Staudinger's work was accomplished during a period when practical application of the concept was in doubt. At that time, the Lewis theory of electronic structure was new. The exact bonding of phosphonium salts was somewhat veiled and controversial. Attempts of an olefin synthesis were put aside. For more detail, see **Wittig Reaction**.

Health and Safety

At ambient temperatures white phosphorus spontaneously ignites when exposed to air. It has an autoignition temperature of 30°C. As a result, any human exposure to white phosphorus can cause severe thermal burns to the skin and eyes. The vapor from phosphorus can cause severe lung irritation, followed by a build-up of fluid in the lungs. Continuous long-term inhalation of white phosphorus vapor (>0.1 mg/m3) can result in bone loss to the jawbone structure causing loosening of teeth and severe pain and swelling of the jaw. This condition is commonly referred to as phossy jaw. Some evidence exists that increased infant mortality can result when pregnant women are exposed to P_4 vapor in excess of 0.075 mg/kg/day. Ingestion of white phosphorus is potentially fatal. The lowest reported fatal dose is 1 mg/kg for humans. Absorption through the skin is also possible but is only considered to be a moderate hazard compared to the other routes of exposure.

When exposed to air, white phosphorus oxidizes to phosphorus pentoxide forming copious quantities of white smoke. This smoke may be irritating but is not considered to be toxic. White phosphorus solid, liquid, or vapor is also extremely reactive with oxidizers such as strong acids, alkaline hydroxides, halogens, and nitrates. Contact of phosphorus with water or oxidizers also generates phosphine CAS: 7803-51-2, PH_3, a highly toxic and flammable gas. Phosphine has an 8-h time-weighted average exposure limit of 0.3 ppm. Under alkaline conditions the rate of PH_3 formation is high. At neutral or acidic pH, the PH_3 generation is slow but still very hazardous if the PH_3 is allowed to accumulate in a confined vapor space. The safest commercial handling conditions for molten phosphorus are generally considered to be from pH 6 to 8 at 45–65°C.

Phosphorus production plants and users should ensure that processing of the material is contained and that potential high exposure areas are well ventilated. Workers must wear aluminized fiber glass or Kevlar flame-retardant full protective clothing, face shield with hard hat, rubber boots, and heavy rubber gloves when handling or transferring the product. The phosphorus should always be kept under neutral pH water at temperatures less than 65°C or under an inert atmosphere to avoid oxidation and exposure hazards. High potential exposure areas should also be equipped with well-maintained, water-filled safety tubs, deluge systems, and water-spray extinguishing systems as a precautionary measure. If high exposure levels to phosphorus vapors or phosphine are anticipated, then self-contained breathing apparatus units should be utilized. Individuals exposed to phosphorus through skin or eye contact should have the exposed area flushed immediately with large amounts of water. The affected area should be kept wet until all of the phosphorus is removed or flushed away. Victims of phosphorus inhalation should immediately be removed to an area with fresh air and have artificial respiration administered, if necessary. Workers who have had dental surgery and pregnant women should be kept away from phosphorus exposure areas completely. Anyone who ingests phosphorus should drink a large volume of water and be induced to vomit. Medical assistance should be obtained as soon as possible after any instance of phosphorus exposure.

PHOSPHORUS (In Biological Systems). Phosphorus is required by every living plant and animal cell. Deficiencies of available phosphorus in soils are a major cause of limited crop production. Phosphorus deficiency is probably the most critical mineral deficiency in grazing livestock. Phosphorus, as orthophosphate or as the phosphoric acid ester of organic compounds, has many functions in the animal body. As such, phosphorus is an essential dietary nutrient.

The biological roles of phosphorus include: (1) anabolic and catabolic reactions, as exemplified by its essentiality in high-energy bond formation, e.g., ATP (adenosine triphosphate), ADP (adenosine diphosphate), etc., and the formation of phosphorylated intermediates in carbohydrate metabolism; (2) the formation of other biologically significant compounds, such as the phospholipids, important in the synthesis of cell membranes; (3) the synthesis of genetically significant substances, such as DNA (deoxyribonucleic acid) and RNA (ribonucleic acid); (4) contributing to the buffering capacity of body fluids, cells, and urine; and (5) the formation of bones and teeth. Like calcium, the majority of the phosphorus in the vertebrate body is contained in the hard tissues; in the adult, approximately 80–86% of the total body phosphorus is contained in the bones and teeth, with the balance found in the soft tissues and body fluids.

In a very interesting dissertation by F.H. Westheimer (*Science*, **235**, 1173–1177, 1987), the role of phosphates in living substances is described. As pointed out by Westheimer, phosphate esters and anhydride dominate the living world but are seldom used as intermediates by organic chemists. Phosphoric acid is specially adapted for its role in nucleic acids because it can link two nucleotides and still ionize; the resulting negative charge serves both to stabilize the diesters against hydrolysis and to retain the molecules within a lipid membrane. A similar explanation for stability and retention also holds for phosphates that are intermediary metabolites and for phosphates that serve as energy sources. Phosphates with multiple negative charges can react by way of the monomeric metaphosphate ion PO_3^- as an intermediate. No other residue appears to fulfill the multiple roles of phosphate in biochemistry. Stable negatively charged phosphates react under catalysis by enzymes; organic chemists, who can only rarely use enzymatic catalysis for their reactions, because they need more highly reactive intermediates than phosphates.

Most of the coenzymes are esters of phosphoric or pyrophosphoric acid. The main reservoirs of biochemical energy, adenosine triphosphate (ATP), creatine phosphate, and phosphoenolpyruvate are phosphates. Many intermediary metabolites are phosphate esters, and phosphates or pyrophosphates are essential intermediates in biochemical syntheses and degradations. The genetic materials DNA and RNA are phosphodiesters.

Phosphorus deficiencies are not common in humans and most other species, but they have been observed in ruminants. Symptoms of the deficiency are loss of appetite and a depraved appetite (termed "pica") where the animal chews and consumes extraneous items, such as wood, clothing, bones, etc. Vitamin D deficiency may accentuate a marginal lack of phosphorus in the diet.

Cereals and meats are the major sources of phosphorus in human diets. Phosphorus deficiencies in most regions have not been a serious problem in human nutrition. Insofar as food is concerned, the primary value of phosphorus fertilizers is that they generally increase the total food production; not the content of phosphorus in the food per se.

Experimental phosphorus deficiency can be induced by feeding diets low in this element and by including excesses of calcium, strontium, barium, beryllium, and other cations that precipitate phosphates in the intestinal tract. In this situation, bone formation ceases, and the following histological bone changes have been noted in experimental animals: (1) a thickening of the epiphyseal plate and the formation of a typical rachitic metaphysis; (2) wide osteoid borders of trabecular bone and a considerable rarefaction of the shaft; and (3) irregular or complete cessation of calcification of the zone of provisional calcification of the cartilage matrix. Rickets can be produced in the laboratory by feeding a diet high in calcium and low in phosphorus, and containing little or no vitamin D.

The nutrient requirement for phosphorus depends upon the particular species and the physiological status of the animal. During growth, lactation, gestation, and egg laying, a higher phosphorus content of the diet is generally required in poultry than for the maintained adult. The availability of phosphorus in the diet varies with its chemical form and the animal species in question. Diets high in foods of plant origin may contain a considerable portion of phosphorus in the form of phytic acid, which is the hexaphosphoric acid ester of inositol. When the acid occurs as salts of calcium, magnesium, sodium, etc., it is referred to as phytin. Phytate phosphorus usually is less available than inorganic phosphate to such species as rat, chicken, dog, pig, and human. However, a phytase has been shown to be present in the intestine and intestinal secretions of some animals, and the formation of this enzyme is dependent, in part, on the presence of vitamin D. Through the action of phytase, some of the phytate phosphorus would be made available for absorption.

Experimentation has indicated that, under normal dietary conditions and calcium intake, food phytate is of no nutritional concern in humans. The microbial population of the ruminant also elaborates a phytase enzyme that makes phytate phosphorus readily available in this class of animals. Phytates may be of nutritional consequence for another reason—dietary calcium can be bound in an unavailable, insoluble complex, thereby decreasing the absorption of this element.

Many studies have involved determination of the availability of phosphorus from other organic and inorganic sources. In chicks, orthophosphates, superphosphates, and phosphate rock products are good sources of phosphorus, whereas metaphosphate and pyrophosphate are relatively unavailable to the species. Most organic phosphorus sources, such as casein, pork liver, and egg phospholipid are found to be as available as inorganic phosphorus. Commonly used phosphorus supplements in human or animal nutrition or both are steamed bone meal, ground limestone, dicalcium phosphate, and defluorinated rock phosphates. Phosphorus dietary supplements include magnesium phosphate (dibasic and tribasic) manganese glycerophosphate and manganese hypophosphate, potassium glycerophosphate, sodium ferric pyrophosphate, sodium phosphate (mono-, di-, and tri-), and sodium pyrophosphate. Of course, phosphate compounds are not always added in the interest of augmenting phosphorus, but for the other elements which may be contained in the compound.

Absorption of Phosphate

The phosphate ion readily passes across the gastrointestinal membrane. The rate of absorption of phosphate at various intestinal sites in rats has been observed to be most rapid in the duodenum, followed in decreasing order by the jejunum, ileum, colon, and stomach. When transit time is considered, most of the phosphorus is absorbed by the ileum.

The triangular relationship between calcium, phosphorus, and vitamin D is described briefly in entry on **Calcium (In Biological Systems)**.

Plasma Phosphate

Once absorbed, phosphorus enters the blood and the majority is present therein as orthophosphate ions. At an ionic strength of 0.165 and at 37°C (98.6°F), calculations show that the proportional concentration of the orthophosphate ions in plasma for $H_2PO_4^-$ is 18.6×10^{-30}; for HPO_4^{2-} is 81.4×10^{-30}; and for PO_4^{3-} is 8×10^{-30}. About 12% of the

phosphorus present is bound to proteins. During egg laying in birds, the concentration of nonionized phosphorus compounds in plasma is greatly increased. The administration of diethylstilbestrol (regulated in some countries) to cockerels results in the formation of a plasma phosphoprotein, which forms relatively firm complexes with calcium. The function of the phosphoprotein appears to be one of phosphorus transport; in laying birds, the phosphoprotein is incorporated in egg yolk.

The approximate average plasma phosphorus levels for several species, in milligrams per 100 milliliters of plasma, are: pigs, 8.0; sheep, cattle, and goats, 6.0; horse, 2.3. Erythrocytes contain considerably more phosphorus than plasma, mostly in the form of organic esters. Some of the latter are acid soluble and hydrolyzable by intracellular enzymes.

Plasma phosphate appears to be homeostatically controlled. The primary organ concerned appears to be the kidney, although the skeleton also may play a role. Parathyroid hormone, by way of its direct action on the kidney and bone, is a significant hormonal factor.

Phosphate Excretion

The excretion of body phosphorus occurs via the kidney and intestinal tract, the distribution between these pathways varying with species. For example, relatively small amounts of phosphorus are endogenously excreted into the feces of rat, pig, and human, but in the bovine, perhaps 50% or more of the fecal phosphorus may be from endogenous sources.

The amount of phosphorus excreted in the urine varies with the level of ingested phosphorus and factors influencing phosphorus availability and utilization. It has been shown that in the dog, when plasma phosphate is normal or low, over 99% of the filtered ion is reabsorbed, presumably in the upper part of the proximal tubule. Increased plasma concentrations of alanine, glycine, and glucose depress phosphate reabsorption.

Phosphate of Hard Tissues

Body phosphorus contained in the intracellular matrix of bone and teeth is of the general form of hydroxyapatite, $Ca_{10}(PO_4)_6(OH_2)$, this calcium phosphate salt providing the characteristic hardness of ossified tissue. Phosphate ions are also adsorbed onto the surface of bone crystals and exist in the hydration layers of the crystals. Early theories of calcification placed special emphasis on the role of alkaline phosphatase and organic esters of phosphoric acid. As part of the theory, it was stipulated that, with the hydrolysis of phosphate esters at the site of calcification, the K_{sp} for bone salt would be exceeded. Although phosphatase may have a function in bone formation, as in the synthesis of organic matrix, its role as earlier depicted has been revised. Later research emphasized the specific and characteristic properties of collagen and other substances, such as chondroitin sulfate. This is related to the local mechanism of calcification; the other component of calcification is the humoral mechanism whereby an adequate supply of calcium, phosphate, and other ions is made available to the calcifying site. A later theory proposed that either the functional groups on collagen are anionic, initially binding Ca^{2+}, or that the first reaction is with phosphate or phosphorylated intermediates. The first-held moiety of bone salt (Ca^{2+} or phosphate) subsequently attracts or binds the other component, providing the aggregation or "seed" for subsequent crystal growth. Since an ATPase-type enzyme has been demonstrated in cartilage, suggesting that ATP may be intimately involved in the calcification mechanism, another proposal is along the line that pyrophosphate is transferred from ATP to free amino groups of collagen, leading to nucleation and followed by combination with calcium and bone salt formation. Or, the ATP provides energy which increases the calcification mechanism.

Dietary inorganic phosphates have been shown to protect experimental animals against dental caries. Orthophosphates were effective cariostats, but $Na_4P_2O_7$ and $Na_5P_3O_{10}$ were not. Dicalcium phosphate, $CaHPO_4$, did not decrease dental caries unless a high level of NaCl was also included in the diet.

Toxicity

Although many phosphorus-containing compounds are vital to life processes, as previously described, there are also many phosphorus compounds that are quite toxic—elemental phosphorus, for example. While the elemental form is dangerous because of its low combustion temperature, its absorption also has an acute effect on the liver. The long and continued absorption of small amounts of phosphorus can result in necrosis of the mandible or jaw bone (sometimes called "phossyjaw"). Chronic phosphorus poisoning occurs particularly through the lungs and gastrointestinal tract. The most common symptom is the necrosis of the jaw already mentioned, but this is also usually accompanied by anemia, loss of appetite, gastrointestinal weakness, and pallor. Other bones and teeth may be adversely affected.

Phosphine is a very toxic gas. Inhalation of phosphine causes restlessness, followed by tremors, fatigue, slight drowsiness, nausea, vomiting, and, frequently severe gastric pain and diarrhea. Although most cases recover without after-effects, in some cases, coma or convulsions may precede death.

Phosphorus-halogen compounds are quite toxic.

Phosphorus in Soils

When phosphorus fertilizers are added to soils deficient in available forms of the element, increased crop and pasture yields ordinarily follow. Sometimes the phosphorus concentration in the crop is increased, and this increase may help to prevent phosphorus deficiency in the animals consuming the crop, but this is not always so. Some soils convert phosphorus added in fertilizers to forms that are not available to plants. On these soils, very heavy applications of phosphorus fertilizer may be required. Some plants always contain low concentrations of phosphorus even though phosphorus availability from the soil may be good. See also **Fertilizer**.

PHOSPHORYLATION (Oxidative). This is an enzymic process whereby energy released from oxidation-reduction reactions during the passage of electrons from substrate to oxygen over the electron transfer chain is conserved by the synthesis of adenosine triphosphate (ATP) from adenosine diphosphate (ADP) and inorganic orthophosphate. Since ATP is the major source of energy for biological work, and since most of the net gain of ATP in the animal cell derives from oxidative phosphorylation, research in the area has been very active.

Oxidative phosphorylation was discovered simultaneously and independently in 1939 by Kalckar (Denmark) and by Belitzer (the former U.S.S.R.). It was recognized by these workers that aerobic phosphorylation was different from and independent of phosphorylation supported by glycolysis. In addition, they found that the stoichiometry of phosphate esterification (ATP synthesis) and oxygen utilized was two or more, or that the reduction of one atom of oxygen to form water may be accompanied by the "activation" of two or more molecules of phosphorus (P_i), thus leading to an expression of the efficiency of the energy-conserving system. The efficiency expression is known as the P/O ratio, i.e., the ratio of molecules of P_i esterified per atom of oxygen utilized.

The quantitative importance of the ATP synthesized at the expense of energy liberated during electron transfer in the mitochondrion is realized when one follows the conservation of energy during the metabolism of a molecule, such as glucose in the cell. The oxidation of one mole of glucose to carbon dioxide and water is accompanied by the release of 673,000 calories. In order to degrade the glucose molecule to a form that can be metabolized further by mitochondrial enzymes, the glycolytic enzymes consume two molecules at ATP and also synthesize two molecules of ATP in the presence of oxygen, a net energy conservation of zero. The mitochondrion may then degrade the pyruvate supplied by glycolysis to carbon dioxide and water, yielding a net total of 38 molecules of ATP, mostly at the level of the electron transfer process. Thirty-eight molecules of ATP per molecule of glucose results in between 260,000 and 380,000 calories conserved, between 39 and 56% of the total energy released in the complete oxidation of glucose, the remainder being released directly to heat. Inasmuch as the mitochondrion is approximately 50% effective in conserving energy from its major substrate, it is indeed an efficient machine.

PHOSPHORYLATION (Photosynthetic). Photosynthetic conversion of light energy into the potential energy of chemical bonds involves an electron transport chain, and the phosphorylation of ADP (adenosine diphosphate)

$$\text{ADP} + \text{P} \xrightarrow[\text{Chlorophyll}]{\text{Light}} \text{ATP}$$

as intermediate stages. The process of phosphorylation defined by the foregoing equation was discovered simultaneously by Arnon and coworkers for green plant chloroplasts and by Frenkel, working with Geller and Lipmann, for bacteria in 1954. For both systems, the heart of the mechanism is the creation of a very oxidizing and a very reducing

component, utilizing the energy of the photoexcited stage of one of the pigment (chlorophyll) molecules. This process will be designated a photoact. The redox components are both members of a photosynthetic electron transport chain, bound to the membranes of the chloroplasts (for green plants) or chromatophores (for bacteria). The photoact can be considered as electron transport against the thermochemical gradient, i.e., away from the member which is a better electron acceptor (high oxidation-reduction potential), through the excited chlorophyll, then to the member which is a better electron donor (low oxidation-reduction potential). Subsequent steps consist of ordinary, dark electron transport with the thermochemical gradient. The energy in at least one of these redox reactions is conserved as ATP by a phosphorylation reaction analogous to that found in oxidative phosphorylation by mitochondria. See also **Phosphorylation (Oxidative)**.

In bacteria, the photoact proper is accomplished by a special kind of bacteriochlorophyll, amounting to only 3% of the total present. It is unique in having a peak in absorption at 870–890 micrometers, or further into the infrared than the remaining 97% of the chlorophyll molecules. It is unique not by virtue of a difference in structure, but because of its environment—most probably in close association or complexing with cytochrome molecules. Since its absorption extends to longer wavelengths, it is an energy trap, and the function of the bulk of the bacterio-chlorophyll is that of capturing light and transmitting it to this active center.

Components of the electron transport chain in bacteria have been shown to include *b*- and *c*-type cytochromes, ubiquinone (fat-soluble substitute quinone, also found in mitochondria), ferredox (an enzyme containing nonheme iron, bound to sulfide, and having the lowest potential of any known electron-carrying enzyme) and one or more flavin enzymes. Of these a cytochrome (in some bacteria, with absorption maximum at 423.5 micrometers, probably c_2) has been shown to be closely associated with the initial photoact. Some investigators were able to demonstrate, in chromatium, the oxidation of the cytochrome at liquid nitrogen temperatures, due to illumination of the chlorophyll. At the very least this implies that the two are bound very closely and no collisions are needed for electron transfers to occur.

In both bacterial chromatophores and green plant chloroplasts, the existence of photo-induced high-energy intermediates or states leads to reversible confirmational changes in the structures of the membranes, and to gross swelling and shrinking. These are observed by changes in light scattering, viscosity, and sedimentation properties, and by electron microscope studies. The mechanisms may include ion transport, followed by water diffusion, internal pH changes leading to conformation changes of proteins, or possibly something resembling a contractile protein.

PHOTOCHEMISTRY AND PHOTOLYSIS. When certain substances are subjected to light, a chemical change results. Such reactions comprise *photochemistry*. The production of an image on a photographic plate is an example. Photosynthesis in the green leaf of a plant is another. Where the change involves chemical decomposition of the radiated material, the process is termed *photolysis*. As used in this context, the term light includes both visible light and ultraviolet radiation. One of the better known and most extensive examples of photolysis is the production of ozone, O_3, in the upper atmosphere, a reaction critical to life on earth because ozone acts as a filter of the middle- and far-ultraviolet radiations which destroy living organisms. The oxygen molecule, O_2, absorbs solar ultraviolet radiation with a wavelength of 190 nanometers, and the energy absorbed breaks the molecule to the atomic state. The released oxygen atoms may combine with oxygen molecules present to form ozone, or the freed oxygen atoms may recombine to form O_2. Thus, there is a continuing combination of processes in dynamic equilibrium, that is, the synthesis and the photolysis of ozone.

Similarly, oceanic nitrite (NO_2^-) photolysis by natural light produces detectable concentrations of nitric oxide (NO). This latter forms in the oceans during daylight and disappears rapidly at sunset when recombination occurs: $NO_2 \longrightarrow NO + O \longrightarrow NO_2$.

Isomerism can also be induced photochemically, although such processes are less well understood and probably require the presence of additional free radicals. The cytotoxic metabolite bilirubin can cause brain damage in infants with neonatal jaundice; this is prevented by exposing the child to intense blue light. The bilirubin is photochemically converted in the skin to metastable geometric isomers, which can be transported in the blood and excreted in bile.

Two major instances of photochemical reactions that have reached deeply into modern civilization are the photosensitive silver and uranium salts and dyes which are the basis of photography and the manufacture of Vitamin D by the ultraviolet irradiation of ergosterol.

Photochemical reactions are highly specific and their products are quite different from those of thermochemical reaction processes.

Sunlight in the near infrared, visible, and near ultraviolet regions possesses considerable energy; utilization of this through photochemical reactions could make a considerable contribution to energy resources. Since biosynthesis itself is relatively inefficient in conversion of solar energy, emphasis has been placed upon the fabrication of *artificial* photochemical systems. One of the more promising approaches has involved application of photoelectric chemical cells or catalysts of semiconductor materials.

The absorption of light by semiconductors creates electron-hole pairs (e^-h^+) which can be separated because their components diffuse in different directions. The energies of these moieties can be stored by several mechanisms or used in photocatalysis or photosynthesis for nitrogen fixation, formation of amino acids, methanol, etc. The efficiencies of such conversions depend almost entirely upon the semiconductor material, and as yet these efficiencies are too low for significant application. Currently the most promise is demonstrated by the use of titania on a platinum substrate or single crystals of strontium titanate. See also **Photoelectric Effect**.

Fundamental Considerations. In photochemical reactions, light supplies the energy necessary for the activation of the reacting molecules (Grotthus, 1818, and Draper, 1839). Sometimes the light waves absorbed by a body produce only an increase in temperature, sometimes fluorescence as in the cases of eosin and fluorescein, and sometimes chemical change. The reaction of hydrogen and chlorine in light was studied by Bunsen and Roscoe (1862), and they discovered that the amount of chemical change is proportional to the intensity of the light and to the length of time of exposure to the light. The first law of photochemistry (Draper-Grotthus) states that light that is absorbed causes chemical change. The energy of light is measured in quanta, and according to the Stark-Einstein law,

$$E = Nhc/\lambda$$

where N is Avogadro's constant, h is Planck's constant, c is velocity of light, λ is wavelength of light; that is, each molecule that takes part in a chemical reaction induced by exposure to light absorbs one quantum of radiation causing the reaction. Photochemical processes are of two kinds: primary and secondary. The primary process in a photochemical reaction is limited by the Einstein law to the absorption of one quantum by a molecule or atom. A knowledge of the spectrum of the reactants is necessary to determine what happens in this process. The molecule may be disrupted into fragments or an electron may be excited from a lower orbit to a higher one. Which of these events takes place can often be determined by spectroscopic studies. The secondary process deals with the fate of the molecular fragments or of the excited molecules. The excited molecule may emit its extra energy as light, causing fluorescence; it may lose it by transferring it to other molecules as thermal energy; or it may cause a chemical reaction. On the other hand, the molecular fragments may either recombine to give the original reactant or cause further chemical reactions. The study of the quantum yield (which is the number of molecules reacting divided by the number of quanta absorbed), is used as a means of formulating the secondary processes. If the quantum yield is less than one, fluorescence, deactivation or recombination of fragments must take place. If the quantum yield is unity every photon absorbed decomposes one molecule. When the quantum yield is greater than unity (and in some reactions it may be as high as a million) chain reactions are involved. The classical example of such a reaction is the combination of hydrogen and chlorine. The primary reaction is Cl_2 and light $\longrightarrow$ 2Cl. The chain propagation reactions are

$$Cl_2 + h\nu \longrightarrow 2Cl$$

$$Cl + H_2 \longrightarrow HCl + H$$

$$H + Cl_2 \longrightarrow HCl + Cl$$

creating a cycle which is only stopped by

$$Cl + Cl \longrightarrow Cl_2$$

$$H + H \longrightarrow H_2$$

Since the last two processes are slow compared to the two before them, one quantum of light can bring about a combination of a million molecules of hydrogen and chlorine.

See also **Photosynthesis**.

The existence of microbes capable of utilizing light energy to drive the synthesis of cellular components was firmly established by Winogradsky and Molisch by the late 19th century, but it was largely through the work of Van Neil in the 1930s on the physiology of the purple sulfur bacteria that a clearer picture of their photosynthetic processes started to emerge. The photochemical reaction center (RC) is a now well-defined physical entity which exists as an energy sink able to convert the energy of excitation into an electron transfer event. From the use of this RC, three broad patterns of microbiological photosynthesis are known. See Table 1.

The chlorophylls are the pigments responsible for initiating primary photochemistry in the cyanobacteria and higher plants and absorb light energy at 870 nm converting appropriate species to the single excited state and rapidly transferring an electron to a single molecule. Chlorophyll is remarkably similar to hemoglobin in that iron is replaced by magnesium as the chelated metal. Any other transition metals in that position would cause quenching of the initial photochemical reaction.

The carotenoids are largely responsible for the color of the green and purple bacteria and function in both light absorption and energy transfer processes as well as extending the usable light wavelengths and protecting against harmful photooxidation.

In green and purple photosynthetic bacteria, most of the bulk bacterial chlorophyll is inactive in photochemistry and does not undergo photooxidation when excited. Energy is transferred randomly between adjacent pigment molecules until trapped by the RC or lost as fluorescence or heat.

But the photochemistry of bacterial activity must also be associated with photoeffects in the surrounding media, and in this context a rapid increase in the concentration of hydrogen peroxide has been observed when natural surface and ground waters are exposed to sunlight. The hydrogen peroxide is photochemically generated from organic constituents present in the water. Humic materials are believed to photochemically reduce oxygen to give the superoxide anion, which subsequently disproportionates to hydrogen peroxide. Since both hydrogen peroxide and peroxide radical are known to affect biological systems, they may be important factors in the photochemical reactions of photosensitive bacteria and other natural life forms.

Laser Chemistry

Lasers generate a high-intensity output of monochromatic photon energy, and studies of the photochemical reactions induced by this have created a virtual subdivision of photochemistry known as "laser chemistry." While the output of a laser can heat, anneal, burn, cut, or be used instrumentally as a spectral source, we are concerned here only with those chemical effects attributable to the photon output at wavelengths between near infrared and near ultraviolet, i.e., between about 12 and 0.2 microns.

When atoms or molecules are excited conventionally by elevated temperatures or pressure, they can follow several reaction paths yielding a variety of byproducts in addition to the desired substance. Since the basis of a chemical reaction is to weaken or break or make specific chemical bonds to yield the final product, energy ideally should be selectively introduced at the particular level necessary to accomplish this. The high energy and monochromaticity of laser output are ideal for imposition of the specific energy changes that induce or catalyze chemical changes.

The absorption of a quantum of energy by an atom or a molecule takes it from a low energy state to a higher one, and the jump will affect the different properties of the atom or molecule depending upon the amount of energy in the quantum. When absorbed, a quantum of visible or ultraviolet radiation raises an electron to a higher orbit; on the other hand, a quantum of infrared radiation will alter energy levels on an atomic basis.

A laser can supply a precise amount of energy to an atom or molecule, thus effecting a transition from one excited state to a higher excited one. Once known of the energy level displacement required to effect a chemical reaction is available, the laser can provide the specific energy for the specific excitation required. However, the energy input must be related to the total energy dissipation, for, if excess energy leads to ionization or dissociation, a continuum of allowed energy levels will be developed rather than the required discrete levels. If the energy is thus fragmented, the required reaction will proceed only weakly, if at all. Excess energy may be redistributed in two ways. It is either transferred from the excited vibrational state to one or more other vibrational states of the molecule, or it is transferred directly into rotational and translational states. The first mode of energy translation proceeds appreciably more rapidly than the second. Time is a further controlling factor in laser chemistry. The reaction must proceed in time either shorter than, or equal to, that required for transfer of vibrational energy from one state to another in the same molecule; molecule dissociation or atom ionization must take place before there is any depletion of energy by molecular or atomic collisions. Where a reaction proceeds within the lengthy period required for transfer of energy from the initial vibrational state to the much lower rotational and translational states, one cannot hope for laser action to effect a significant degree of reaction specificity, since the effect is basically a thermal one.

A goal of early laser-induced photochemistry was the initiation of specific chemical reactions, to fabricate specific chemicals, or to separate isotopes. Although the specificity of laser-induced photochemistry is important, equally significant is the ability of the laser to confine excited regions to microscopic areas. Thus, one of the better known capabilities of the laser beam is that even a low-powered laser can produce highly intense spots of light of submicrometer dimensions.

In many photochemical reactions, a specific excitation wavelength leads to a specific set of molecular fragments and ultimately products. This has enabled the dissociation of a large variety of molecular gases which can then deposit on, dope, or etch a semiconductor wafer. Further, laser excitation can photodeposit metals, insulators, and semiconductors by decomposing one or more photosensitive gases. Direct writing with lasers through such reactions as:

$$CF_3Br \xrightarrow{hv} CF_3 + Br; \text{or } Al(CH_3)_3 \xrightarrow{hv} Al + 3\ CH_3$$

is just beginning to be applied to the fabrication of complete microelectronic devices and the modification of actual circuits.

Operation of visible-light and ultraviolet lasers costs more per photon produced than does infrared laser operation. Partly because of this, appreciable interest has centered over the past several years on unimolecular reactions driven by infrared lasers. But absorption of a single infrared photon will raise a molecule only one step in the energy ladder, and, to be dissociated, the molecule will require the absorption of many infrared photons in sequence. The carbon dioxide laser can supply this requirement cheaply and efficiently. A mole of photons (6.02×10^{23}) costs only a few cents in the infrared, but several dollars in the visible and near ultraviolet ranges. This has aided continued study of multiple-photon infrared laser excitation. Much study has gone into an exciting and fundamental reaction and its implication. When sulfur hexafluoride (SF_6) is irradiated by infrared laser light, it decomposes to the pentafluoride (SF_5) and fluorine (F). When the laser is tuned to the vibrational absorption of $^{32}SF_6$ in a mixture with $^{34}SF_6$, only the $^{32}SF_6$ decomposes, leaving the residual gas enriched some 3000-fold in $^{34}SF_6$. Changing the frequency of the irradiating light slightly from emission at 10.61 μ to emission at 10.82 μ selectively decomposes the $^{34}SF_6$ molecule. This method of isotope separation by lasers is being extensively studied for the separation of fissionable U^{235} from nonfissionable U^{238}.

Laser-induced processes are expected to increase in number and expand in application, but the principal obstacle to large-scale introduction of the

TABLE 1. BROAD PATTERNS OF MICROBIOLOGICAL PHOTOSYNTHESIS*

Bacterial group	Type of photosynthesis	Pigment in primary photoactivation	Electron donors	Products	Carbon sources

(* *After Keely and Dow.*)

laser into the chemical industry is an economic one. Laser photos are still much more expensive than those from thermal sources, and the initial application will undoubtedly be directed to those specialty chemicals and isotopes whose current cost far exceeds that of large volume chemicals.

A typical example of this is in the preparation of extraordinary divalent carbon intermediates (carbenes) by application of ultrafast laser techniques. Thus, photoexcitement of diphenyldiazomethane (DPDM) to an excited singlet state breaks the $C{=}N_2$ bond, releasing diphenylcarbene (DPC) in a singlet state and ultimately allows its stabilization in the triplet ground state.

The increasing number of known photochemical reactions is still very small in comparison with those in ground state chemistry, and our understanding of all the factors controlling photochemical reactions is quite primitive. In some cases it is the ease of conversion to the ground state that is significant, while in others it is the energy hypersurface surrounding the excited state that dictates the energy pathways through which the free electrons will move back toward the ground state, and hence the nature of the photochemical products.

Laser Femtochemistry

As explained by A. H. Zewail (California Institute of Technology), "Femtochemistry is concerned with the very act of the molecular motion that brings about chemistry, chemical bond breaking, or bond formation on the femtosecond (10^{-15} second) time scale. With lasers it is possible to record snapshots of chemical reactions with sub-angstrom resolution. This strobing of the transition-state region between reagents and products provides real time observations that are fundamental to understanding the dynamics of the chemical bond."

A longstanding problem in chemistry has been the development of a better understanding of the transition state between reagents and products. Several investigative approaches, including thermodynamics, kinetics, and synthesis, have been used to systematize masses of experimental data to ascertain the rates and mechanisms of reactions. Over the past few decades, advanced understanding of molecular reactions have stemmed from the use of molecular beams, chemiluminescence, and, more recently, laser techniques. In laser-molecular beam research, a laser is used (1) to excite one of the reagent molecules, thus influencing reaction probability, or (2) to initiate a unimolecular process simply by providing energy to a molecule. In what has been called a "half-collision" unimolecular process, the fragmentation of the excited molecule can be determined. As pointed out by Zewail, "During the last three decades many reactions have been studied and these methods, with the help of theory, have become the main source of information for deducing the nature of the potential surface of a reaction."

Unimolecular reactions, as typified by

$$ABC^* \longrightarrow [A \cdot BC]^{\ddagger *} \longrightarrow A + BC,$$

and bimolecular reactions, as shown by

$$A + B \longrightarrow [ABC]^{\ddagger} \longrightarrow AB + C,$$

have been studied in terms of their *time scale*.

In an excellent paper, commenting on the progress made from the "picosecond" era to the "femto-second" era of research, Zewail observes, "Prior to femtochemistry, molecular beams and picosecond lasers were combined, which led to studies of collision-free energy redistribution in molecules and state-to-state rates of reaction, but the time resolution was still not sufficient to directly view the process of bond breaking or bond formation. However, in femtochemistry, the 'shutter speed' has reached the 10^{-15} regime, so it is now possible to observe chemistry as it happens—the transition-state region between reagents and products. ··· The strobing of these ultrafast molecular reactions, stemming from the happy marriage between ultrafast lasers and chemistry, is what forms the central theme in real time femtochemistry."

In an extension of this technology, A. S. Moffat reported in 1992 two additional goals of development: (1) the use of lasers to *control* chemical reactions, and (2) development of "tunable" lasers that can vary the wavelength of the light they generate. Thus, the light source can be tailored exactly to the vibrational frequency of the bond targeted.

Time-Resolved Photoacoustic Calorimetry

As defined by K. S. Peters and G. J. Snyder (University of Colorado), time-resolved photoacoustic calorimetry is an experimental technique

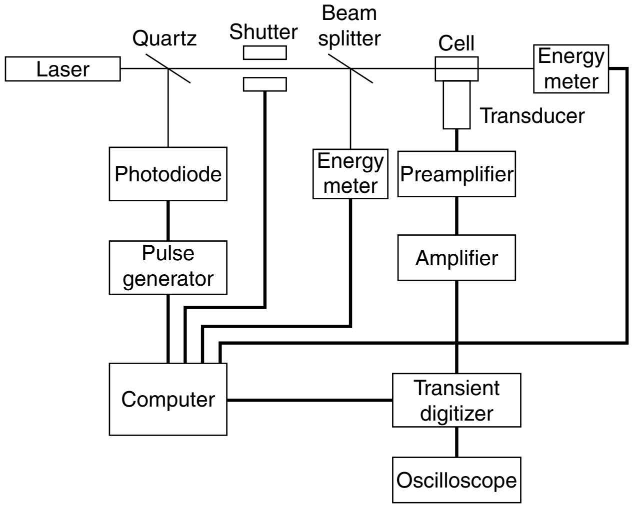

Fig. 1. Schematic representation of the time-resolved photoacoustic calorimeter. Solid lines indicate light path; heavy solid lines represent signal paths. (*After Peters and Snyder*)

that measures the dynamics of enthalpy changes on the time scale of nanoseconds to microseconds for reactions initiated by absorption of light. As pointed out, "When the reaction is carried out in water, it is also possible to obtain the dynamics of the corresponding volume changes. This method has been applied to a variety of biochemical, organic, and organometallic reactions."

Although pulsed time-resolved photoacoustic calorimetry is in an early phase of development (1994), it is proving to be a powerful technique for understanding the dynamics of enthalpy and volume changes for ground- and excited-state species. Peters and Snyder, developers of the technique, observe, "For reactions in water, the problem is directly approached through temperature-dependent studies. For reactions in organic solvent, there must be further investigations into the magnitude of the effect. At some future date, time-resolved photoacoustic calorimetry will be extended onto the 1 ns time scale .... The technique should find wide ranging applications to problems in chemistry and biochemistry that include solid-state reactions and dynamics of proteins in membranes."

A schematic representation of the instrumental technique used is shown in Fig. 1.

PHOTOELECTRIC CONSTANT. A quantity equal to h/e where h is the Planck constant, and e, the electronic charge, and which multiplied by the frequency of any radiation exciting photoemission gives the potential difference corresponding to the quantum energy absorbed by the escaping photoelectron.

$$h/e = 4.1349 \times 10^{-7}\text{erg} \cdot \text{sec} \cdot \text{emu}^{-1}$$
$$= 1.3793 \times 10^{-17}\text{erg} \cdot \text{sec} \cdot \text{esu}^{-1}$$

PHOTOELECTRIC EFFECT. Changes in electrical characteristics of substances due to radiation, generally in the form of light. Radiation of sufficiently high frequency (short wavelength), impinging on certain substances, particularly, but not exclusively, metals, causes bound electrons to be given off with a maximum velocity proportional to the frequency of the radiation, i.e., to the entire energy of the photon. The Einstein photoelectric law, first verified by Millikan, states:

$$E_k = hv - \omega$$

where E_k is the maximum kinetic energy of an emitted electron, h is the Planck constant, v is the frequency of the radiation (frequency associated with the absorbed photon), and ω is the energy necessary to remove the electron from the system, i.e., the photoelectric work function for the surface of the emitting substance. An inverse photoelectric effect results from the transfer of energy from electrons to radiation. For example, in an x-ray tube, there is observed the transfer of energy from electrons accelerated by the anode voltage to radiation emitted by the target. This radiation exhibits a continuous spectrum at lower voltages, upon which are superimposed, at higher voltages, intense lines characteristic of the anode material.

Two principal aspects of the photoelectric effect are described here: (1) Photoconductivity; and (2) photovoltage.

Photoconductivity is the phenomenon evidenced by the increase in electrical conductivity of a material by the absorption of light or other electromagnetic radiation. Although insulating or semiconducting materials exhibit this effect to some degree, there are relatively few materials that give sufficiently large changes of conductivity with illumination for application of the principle in useful devices. The principle can be explained briefly by using a cadmium sulfide photoconductor as an example. As in the case of luminescence, the band-type of energy level diagram is useful. See Fig. 1. Transition 1 represents absorption of a photon of energy at least equal to that of the band gap, giving rise to a free electron and a free hole. Transition 2 represents absorption at a local crystalline imperfection (defect or impurity), also producing a free electron, but with a hole trapped in the vicinity of the imperfection. While these carriers are "free" in the crystal, the conductivity can be greatly enhanced, so that the conductivity in the light can be a million times that in the dark. Recombination of the carriers may occur via transition (3), which is a "direct" electron-hole recombination across the band-gap, or via step 4, an electron recombining with a center containing a hole, so that they no longer contribute to the conductivity.

For a material in which one type of carrier predominates (i.e., electrons), the change in conductivity with illumination can be given as:

$$\Delta\sigma = \Delta ne\mu + en\Delta\mu \tag{1}$$

where $\Delta\sigma$ = conductivity change, Δn is the change in free carrier density, e is the electronic charge, μ is the carrier mobility, and $\Delta\mu$ is the change in carrier mobility. Usually, the first term in Equation (1) predominates.

Photoconductivity gain, G, may be defined as the number of interelectrode transits that can be made by an electron until the photogenerated hole is eliminated by recombination. For the case treated here, namely where one type of carrier predominates, the gain, G, can be stated as:

$$G = \tau\mu^{VL-2} \tag{2}$$

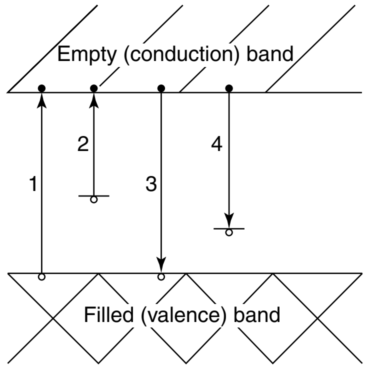

Fig. 1. Simplified band model for photoconduction processes

where τ is the carrier lifetime, μ is the mobility, V is the applied voltage, and L is the spacing between electrodes. Since the specific sensitivity, S, varies as the product of carrier lifetime and mobility, $S\alpha\mu\tau$, we can state that

$$G\alpha(VL^{-2}S) \tag{3}$$

Commercially, photoconductive devices are used as (1) Detectors of radiation; (2) switches which are sensitive to light and which can actuate relays; and (3) in combination with other photoelectronic materials, such as electroluminescent materials, as image intensifiers. Germanium and silicon devices of the $p - n$ junction phototransistor type have long been used in computer detectors; lead sulfide has been used in photocells for infrared detection; cadmium sulfide or cadmium selenide have been used in photocells for detection of light in the visible range; zinc oxide and selenium devices have been used in photocopying machines; antimony sulfide has been used in television pickup tubes. There are numerous other applications.

Photovoltage or the *photovoltaic effect* may be defined as the conversion of light photons to electrical voltage by a material. Becquerel, in 1839, was the first to discover that a photovoltage was developed when light was shining on an electrode in an electrolyte solution. Nearly half a century elapsed before this effect was observed in a solid, namely, selenium. Again, many years passed before successful devices, such as the photoelectric exposure meter, were developed. Radiation is absorbed in the neighborhood of a potential barrier, usually a *p-n* junction, or a metal-semiconductor contact, giving rise to separated electron-hole pairs, which create a potential. An equivalent circuit for a photovoltaic cell is shown in Fig. 2, where R_{SH} and R_S are the internal shunting and series impedances; I_J is the junction current; R_L is the load resistance; I_S is a constant-current generator; and V_L and I_L are the voltage and current developed across the load. With R_L optimum, the maximum conversion efficiency, $\eta_{\max;}$ can be given by:

$$\eta_{\max} = \frac{100\ V_{mp}I_{mp}}{P_{in}}$$

in which case, V_{mp} and I_{mp} are the voltage and current across R_L, and P_{in} is the radiant input power.

Photovoltaic cells have found numerous applications in electronic and aerospace applications, notably in satellites (solar cells) for instrument power. See also **Solar Energy**. Materials used, in order of decreasing theoretical efficiency, include gallium arsenide (24%); indium phosphide (23%); cadmium telluride (21%); silicon (20%); gallium phosphide (17%); and cadmium sulfide (16%). See Fig. 3. In the past, disadvantages of photovoltaic cells have included: (1) high susceptibility to radiation damage; (2) high cost; and (3) requirement for auxiliary battery power

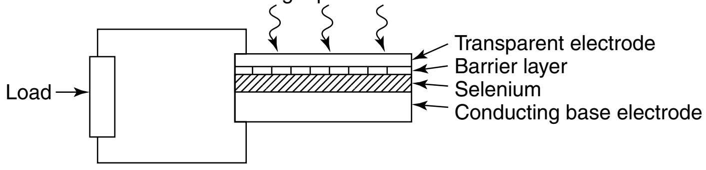

Fig. 2. Diagram of photovoltaic cell

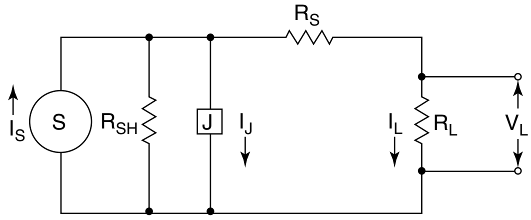

Fig. 3. Photovoltaic cell equivalent circuit

when a source of radiation for the cells is not available. Intensive research is underway in the mid-1970s to improve the production of known materials, i.e., upping the practical efficiency to approach the theoretical efficiency—as well as decreasing production costs; and to find new materials and combinations. Such findings are extremely important to certain of the proposed approaches for utilizing solar energy on a large scale. Much of this research is currently of a proprietary nature. The scope of the problem can be visualized from published Figures giving ranges of 0.2 to 0.5 volts per cell with current output of a cell with an area of two square centimeters amounting to only about 0.05 ampere. Consequently, without significant materials and efficiency improvements, extremely large numbers of cells are needed for any large-scale, practical solar energy application. Also, for maximum utility, a means must be found to orient the cells wherever possible so that the incident light will be perpendicular to the face of the cells.

See also **Photoemission and Photomultipliers**; **Photometers**; **Photon and Photonics**; and **Photovoltaic Cells**.

PHOTOEMISSION AND PHOTOMULTIPLIERS. Photoemission is the ejection of electrons from a substance as a result of radiation falling on it. Photomultipliers make use of the phenomena of photoemission and secondary-electron emission in order to detect very low light levels. The electrons released from the photocathode by incident light are accelerated and focused onto a secondary-emission surface (called a dynode). Several electrons are emitted from the dynode for each incident primary electron. These secondary electrons are then directed onto a second dynode where more electrons are released. The whole process is repeated a number of times depending upon the number of dynodes used. In this manner, it is possible to amplify the initial photocurrent by a factor of 10^8 or more in practical photomultipliers. Thus, the photomultiplier is a very sensitive detector of light.

The major characteristics of the photomultiplier with which the user is generally most concerned include: (1) sensitivity, spectral response, and thermal emission of photocathodes; (2) amplification factor; and (3) noise characteristics and the signal-to-noise ratio.

Many different types of photocathodes are used in photomultipliers. With a selection of various cathodes, it is possible to cover the range of response from the soft x-ray region (approximately 5 to 500 Å) to the near infrared (approximately 12,000 Å). Materials and combinations used include cesium-oxygen-silver; cesium-antimony; cesium-antimony-bismuth; sodium-potassium antimony; sodium-potassium-cesium-antimony; copper-iodine; and cesium-iodine. The thermal emission at 25°C of copper iodide and cesium iodide tends to run less than the other materials.

The amplification factor in a photomultiplier depends upon the secondary emission characteristics of the dynode and to some extent on the design of the multiplier structure. Important secondary-emission surfaces used in commercial photomultipliers are of two types: (1) alkali metal compounds, e.g., cesium-antimony; and (2) metal oxide layers, e.g., magnesium oxide on silver-magnesium alloy. The alkali metal compounds have higher gain at low primary electron energy (of the order of 75 volts). The metal oxide layers show less fatigue at high current density of emission (i.e., at several microamperes per square centimeter or higher).

The multiplier structures may be divided into two main types: (1) dynamic; and (2) static. The dynamic multiplier in its simplest form consists of two parallel dynode surfaces with an alternating electric field applied between them. Electrons leaving one surface at the proper phase of the applied field are accelerated to the other surface where they knock out secondary electrons. These electrons, in turn, are accelerated back to the first plate when the field reverses, creating still more secondary electrons. Eventually, the secondary electrons are collected by an anode placed in the tube; if they are not, a self-maintained discharge occurs. In practice, dynamic multipliers have been replaced by static ones mainly because the latter have better stability and are easier to operate.

Static multipliers may be either magnetically or electrostatically focused. In a magnetic type, primary electrons impinging on one side of a dynode cause the emission of secondary electrons from the opposite side. These electrons are then focused onto the next dynode by means of the axial magnetic field. The more common types of electrostatic multiplier structures use focusing from one stage to the next. Deposition of thin semiconductor secondary emission surfaces onto insulating substrates has been used in designing rugged miniature multiplier structures. In unfocused electrostatic structures, there is less sensitivity to stray electric and magnetic fields.

Dark noise in photomultipliers is caused by: (1) leakage current across insulating supports; (2) field emission from electrodes; (3) thermal emission from the photocathode and dynodes; (4) positive ion feedback to the photocathode; and (5) fluorescence from dynodes and insulator supports. Careful design can eliminate all but item (3). Associated with the photocurrent from the photocathode is shot noise. There is also shot noise from secondary emission in the multiplier structure.

A major use for photomultipliers has been in the scintillation counter where in combination with a fluorescent material, it is used to detect nuclear radiation. They also have been used in star and planet tracking for guidance systems as well as in star photometry and quantitative measurements of soft x-rays in outer space. Additional uses include facsimile transmission, spectral analysis, process control, and wherever extremely low-light levels must be detected. For applications in photometers, see also **Photometers**.

PHOTOGRAPHIC CHEMISTRY. In photographic films and papers the sensitive surface usually consists of microscopic grains of a silver halide, suspended in gelatin. Exposure to light renders the halide particles susceptible to reduction to metallic silver by developing agents containing a reducing agent, as well as an accelerator, preservative, and restrainer. The accelerator increases the activity of the reducing agent (due principally to ionization of the phenolic agents to their active form) and is usually an alkaline compound. The preservative, usually sodium sulfite, minimizes air oxidation. The restrainer helps to prevent "fog" (reduction of silver halide gains that have not been exposed to light) and is almost always potassium bromide.

Color sensitizers are dyes added to silver halide emulsions to broaden their response to various wavelengths. Unsensitized emulsions are most responsive in the blue region of the spectrum and thus do not correctly represent the light spectrum striking them. Widely used sensitizers include the cyanine dyes, the merocyanines, the benzooxazoles, and the benzothiazoles. Cryptocyanine sensitizes the extreme red and infrared.

In color photography diethyl-p-phenylenediamine is an important developer because its oxidation product readily couples with a large number of phenol and reactive methylene compounds to form indophenol and indoaniline dyes, which are the basis of most of the current color processes.

See also **Holography**; and **Photography and Imagery**.

PHOTOGRAPHIC GRADE. A chemical in which impurities known to be photographically harmful are limited to safe levels and inert impurities are restricted to levels that will not reduce the required assay strength.

PHOTOGRAPHY AND IMAGERY. The unique light-sensing properties of silver halide crystals have been recognized since the 1500s. In spite of many technical advances in nonsilver halide (e.g., electronic) technologies, chemically based silver halide systems continue to dominate in the ability to record images of superb image quality and archival characteristics. Photochemical reduction in which the silver ion, Ag+, in the ionic silver halide crystal is reduced to elemental silver, Ag0 was first observed by the alchemist Fabricius in 1556. As photochemical reduction continues, elemental silver atoms aggregate and grow into clusters of a colloidal size sufficient to scatter light and produce hue shifts. The science of photography uses this photochemical property of silver halide to form images and record scenes. One of the earliest researchers to produce such a photochemical image was Schultze in 1727.

Imagery is the representation (pictorial, graphical, etc.) of a subject by sensing quantitatively the patterns of electromagnetic radiation emitted by, reflected from, or transmitted through a subject of interest (object, body, scene, etc.). Imagery is not wavelength-limited, but is achievable

(theoretically if not practically) with all bands of the electromagnetic spectrum—gamma rays, x-rays, ultraviolet radiation, visible light, infrared radiation, radar and radio waves.

Chemical imagery or *traditional photography*, as initially conceived and as commonly practiced, depends upon visible light and uses an optical light-gathering and focusing system (camera) and a light-sensitive medium (film emulsion) to record (store) the image—a *photo-image*. The subsequent availability of infrared, ultraviolet, and x-ray sensitive films extended the capabilities of traditional photography well beyond its dependence upon visible light. The word *photography* derives from the Greek roots *photos* (light) and *graphos* (to draw). Coining of the term is usually attributed to Herschel, although this has not been proved conclusively. Herschel did use the term in a memo dated January 17, 1839 and in a technical paper given on March 14, 1839.

Electronic Imagery, instead of using chemical means (emulsions), takes advantage of the sensitivity of various electronic detectors to different bands of the electromagnetic spectrum. The energy received is transduced by these sensors into an electronic or electrical effect (change of resistance, current, emf, the emission of electrons, etc.), from which effects an option of ways to process and display the information is available. The most common form of electronic imagery is found in television. Image orthicons, vidicons, and the more recent TV cameras using charge-coupled devices are among recent developments in electronic imagery.

Electronic imagery is particularly attractive for situations where image information must be transmitted over long distances where digitized signals offer greater accuracy and reliability—and where the incoming information is immediately compatible with digital data processing and computing equipment. Electronic imagery also has made certain imaging tasks possible, such as radar imaging, where traditional photographic means do not suffice.

While techniques are available in traditional photography to enhance raw information, these methods are largely of a qualitative, aesthetic nature rather than of a quantitative, scientific nature. In handling tiny pixels (one of the dots or resolution elements making up a digitized picture) of information, it becomes possible to computer program the processing of image information as it is received or after it is retrieved from tape or other electronic storage medium. The pixels can be measured one at a time at a rapid rate for brightness, sense (detection of obviously bad information), and other quantities, and over a wide scale of selections (for example, black = 0; medium gray = 32; white = 63) so that groupings of input information can be made to provide better contrasts (in pattern and blackness or color) when the information is all regrouped and reassembled for display. Accomplishments of this nature are probably best exemplified by the image intensification and color enhancement of pictures returned to earth from various space explorations. This is discussed further in this entry, but also see entries on specific planets.

With the flexibility of modern data processing and computing equipment, a vast array of programming techniques can be applied to the handling of pixels similar to the handling of any other kind of information. Also, with electronic imagery, a full reconstitution of a scene need not always be a primary objective. For example, as color may be related to chemical composition (discussed later) an astrochemist may call for the proportion of certain "colored" pixels in an entire scene or part of a scene and thus make at least a preliminary judgment as to the composition of rocks or soil in a scene without having to see the entire scene reconstituted.

Whereas the final results of traditional photography are usually in the form of prints or transparencies (with attendant problems), electronic imagery can be projected at will on cathode ray tubes and, if desired, combined with computer graphics—or conventional photos can be made from digitized information.

Early History of Photography. The concept of a camera obscura (dark chamber) was first described by Giovanni Battista Porta in 1558 when he put a lens in a hole in the shutter of an otherwise fully darkened room. His objective was to drawn an image of the outside by means of tracing a pattern projected by the lens onto the screen rather than attempting to draw the scene simply by looking at it. Because there was a great desire to capture scenes and subjects on paper, canvas, and other media, but a scarcity of artistic and drawing abilities among many of the populace, the principle of the camera obscura persisted for some 250 years, with improvements and refinements of the optical system used.

During the sixteenth and seventeenth century, it became known to technically curious persons that a number of substances would change color when exposed to light. These observations provided the first hint that perhaps an image could be captured permanently and thus save a lot of time and labor and also provide a means of relatively quickly producing duplicates of any given subject. There were two main problems: (1) finding a suitable medium that would respond within a reasonably short time span to the projected image; and (2) finding some way to hold or fix an image without permitting the medium to follow a full course of development and thus completely obliterate the captured image. The properties of silver salts were discovered in 1725 by Johann Heinrich Schulze at the University of Altdorf. He found that chalk, when moistened with a solution of nitric acid and silver nitrate, became darker upon exposure to light. Early experiments involved contacting objects with the silver medium to produce silhouettes. The first image obtained through use of a camera-like technique was achieved in France by Joseph NicÉphore Niepce. His first success came in 1813, using paper which he had soaked in sodium chloride, followed by immersion in a silver nitrate solution, upon which silver chloride was precipitated throughout the paper. The crude image obtained was a negative and persisted for only a short period because he had not developed a required fixative. Niepce then turned his efforts to an asphalt process, known as *heliogravure*, which he used for copying prints. The process was quite insensitive, but an image (exposure of about 8 hours in direct sunlight) of some buildings is regarded as the *first photograph*. This old photograph is now part of the Gernsheim collection in the United States.

Daguerreotype. The first practical process of photography was invented by Louis J.M. Daguerre of Paris in 1837, although the details of the process were not published until 1839. The process was used chiefly for portraiture and became obsolete within a few years after the introduction of the wet collodion process in 1851. Although the daguerreotype process was the original, modern photography is based on the negative-positive methods introduced the same year by William H. Fox-Talbot of England. This was known as the *calotype* process. In the daguerreotype process a light-sensitive layer of silver iodide is formed on a silver plate by contact with iodine. After exposure in the camera, a positive image is produced when the image is exposed to mercury and heated. The mercury, by attaching itself to the unexposed portions, forms a positive image. The silver iodide remaining was removed at first with a solution of sodium chloride (salt) which was soon replaced, however, with sodium thiosulfate (hypo), the properties of which had been discovered by Herschel in 1819. The daguerreotype image so produced is very weak. In 1840 Fizeau described a process of toning with gold which greatly increased the strength of the image and was generally adopted.

At first, from 5 to 10 minutes' exposure was required on open landscapes and street scenes. The invention of a fast, large-aperture portrait lens by Petzval in 1841 and the discovery by Goddard in London (1840) of the superior sensitivity of silver bromide reduced the time of exposure to a few seconds.

Problems were encountered in preparing positive prints from the calotype negatives because of reproduction of the grain of the paper that contained the negative. Attempts were made to wax or oil paper negatives, but these were essentially unsuccessful. De Saint-Victor attempted to coat plates with albumin (egg white). Upon hardening of the albumin, the plates were bathed in silver nitrate, causing precipitation of silver iodide within the film of albumin. This was not successful because the sensitivity of the plates was greatly lowered.

Early Emulsions. The use of collodion in photographic emulsions dates from 1851 when Frederick Scott Archer published details of his wet collodion process. Although this process is no longer in general use, it can be used in making the half-tone negatives required in photoengraving. In the collodion process, a clean glass plate is first coated with collodion containing potassium iodide and potassium bromide. It is next sensitized by immersion in a solution of silver nitrate. It is then placed in a plate holder—specially designed for the handling of the wet plate—and the exposure made. After exposure it is developed in a solution of ferrous sulfate and fixed in potassium cyanide, or in hypo, washed and dried. The wet collodion process, as it is used by the photoengraver, results in a negative of high density and extreme contrast, high resolution and with an extremely fine grain. These characteristics render wet collodion well adapted to the requirements of photoengraving. Much later, the wet collodion process was essentially replaced by the gelatino-bromide emulsions of similar characteristics.

Collodion printing-out paper was introduced by Obernetter of Munich in 1867 and was for many years the favorite printing process of the portrait

and professional photographer. It was in general use until the early years of the present century when it was gradually replaced by developing-out paper.

Gelatin Emulsions. Not true emulsions, but suspensions of minute silver halide crystals dispersed in a protective colloid medium (gelatin), the suggestion of replacing collodion with gelatin was first made by R.L. Maddox in 1871. The first plates made by Maddox were not very sensitive, but their advantages far outweighed their defects, leading to further developments by Charles Bennett in England in the late 1870s, and the first mass production attempts by George Eastman in 1880. One of the several contributions of Eastman to photography was his early recognition of making and marketing gelatin dry plates on a large scale, eliminating the need for the photographer to prepare his own plates, as well as the need for developing and fixing the plates immediately thereafter. There soon followed the concept of strip film, making it unnecessary to change plates after each exposure. Eastman avoided the grain problem by using a coating that enabled the stripping of the thin layer of gelatin from the paper support. Later, in 1889, he replaced the paper support with a transparent plastic support (nitrocellulose), thus making it possible to produce prints without the need of stripping the gelatin layer from the support. Eastman's goals were to make it easy for the masses of people to take photographs in a simplified manner and, through mass production, market equipment at a price within grasp of the public.

Gelatin is a preferred photographic colloid because the sensitizing bodies in the gelatin make possible emulsions with great sensitivity and speed. Gelatin is an excellent emulsifying agent and is readily transformed, from gel to a liquid or the reverse, by changes in temperature. The latter property makes coating of supports and emulsion processing and working feasible. The strong protective action of gelatin lowers the rate of reduction of unexposed silver halide crystals in developers so that image formation is readily obtained.

Silver halides employed in emulsions are the chloride, the bromide and the iodide. Negative emulsions are composed of silver bromide with a small amount of silver iodide. Positive emulsions for films and paper contain silver chloride, or mixtures of silver chloride and silver bromide in varying amounts, according to the tone, speed, and contrast desired.

In photomicrographs of negative emulsions, the crystals of silver bromide appear as flat triangular or hexagonal plates with rounded corners. Some globular, needle-shaped or diamond shaped crystals may also be observed, as in Fig. 1. The thickness of the flat plates is approximately one-tenth of their diameter. The size of silver bromide crystals range from less than one to four micrometers. Crystals of silver bromide, as used in positive emulsions, are quite uniform and seldom exceed 0.5 micrometer in diameter. Multi-layered emulsions contain approximately 1 billion (10^9) crystals per square centimeter for low-speed emulsions to 1.0×10^{-8} centimeter for high-speed negative emulsions.

The characteristics of an individual emulsion are primarily dependent on two factors, the size-frequency distribution of the crystals and the composition of the silver halide crystals. For instance, Fig. 2 illustrates silver bromide grains with slightly rounded corners due to the presence of a silver complexing agent. The chief problems of the emulsion-maker are the production of uniform suspensions of silver halide crystals with proper size-frequency distribution and the correct composition in gelatin, and the ability to reproduce results. In an attempt to meet these needs along with increased sharpness for high-speed negative color films, *Eastman Kodak* has developed T-Grain type emulsions of silver bromide which also contain some iodide. Illustrated in Fig. 3, these new emulsions exhibit flat grains with relatively sharper edges. As a result, when compared to traditional high-speed color negative films they are capable of producing more clearly defined images.

Classification of Emulsions

1. *Printing-out emulsions.* These emulsions produce images on exposure without development. They are used largely for making portrait proofs which are distinguished by their red or purplish color. Emulsions of this type differ from others in that they usually contain silver nitrate, some free silver, silver salt of an organic acid and a weak free acid. These are known as P.O.P. Proof Papers.

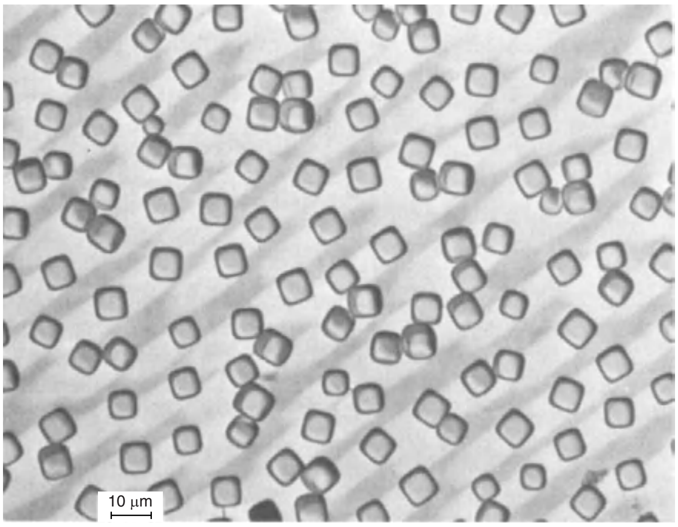

Fig. 2. Using the carbon replica technique, this is an electron micrograph of cubic silver bromide grains in which the corners have been slightly rounded due to the presence of a silver complexing agent. (*Photo by Dr. Donald L. Black, Eastman Kodak Company*)

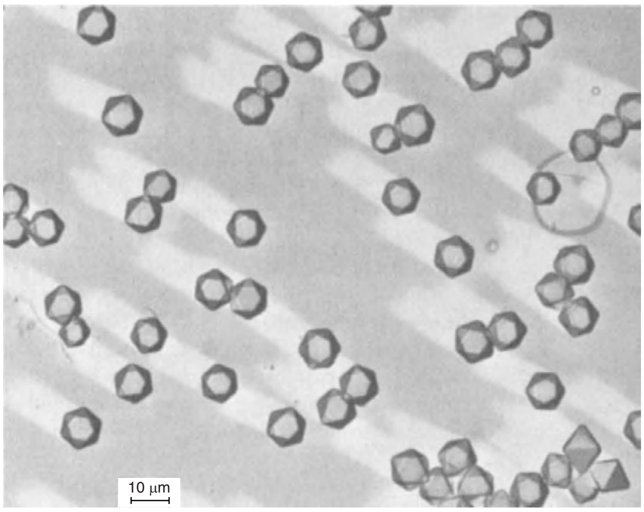

Fig. 1. Using the carbon replica technique, this is an electron micrograph of octahedral silver bromide grains. (*Photo by Dr. Donald L. Black, Eastman Kodak Company*)

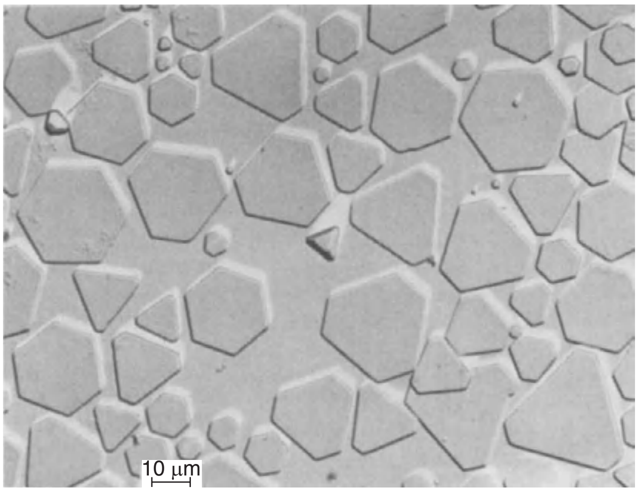

Fig. 3. Using the carbon replica technique, this is an electron micrograph of an Eastman Kodak T-Grain type emulsion of silver bromide that contains some iodide. (*Photo by Dr. Donald L. Black, Eastman Kodak Company*)

2. *Developing-out emulsion.* Emulsions for development have an excess of alkaline halides. By varying the composition of the silver halide and treatment, developing-out emulsions may be prepared which are suitable for either negative or positive purposes.

   a. *Negative emulsions.* Negative emulsions are prepared by adding a small amount of a soluble iodide to the bromide used in making the silver halide. The mixed crystals of silver-bromiodide formed are more sensitive to light and produce emulsions with greater speed than silver bromide alone. Negative emulsions are referred to as neutral emulsions if precipitation of the silver halide is carried out in a gelatin solution with an excess of soluble bromide. They are referred to as ammonia emulsions if the precipitation takes place in a gelatin solution with an excess of soluble bromide in the presence of ammonia or ammoniacal silver. The latter method produces emulsions with coarser grains, which have the highest sensitivity.
   b. *Positive emulsions.* Positive emulsions are prepared by precipitating silver halides containing chloride or mixtures of chloride and bromide in gelatin. The size of the crystals formed are smaller than those of negative emulsions and have a lower sensitivity. Positive emulsions are divided into four classes, according to the composition of the silver halides and their properties.

      - *Chloride Emulsions.* Because of their slow speed chloride emulsions are used largely for contact printing.
      - *Bromide Emulsions.* Bromide emulsions are very sensitive and fast. They are used for projection printing exclusively.
      - *Chlor-Bromide Emulsions.* In chlor-bromide emulsions the amount of silver chloride is greater than that of silver bromide. These emulsions are somewhat faster than chloride emulsions and used for contact or slow projection printing. Chlor-bromide emulsions produce warm-toned silver images with a brown or brown-black color.
      - *Brom-Chloride Emulsions.* Brom-chloride emulsions contain more silver bromide than silver chloride. They are faster than chlor-bromide emulsions and used for projection printing where black images and speed printing are desired. Image tones of brom-chloride emulsions are not as warm as chlor-bromide images nor as cold as bromide images.

Other Emulsion Additives. In addition to chemical and spectral sensitizers, several other classes of chemical compounds are added to emulsions before coating. Additives are used to facilitate coating operations, e.g., surfactants (qv) and viscosity enhancers; to reduce spontaneous development in unexposed regions, e.g., tetraazaindenes and mercaptotetrazoles; and to reduce abrasion and permit high temperature processing, e.g., aldehydes.

For certain component compositions the viscosity and surface tension of the melted emulsion may not allow adequate emulsion spreading on the support during the coating procedures. For these situations, various surfactants that act as spreading agents are available to control the surface tension. The sulfiding reaction is a thermally activated process with an activation energy near 126 kJ/mol (30 kcal/mol). Therefore, quenching the reaction by cooling the emulsion from 60 to 25°C does not eliminate the reaction but rather reduces the rate by about two orders of magnitude. After long storage of the emulsion, continued sensitization may produce a catalytic activity in the silver halide grains and unwanted photographic fog upon development. This can be controlled partly by additions of such stabilizers as halide ions, acid, benzimidazoles, benzotriazoles, benzothiazolium salts, and mercaptotetrazoles. Many of these compounds adsorb to silver and complex with silver ions. Specifically as a result of these interactions, phenylmercaptotetrazole restrains development and enhances sensitivity even in freshly coated samples. Quantum-mechanical analyses coupled with photographic data suggest that the best stabilizers not only bind with silver ions but are also poor reducing agents. Azaindene compounds satisfy both of these properties and are effective stabilizers and development antifoggants. Fog control for Au-sensitized emulsions can be, in part, achieved using thiocyanate. Gelatin cross-linking agents (hardeners) represent another class of materials that may be added before coating. These compounds render the coated emulsion layers more resistant to abrasion during handling and improve the thermal stability of the gelatin.

The desire for reduced development times required to produce an image has necessitated the use of solutions with increased activities. Temperature increases, pH increases, and increased oxidizability are all variations directed toward shortening process times. Unfortunately, high temperature processing tends to soften and dissolve the gelatin emulsions; therefore the gelatin must be hardened before development. The enhanced thermal stability and improved mechanical durability produced by hardeners result from the formation of three-dimensional bridging of various sites within the gelatin molecules. Both inorganic, e.g., chromium salts, and organic, e.g., aldehydes, compounds have been used as hardeners. Chromium appears to complex with carbonyl groups, whereas many of the organic hardeners seem to cross-link between the amino groups in the gelatin molecules.

In most color photographic products, organic compounds such as couplers or redox dye releasers are added to the melted emulsions before coating. These compounds are essential to the development reactions that produce the dye molecules composing color images.

Manufacture of Commercial Emulsions. Although the details are proprietary, the basic procedures of manufacturing commercial emulsions are known. A portion of the gelatin in the formula is swelled by soaking in water and later dissolved with heat. Mixtures of soluble bromides and iodides, or chlorides, are placed in water solution and added to the gelatin solution. Precipitation of silver halides is accomplished by slowly adding a solution of silver nitrate, while stirring, to the mixture. The relative concentration of the solutions, the rate of addition and temperature during mixing, are factors which control the formation, size and dispersion of the crystals in gelatin. The emulsion is then heated or "ripened" at 40–80°C to recrystallize the silver halides and readjust the size-frequency distribution. Following ripening, more gelatin is added and the emulsion is chilled so it will set quickly. The emulsion is then placed in a press and forced through a screen to break it into shreds or noodles, which are washed, in cold running water to remove the potassium nitrate formed, the excess soluble halides, and certain soluble byproducts of the reaction. Chloride emulsions are often prepared without washing or with only a limited washing. After washing, the emulsion is drained, remelted, and additional gelatin and certain agents, such as fog preventatives, are added. The emulsion is then heated, or "after-ripened," to form sensitizing nuclei on the silver halide crystals. This operation increases the sensitivity and contrast of the emulsion and is necessary for the preparation of high-speed negative emulsions. Certain preservatives, or stabilizers, are added so the emulsion can be stored in refrigerated rooms until needed. Before coating the emulsion is melted and sensitizing dyes, hardening agents, wetting agents, etc., are added. After thorough mixing, filtering and heating to coating temperature, it is placed in a coating machine. Supports, as film, paper, or glass, with substratum coatings are fed through machines at proper rates so they become coated with emulsions in uniform layers of desired thickness. The coated supports pass over chill boxes to set the emulsion and then through a series of drying compartments where the rate of drying is carefully controlled so as not to change the sensitivity on the surface. Following drying, the coatings are inspected under proper safelights and the film or paper is cut to desired size and packaged.

Numerous variations in the manufacturing process make possible a wide range of film characteristics, including film speed and spectral sensitivity. Film, unlike the human eye, can extend beyond the visible region of the spectrum. High-speed film can capture the details of a fast-moving object, seen only as a blur by the eye. By extended exposure, film can capture images entirely too faint to be seen by the eye. The three main types of film emulsions for black-and-white photography are: (1) *ordinary* (color-blind; sensitive to blue light only); (2) *orthochromatic* (sensitive to all but red light); and (3) *panchromatic* (sensitive to light of all colors). Ordinary and orthochromatic films generally offer greater contrast than most panchromatic emulsions. However, the response of panchromatic emulsions can be modified by use of color filters. Film is available in several sizes and formats. Obviously, a delineation of film specifications is beyond the scope of this encyclopedia. Some excellent references are listed at the end of this entry.

Color Films. The trichromatic theory of vision was first proposed by Thomas Young, a British physicist in 1801. He was the first to propose that the retina of the eye incorporates three different types of receptors, responding to blue, green, and red light, respectively. The theory was elaborated upon to the extent that color perception is based upon the stimulation of two receptors, with light stimulating both red and green receptors seen as yellow light; light equally stimulating all three types of

receptors seen as white, etc. Young concluded that it should be feasible to match any color of the spectrum through the proper mixing of blue, green, and red light. Although not essentially interested in color photography, Maxwell effectively demonstrated the principle by way of specially-prepared lantern slides before the Royal Institution in London in 1861. Maxwell had demonstrated the *additive color principle* (mixing of blue, green, and red light).

Practical color photography on a massive amateur scale, of course, could not depend upon the preparation of three separate photographs and the use of three projectors, but rather dictated a process that would combine the three records on one plate. In 1907, the LumiÈre Autochrome plate was developed. This was comprised of a very coarse mosaic of potato starch grains, one third of which was dyed blue; another third, green, and the remaining third, red. An emulsion layer was exposed, with the light first passing through the mosaic. In the *Kodacolor* system of 1928, filters in the camera were used instead of color mosaics. A major problem of the mosaic and filter approaches was that of loss of light as it passed through one or the other media, greatly reducing sensitivity and loss of brightness of a projected image. See also **Additive Color Process**.

In the *subtractive color system*, the phenomenon of absorption is involved. A dye that will absorb red light will, in turn, reflect green and blue light, thus appears a greenish-blue (cyan); a dye that will absorb green light appears a bluish-red (magenta); and a dye that absorbs blue light appears yellow. Thus, cyan, magenta, and yellow are the three primary subtractive colors. A mixture of all three dyes in proper portion will absorb all primary light and thus appear black. Most processes of color photography make use of a subtractive synthesis to yield prints or transparencies. See also **Subtractive Color Process**.

Color-separation negatives are photographic negatives that record the relative intensities of the primary colors used in the analysis necessary to reproduce a subject by means of color photography. In three-color photography, for example, the separation negatives are records, in terms of silver densities, of the amounts of red, green and blue light received at the camera from the subject.

A set of color-separation negatives may be prepared by photographing the subject three times on separate color-sensitive emulsions so that each is a record of one of the primary colors. A panchromatic emulsion is generally employed with a set of tricolor filters, the colors of the primaries. It is only necessary, however, to obtain the color records on separate negatives so it is also possible to use for each record any combination of color filter and emulsion sensitivity that will record one of the primary colors. A set of color-separation negatives may be made by exposing (1) each one in turn in a camera, (2) by the use of a color camera that will expose them simultaneously, or (3) in a tripack.

It is common practice to balance a set of color-separation negatives, by altering the exposure and development times, so that a gray scale will be recorded equally on each negative. The particular densities desired are dependent on the method of color synthesis to be employed.

The majority of color is by use of integral tripacks. There are three layers of photographic emulsion in the tripack, one layer sensitive to red light, another layer to green light, and another to blue light. They are coated, one on top of the other. Since silver iodobromide emulsions usually selected for film emulsions are sensitive to blue light, sensitivity to the green and red light must be conferred by sensitizing dyes. Although this sensitivity can be obtained, the dyes do not negate the emulsion's natural sensitivity to blue light. Thus, those layers that are sensitive to green and red light must be protected from blue light. This is accomplished by inserting a yellow filter layer that will absorb the blue light. Chloride emulsions on the other hand are sensitive only to ultraviolet light. Whereas they do not require a yellow-filter layer, they have to incorporate a filter for exclusion of ultraviolet light. There are a number of dyes that may be used in dye-transfer systems, but for tripacks it is necessary to select only those dyes that will be formed during the development process. In 1912, the German scientist, Rudolf Fischer, discovered the role of couplers. In his early version of a color film, he placed three layers of emulsion one atop another as previously described and he also incorporated a coupler in each layer to cause the development of a particular color. Fischer's concept was brilliant, but the actual process failed because the couplers and sensitizers tended to wander from layer to layer.

In 1931, Leopold Godowsky, a violinist, and Leopold Mannes, a pianist, and both avid amateur photographers made crude experiments in a home laboratory on a type of color film that ultimately became *Kodachrome*, released by Eastman in 1935. In the *Kodachrome* process, the couplers are laced in the developers instead of in the emulsions. Phenols are usually the couplers that form cyan dyes; nitriles or pyrazolones form magenta dyes; and esters, ketones, or amides form yellow dyes. There are many hundreds of couplers and, consequently, there is continuing improvement in color film. Space here does not permit a detailed description of such important matters as the negative-positive system, reversal systems for transparencies, color corrections, etc., but these areas are well covered in some of the listed references.

Direct Positive Images. Even in the early days of black-and-white photography and the early work of Daguerre and Fox-Talbot, it was realized that there would be a great advantage gained from a system that would initially produce a positive rather than a negative image. As early as the late 1930s, Hippolyte Bayard and Robert Hunt proposed systems, but these did not produce satisfactory results. The *chemical transfer* process was developed by A. Rott in Belgium in 1939 and found application in the document-copying field. In 1947, E.H. Land demonstrated a camera which produced a finished black-and-white print without need for a negative and one that was available to the photographer within a very short period, approximately one minute. This was the first model of the *Polaroid* camera. In chemical transfer, a normal emulsion is used. Immediately after exposure and while within the camera, it is developed in a solution containing combined developer-fixer agents. The emulsion is in contact with a special positive white paper, not light sensitive, on which the finished image is printed. The developing reagent is of a jellylike consistency and in early models was contained in pouches or pods, one for each picture. The exposed grains develop in the normal fashion. The unexposed grains are dissolved by the fixing agent. Thus, in the unexposed areas, the dissolved halide is silver which forms on the nuclei in the receiving sheet. In connection with partially exposed areas, the developing grains and the receiving sheet nuclei compete for the silver. Thus, a negative image is formed on the original film or paper, whereas a positive image appears on the receiving sheet. Subsequent to the first Polaroid camera, models were developed to provide a permanent negative as well as print, with the processing time reduced to seconds.

To achieve an instant color film that could rival 35 mm color quality, current generation *Polaroid Spectra* system film utilizes two different color chemistries for greater control of the self-developing image formation process. Composed of 18 microscopically thin coated layers in a rectangular format for both horizontal and vertical composition, this film is able to produce photographs of improved color separation, saturation and brilliance. This is a result of combining images created in three chemical sandwiches in the film negative. Each sandwich is sensitive to red, green, or blue light and consists of a photosensitive emulsion and a related image dye.

For the *Spectra* film, the blue-light sensitive sandwich has been radically altered by the utilization of thiazolidine dye release. This required the creation of new molecules and a new dye-release mechanism involving only a minute quantity of silver. By utilizing this hybrid imaging system, chemical interaction and molecular cross talk between the red-, green-, and blue-sensitive sandwiches have been reduced, which results in greater color definition.

This new material also affords substantial improvement in yellow dye saturation and in recording pastels. By controlling chemical crosstalk between the red and green layers, *Spectra* film is further able to produce more brilliant greens, which is a difficult photographic accomplishment because of the low reflectivity of green in nature. This material also reproduces a broader range of hues and tints when compared with earlier-generation self-developing color films. The transparent support through which the image is viewed is thinner than previous *Polaroid* films and enhances image quality.

Special Films

Infrared Films. The first photographs by infrared radiation appear to have been made about 1880 by Sir William Abney, using a specially prepared collodion emulsion. Abney is reported to have photographed a boiling tea-kettle, but efforts by others to repeat his work were not particularly successful. In 1903, the first real infrared sensitizer, Dicyanine, was discovered. While the sensitizing action extended to a wavelength of 960 nanometers in the infrared, the exposure was too long for general

photography and Dicyanine-sensitized plates were used chiefly in infrared spectroscopy. The discovery of more efficient sensitizers in the early twenties, beginning with Kryptocyanine and neocyanine and followed by the penta- and tetra-carbocyanines, has made it possible to prepare films and plates whose sensitivity in the infrared is such that they can be used for general photography, including aerial and motion-picture photography.

Infrared-sensitive films and plates may be divided into two classes: (1) materials of relatively high speed to the extreme red and infrared, i.e., from approximately 700 to 900 nanometers (nm), and (2) materials sensitive to much longer wavelengths but of lower sensitiveness. The former are used for general photography, for aerial photography and cinematography; the latter for spectroscopy in the infrared and other scientific applications requiring sensitivity to wavelengths longer than about 900 nm. All infrared-sensitive materials are sensitive to violet and blue and to the extreme visible red, as well. Photographs made without a filter resemble those made on an ordinary blue-sensitive material. For most purposes it is sufficient to use an orange or light-red filter which will absorb blue and violet light. In this case, the picture is made partly by infrared and partly by the extreme red. The result, however, is generally only slightly different from that obtained with infrared radiation alone. For true infrared photographs, a visually opaque filter transmitting the infrared only must be used. No filter, however, is required when photographing hot bodies such as an electric flatiron, hot castings, or high-pressure boilers, provided that these show no visible glow.

All infrared-sensitive materials must be loaded and developed in total darkness, as safelight screens, even those for panchromatic films and plates, transmit the infrared freely.

Certain precautions are necessary when making pictures with infrared-sensitive materials. The bellows and shutter blades of some cameras, although perfectly safe for ordinary photographic films and plates, transmit the infrared and fog infrared-sensitive films. The slides of some film and plate holders transmit the infrared sufficiently to cause fog. Although some modern lenses are corrected for the infrared, with most, the focal distances for the visible and for the infrared are different. Usually, it is sufficient to extend the lens a distance equal to 2% of the focal length beyond the visual focus. Even this may often be ignored when using a lens of short focal length or a small diaphragm.

Infrared photographs of landscapes are quite different from those made in the usual way. Green foliage is reproduced light and blue sky and water almost black. The shadow portions of the subject are dark and without detail. The general effect is that of a photograph made by moonlight, particularly if the print is made rather dark. As a matter of fact, most night scenes in motion pictures are really infrared photographs.

Since infrared radiation is not scattered by atmospheric haze, as is light, distant objects are rendered sharper and more distinctly in infrared photographs. Objects invisible to the eye because of the intervening haze are often reproduced sharply in an infrared photograph. In fact, one of the most important applications of infrared photography is in photographing distant objects, whether from the ground or the air. Infrared photographs, however, cannot be made through dense fog.

The scientific applications of infrared photography are numerous and important.

Aerial Photography in the Infrared. Extensive use of color infrared film (CIR) has been made in the field of aerial photography for such applications as crop sensing and inventorying, flood assessments, etc. Both normal color film and CIR consist of three separate layers of emulsion on a clear base material. It will be recalled that in normal color film one emulsion layer is sensitive to blue light, one to green light, and one to red light. The images recorded on the three emulsion layers of normal color film combine in the final image to form colors which closely match those of the original subject. CIR film, sometimes referred to as "false color film," also produces combinations of blue, green, and red in the final image; but the blue color results from exposure by green light; the green color from exposure by red light; and red color by exposure of the infrared sensitive layer by infrared energy. Therefore, the images are called false color images. See Fig. 4. Actually, all three layers of CIR film are also sensitive to blue light. For this reason, the film is always exposed through a minus-blue (yellow) filter which eliminates blue light before it reaches the film. The infrared energy needed to expose the infrared sensitive layer

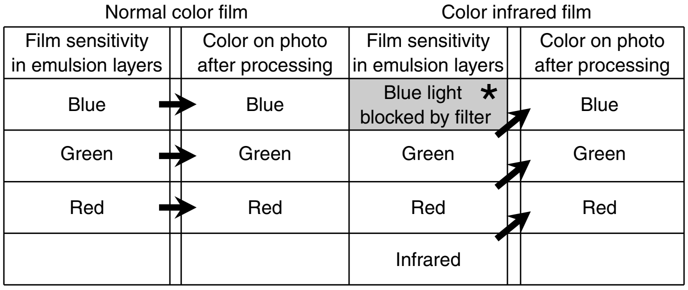

Fig. 4. Film sensitivities and final image color of normal color and color-infrared films. *Blue light absorbed by yellow filter. (*U.S. Geological Survey*)

is reflected energy, not heat energy. Heat energy does not enter into the image forming process of CIR film.

One of the most important features of CIR film is the manner in which vegetation is recorded. Healthy green plants appear in shades of red, because healthy plants reflect sunlight strongly in the photographic infrared region (therefore strongly exposing the infrared sensitive layer) while simultaneously reflecting relatively little energy in the visible region (therefore offering little exposure to the green and red sensitive layers). For all practical purposes, living healthy vegetation is the only natural source of high-infrared reflection coupled with low visible reflection. Because of the unique reflectance characteristic of healthy vegetation, the film was originally used by the military to differentiate between real vegetation and painted camouflage material.

Another unique and variable aspect of CIR photography results from the fact that plants do not reflect strongly in the photographic infrared when they are severely stressed or have died, and as a result, no longer appear red on the photographs, in contrast with normal, healthy vegetation. The reasons behind this phenomenon are complex, yet the ability to distinguish between healthy and stressed or dead vegetation by using CIR is very important for vegetation analysis. This characteristic is particularly useful in determining crop damage due to flooding.

Generalizations about the photographic appearance of other features commonly found on the agricultural landscape can also be made. Clear water usually appears very dark blue or black, but muddy or turbid water appears light to medium blue. This is useful for satellite tracking of pollution situations. Fresh grain stubble appears very light or almost white, whereas clean plowed fields of dark soil usually appear dark blue.

Other Applications of Infrared Film. Among several other scientific uses are:

1. *In Medical Photography.* For the study of the following: diseases and conditions affecting the venous pattern not revealed by light; the progress of healing beneath certain scabs; the eye, to determine atrophy; histological specimens, to reveal structures below the surface and invisible to the eye. Thermography has been used to detect tumors, the skin temperature often being as much as 1 to 2°C higher than that of the surrounding skin.
2. *In Industry.* For the study of irregularities in the dyeing and weaving of textile fibers, the interior of furnaces, the detection of carbon in lubricating oils, infrared spectroscopy of metals and alloys.
3. *In Astronomy.* For detection of nebulae and stars otherwise invisible because of astronomical haze or because their radiation lies chiefly in the infrared; in infrared spectroscopy, for the determination of the composition, the temperature, and the movement of stars and nebulae.
4. *In Criminology.* For deciphering writing or printing that has been crossed out with other inks to render it illegible; for obtaining copies of charred documents, detecting erasures, revealing finger prints, identifying blood and other stains, uncovering secret writings, etc.

Ultraviolet Films. In the near-ultraviolet region, photography is the same as with visible light. However, at shorter wavelengths, many materials are not transparent to ultraviolet radiation. For example, glass is not

transparent at wavelengths shorter than about 3,000 Å. To produce a photograph at these shorter wavelengths, a quartz lens (transparent to about 1,800 Å) or a fluorspar lens (transparent to about 1,200 Å) is required. Inasmuch as gelatin also absorbs radiation of wavelength less than about 2,200 Å, photography in such regions requires specially-prepared plates where a minimal amount of gelatin is used. In some cases, the plates can be coated with a thin film of oil or other substance which fluoresces when exposed to ultraviolet. For particular work, the fact that air absorbs short wavelengths also must be considered and best results will be obtained in a vacuum. Even with these problems, however, spectra have been recorded down to about 50 Å.

Ultraviolet photography and spectroscopy have found particular usefulness in the study of combustion processes. Some of the very short-lived chemical species occurring during combustion can be observed in the near-ultraviolet region. Along with infrared, ultraviolet techniques also have been used for detecting the retouching of paintings.

Descriptions of cameras, other photographic equipment and the many thousands of applications of photography are beyond the scope of this volume.

PHOTOIONIZATION. This process, which is also called the atomic *photoelectric effect*, is the ejection of a bound electron from an atom by an incident photon whose entire energy is absorbed by the ejected electron. This statement means that photoionization cannot occur unless the energy of the photon is at least equal at the ionization energy of the particular electron in the particular atom; any excess of energy in the photon above this value appears as kinetic energy of the ejected electron.

PHOTOLUMINESCENCE. See **Luminescence**.

PHOTOLYSIS. See **Free Radical**; **Photochemistry and Photolysis**.

PHOTOMETERS. Instruments for the measurement of luminous intensity, luminous flux density, and illumination. In usual terminology, only instruments that respond to the central portion of the electromagnetic spectrum, i.e., the ultraviolet, visible, and infrared regions, are called photometers. Essentially, a photometer is comprised of a transducer, which transforms electromagnetic waves (photons) into an electric current, and a current-measuring readout device. In the simplest form, the instrument could be a voltage-generating photocell connected to a microammeter. Photographic exposure meters and light meters that measure ambient illumination are usually of this type. The latter are furnished with green filters, which correspond to the relative spectral sensitivity of the human eye. Photoresistors also are used for this purpose. Photoresistors require a voltage source (battery) in the circuit. The microammeter reads out the change in resistance caused by the illumination. These devices are more sensitive, but not of high precision because of fatigue effects of photoresistors. For precision work, photomultiplier tubes are usually the transducer selected. Some specific types of photometers and spectrophotometers include:

Atomic-Absorption Photometer. This instrument operates on the very specific spectral absorption of an atomized sample rather than emission. The equipment is comprised of a stabilized hollow-cathode lamp (one for each element to be analyzed), a flame with sample nebulizer, a monochromator, and a photometer.

Brightness Meter. A special type of reflection meter for evaluating the brightness of paper and similar products by measuring the diffuse

reflectance in the blue range of the spectrum. Actually, these meters quantify the yellow characteristics of the paper.

Circular Dichrograph. An instrument similar to a spectropolarimeter. Instead of a change in angle of optical rotation versus wavelength, the instrument records the difference in dichroic absorption versus wavelength.

Color-Difference Meter. A specially designed reflection meter for assessing small color variations.

Colorimeter. An instrument for routine chemical analysis. Compounds or ions which absorb light in the visible part of the spectrum (400 to 800 nanometers) or which are convertible by specific reagents to such compounds can be analyzed with a colorimeter. The instrument typically incorporates an incandescent light bulb as light source, filters to separate the spectral region, a cuvette to contain the sample solution, and a photometer. See also **Colorimetry**.

Densitometer. An instrument used to measure the attenuation of a beam passing through, or reflected from the surface of solid samples.

Ellipsometer. An instrument for determining the thickness of very thin films of monomolecular dimensions. Essentially, the instrument is a polarization interferometer that utilizes a photometer as a readout device.

Flame Photometer. See *Atomic-Absorption Photometer* in this entry.

Fluorimeter (also Fluorometer or Fluorophotometer). In this instrument, the sample is excited by a light beam of suitable short wavelength. The remitted fluorescent light is picked up by a photometer, usually placed 90 degrees from incidence. A filter or monochromator is provided which excludes the exciting waveband and transmits the fluorescent light. See also **Fluorometers**.

Footcandle Meter. A color-corrected illumination meter calibrated in footcandles.

Glossmeter. An instrument for measuring specularly reflected light from the surface of a flat sample. The angle of incidence and the angle of light pickup are identical and opposed from the normal to the surface. A typical glossmeter consists of a light source and simple optics to direct a defined beam onto the sample. In the opposite direction, there is a light detector connected to a readout meter.

Hemoglobinometer. A specialized colorimeter for determining hemo globin in blood.

Light-Scattering Photometer. In one type, suspended particles are determined (counted). Another type is used to determine the molecular weight of macromolecules dispersed in solution. The former type operates on the basis of a nephelometer; the latter is of much higher precision and uses monochromatic light.

Lux Meter. Essentially a footcandle meter calibrated in international lux units. (1 footcandle = 10.8 lux.)

Nephelometer. An instrument for determining particle size or particle concentration by measuring the amount of light transmitted or scattered by the suspended particles. Quantitative determinations are made by comparing a given sample with a known standard. See also **Nephelometry**.

Opacimeter. A reflection meter specifically designed to evaluate the opacity of thin sheets, such as paper, by measuring the diffuse reflectance over a white and a black surface in turn.

Optical-Emission Spectrometer. Similar to flame photometer (atomic-absorption photometer) except that an electric spark rather than a flame is used to vaporize (atomize) unknown samples.

Polarimeter. An instrument for determining the concentration of optically active compounds in solution by determining the angle of rotation of plane-polarized light passing through the sample. See also **Polarimetry**.

Reflection Meter. A photometer arranged to pick up diffusely reflected light from the surface of a flat sample. The spectral evaluation of the reflected light permits quantitative color evaluation as seen by the human observer.

Refractometer. An instrument for determining the refractive index of solutes. Most of these instruments use photometric readout systems.

Saccharimeter. A polarimeter calibrated in "sugar degrees" for analyzing the concentration of sugar solutions.

Spectrofluorimeter. A fluorimeter with two separate monochromators. One serves to scan through the spectrum of the exciting light source; the other scans the emitted fluorescent light.

Spectrophotometer. An instrument comprising a light source, means of monochromatizing the light, a sample space, and a photometer. These instruments normally determine concentration of a solute by measurement of light attenuation, the logarithm of absorption being proportional to the concentration. If the instrument is designed to operate in the infrared region, it is known as an infrared spectrophotometer. If in the ultraviolet region, an ultraviolet spectrophotometer, etc.

PHOTON AND PHOTONICS. In common usage, a photon is a quantum of electromagnetic energy. The energy of a photon is hv, where h is the Planck constant, and v is the frequency associated with the photon. The term photon usually refers to a plane-wave quantum of electromagnetic energy, for which the momentum is hv/c, and the component of angular momentum in the direction of the momentum is $\pm\hbar$, where c is the velocity of light and $\hbar$ is $h/2\pi$.

The word *photonics* entered the scientific vocabulary in the mid-1980s to describe a communications transmission system that converted digital information into pulses of light that traveled over an optical fiber cable (fiber optics/light wave communication). The first crude cables were used in the mid-1970s. An exploratory system was established in a network between three buildings in downtown Chicago. Since then, the growth of optical fiber networks worldwide has been no less than dramatic. However, photonics also has a broader connotation and parallels in its hardware and systems aspects the well-established microwave technology, thus, a *photonics technology*. See also **Optical Fiber Systems**.

The existence of the photon was first suggested by Planck's famous research, about 1900, into the distribution in frequency of blackbody radiation. Planck arrived at agreement with the experimental distribution only by making the drastic (for that period in science) assumption that the radiation exists in discrete amounts with energy $E = hf$, where f is the frequency of the radiation and h is Planck's constant, $6.626\ (10)^{-27}$ erg sec. Confirmation of the existence of these quanta of electromagnetic energy was provided by Einstein's interpretation of the photoelectric effect (1905). Einstein made it clear that electrons in a solid absorb light energy in the discrete amounts hf. The full realization that the photon is a particle with energy and momentum was provided by the Compton effect (1922), an aspect of the scattering of light by free electrons. Compton showed that features of the scattering are understood by balancing energy and momentum in the collision in the usual way, the light considered as a beam of photons each with energy hf and momentum hf/c.

The modern point of view is that, for every particle that exists, there is a corresponding field with wave properties. In the development of this viewpoint, the particle aspects of electrons and nuclei were evident at the beginning and the field or wave aspects were found later (this was the development of quantum mechanics). In contrast, the wave aspects of the photon were understood first (this was the classical electromagnetic theory of Maxwell) and its particle aspects only discovered later. From this modern viewpoint, the photon is the particle corresponding to the electromagnetic field. It is a particle with zero rest mass and spin one.

For a photon moving in a specific direction, the energy E and the momentum q of the particle are related to the frequency f and wavelength λ of the field by Planck's equation $E = hf$ and the de Broglie equation $q = h/\lambda$. As for all massless particles, the energy and momentum are related by $E = cq$ and the photon can only exist moving at light speed c. Another property of all massless particles is that, given the momentum, the particle can exist in just two states of spin orientation. The spin can be parallel or antiparallel to the momentum, but no other directions are possible. The photon state with the spin and momentum parallel (antiparallel) is said to be right- (left-) handed and is a right- (left-) hand circularly polarized wave. In analogy with the neutrino, one can say that the state has positive (negative) helicity and can call the right-handed particle the antiphoton, the left-handed particle the photon. There is an operation, CP conjunction, that converts a photon state into an antiphoton state and vice versa. It is possible to superpose photon and antiphoton states in such a way that the superposition is unchanged by CP conjugation and so gives a type of photon that is its own antiparticle. The photons produced by transitions between states of definite parities in atoms or nuclei are their own antiparticles in this sense. As for all particles with integer spin, the photon follows Bose-Einstein statistics. This means that a large number of photons may be accumulated into a single state. Macroscopically observable electromagnetic waves, such as those resonating in a microwave cavity, for example, are understood to be large numbers of photons all in the same state. The photon, among all particles, is unique in having its states be macroscopically observable in this way.

PHOTONEUTRON. A neutron emitted from a nucleus in a photonuclear reaction.

PHOTONUCLEAR REACTION. A nuclear reaction induced by a photon. In some cases the reaction probably takes place via a compound nucleus formed by absorption of the photon followed by distribution of its energy among the nuclear constituents. One or more nuclear particles then "evaporate" from the nuclear surface, or occasionally the nucleus undergoes photofission. In other cases the photon apparently interacts directly with a single nucleon, which is ejected as a photoneutron or photoproton without appreciable excitation of the rest of the nucleus.

PHOTOPOLYMER. A polymer or plastic so made that it undergoes a change on exposure to light. Such materials can be used for printing and lithography plates, photographic prints, and microfilm copying. The light may cause further polymerization or cross-linking, or it may cause degradation. One application involves the use of esters of polyvinyl alcohol that cross-link and so become insoluble, whereas unexposed portions of the material remain soluble.

PHOTOSENSITIVE GLASS. Certain clear silicate glass containing ingredients capable of forming permanent photographic images when subjected to action of X-rays or ultraviolet light and subsequent heat treatment.

See also **Glass**.

PHOTOSYNTHESIS. This is the most important of all biological processes. With negligible exceptions the existence of the entire biological world hinges upon this process. From a few simple inorganic compounds and from the sugar made in photosynthesis are erected all of the complex kinds of molecules essential to the construction of the bodies of plants and animals or to maintenance of their existence. Some of these subsequent synthetic processes occur in the plant body, others in the bodies of animals after they have ingested plant materials as foods. Likewise, the energy used by plants and animals represents sunlight energy that has been entrapped in sugar molecules during photosynthesis. The entire organic world runs by the gradual expenditure of the energy capital accumulated in photosynthesis.

Under suitable conditions of temperature and water supply, the green parts of plants, when exposed to light, abstract and use carbon dioxide from the atmosphere and release oxygen to it. These gaseous exchanges are the opposite of those occurring in respiration and are the external manifestation of the process of photosynthesis by which carbohydrates are synthesized from carbon dioxide and water by the chloroplasts of the living plant cells in the presence of light. For each molecule of carbon dioxide used, one molecule of oxygen is released. A summary chemical equation for photosynthesis is:

$$6\ CO_2 + 6\ H_2O \xrightarrow{\text{light}} C_6H_{12}O_6 + 6\ O_2$$

In this process, the radiant energy of sunlight is stored as chemical energy in the molecules of carbohydrates and other compounds that are derived from them.

All photosynthetic organisms, except bacteria, use water as the electron or hydrogen donor to reduce various electron acceptors, and from the water they evolve molecular oxygen. Anaerobic bacteria cannot endure such oxygen, but derive their sustenance through slightly different photosynthetic routes:

$$2\ H_2S + CO_2 \xrightarrow{\text{light}} (CH_2O) + H_2O + 2S$$

or

$$2\ CH_3CHOHCH_3 + CO_2 \xrightarrow{\text{light}} (CH_2O) + CH_3COCH_3 + H_2O$$

Photosynthesis takes place in chlorophyll-containing cells only when carbon dioxide, water, and light are available, and when a suitable temperature prevails. Although carbon dioxide constitutes, on the average, only 0.03% of the atmosphere, land plants are entirely dependent upon this source for the carbon dioxide used in photosynthesis. It has been shown experimentally that an increase in the carbon dioxide concentration of the atmosphere results in an increased rate of photosynthesis. On the other hand, a deficiency of water results in a reduced rate of photosynthesis. In nature, sunlight is the source of radiant energy used in photosynthesis, although plants will also photosynthesize under artificial light sources of suitable quality and intensity.

The total radiant energy received at the earth's surface is 1–2 gram calories/square centimeter/minute, depending upon altitude, or approximately 1 hp/10–20 square feet. For crop plants in the field, a maximum of 2–3% of this energy remains stored in the plants at the end of the growing season. During that time about 20% more is actually used in photosynthesis and lost by respiration of the plant, the remainder of the energy being dissipated by re-radiation, transmission through the leaves, and evaporation of water from the plant.

The intensity, quality and daily duration of illumination all have influence on the amount of photosynthesis accomplished per day. Clearly,

the longer the daily period of illumination, the more photosynthesis will be accomplished by a plant in the course of a day. The minimum light intensity at which a measurable rate of photosynthesis occurs varies according to species, but is seldom less than 1% of full midday summer sunlight. Under natural conditions, maximum rates of photosynthesis are attained in single leaves of many species at 25–35% of full sunlight intensity, and in some shade species at even lower intensities. For equal intensities, more photosynthesis appears to occur in the orange–short red and blue parts of the spectrum than in the green and yellow. This is because the chlorophyll pigments of the leaves absorb light energy at wavelengths of 6600 and 4250 micrometers. Radiation is most intense in the green and, if this radiation were absorbed, the plant could not utilize it and would overheat.

The range of temperatures most suitable for relatively rapid rates of photosynthesis is not the same for all kinds of plants. In general, it is higher in tropical than in temperate species, and higher in temperate species than in those of subarctic regions. Increase in temperature results in an increase in the rate of photosynthesis up to an optimum which varies with the variety of plant, but which, for most temperate zone species, lies within the range of 20–30°C. With increase above the optimum, the rate of photosynthesis progressively decreases.

In the vascular plants, photosynthesis occurs chiefly in the leaves. Carbon dioxide diffuses into the intercellular spaces of the leaf from the atmosphere via the stomates, and then dissolves in the moist walls of the mesophyll cells. In solution, the carbon dioxide diffuses to the surface of the chloroplasts, which are the actual seat of the photosynthetic process. The first major step in photosynthesis is the absorption of radiant energy by the plant pigments in the chloroplasts, with the generation of electrons. The plant pigment consists of two closely similar pigments, chlorophyll and chlorophyll *b*, which are porphyrin-derived complexes of magnesium and which, upon excitation by radiant energy, become electron donors. See also **Chlorophylls**. The chloroplast is a complex, self-replicating organelle that possesses its own DNA and is able to synthesize at least a few of the proteins needed for its own functioning. It is filled with membranous thylakoid sacs which are specifically designed to harness the energy available in the excited electron and to carry out the light phase of photosynthesis. In this, the light energy captured is converted into the chemical energy of adenosine triphosphate (ATP) and nicotinamide-adenine dinucleotide phosphate (NADPH). See also **Adenosine Phosphates**; and **Coenzymes**. Hydrogen atoms are removed from water and used to reduce NADP, leaving behind molecular oxygen. Simultaneously, adenosine diphosphate (ADP) is phosphorylated to ATP:

In the second, or dark, reaction phase, NADPH and ATP provide the

$$\text{Water} + \text{NADP}^+ + \text{PO}_4 + \text{ADP} \xrightarrow{\text{light}} \text{Oxygen} + \text{NADPH} + \text{H}^+ + \text{ADP}$$

energy to reduce carbon dioxide to glucose and are themselves oxidized or decomposed:

$$\text{CO}_2 + \text{NADPH} + \text{H}^+ + \text{ATP} \longrightarrow \text{Glucose} + \text{NADP}^+ + \text{ADP} + \text{PO}_4$$

Peter Mitchell (Nobel Prize, 1978) of Great Britain was the first to realize, and to propose in his chemi-osmotic theory, that the energy required for the ADP-ATP reaction could be derived by an accretion of protons in the thylakoid sac to the point at which the electrochemical gradient across the membrane could effect the proton transport required as the driving force for this reaction. See also **Phosphorylation (Photosynthetic)**.

In most plants, the water used in photosynthesis is absorbed by the roots from the soil, whence it is translocated to the leaves. Except for a small portion used in respiration, the oxygen liberated in the process diffuses out of the leaf into the atmosphere, mostly through the stomates. Carbohydrates other than hexoses are synthesized in the leaves, apparently as a result of secondary reactions following photosynthesis. Sucrose invariably accumulates in actively photosynthesizing leaf cells. This more complex sugar is built up from the molecules of the simpler hexoses. In most plants, insoluble starch also accumulates in leaf cells during photosynthesis. This carbohydrate is synthesized by the condensation of numerous glucose molecules. The sucrose and starch contents of leaves decrease at night as a result of the continued translocation from the leaves to other parts of the plant. The sucrose is probably translocated as such, but the starch must first be converted into simpler, soluble sugars before it can move out of the leaves. Synthesis of starch is not restricted to the green parts of plants; a familiar example of this is the accumulation of starch in potato tubers. Starch in the nongreen cells is made from glucose, which comes from the leaves or other photosynthetic organs. Starch occurs in cells in the form of small grains, the type of grain formed in each kind of plant being more or less characteristic of that species.

For many years, the nature and location of the complex of proteins (sometimes referred to as the "engine" of photosynthesis) were poorly understood. During the 1980s, much more was learned as the result of research carried out by Johann Deisenhofer (Howard Hughes Medical Institute), Robert Huber, and Harmut Michel (Max Planck Institute), and for this work the investigators were awarded the 1988 Nobel Prize for chemistry. The protein complex, called the membrane-bound proteins, are difficult to define structurally because they do not crystallize readily and thus could not be subjected to x-ray crystallography. However, over a period of three years, the researchers were able to create crystals and thus were able to determine precisely the position of some 10,000 atoms in the protein complex.

With this better understanding, researchers are able to depict how plants, algae, and rhodopseudomonads carry out synthesis. Also, it has been hypothesized that such membrane-bound proteins may have a functional role in some diseases, such as cancer and diabetes.

Finally, it must be realized that photosynthesis is not the sole prerogative of the higher plants. More than half the photosynthesis on the earth's surface is carried out in the oceans by phytoplankton.

PHOTOVOLTAIC CELLS. A photovoltaic (PV) solar power system is a complete electrical source that uses solar cells to directly convert light energy into electricity. The system can be self-contained and completely autonomous or it can work in tandem with other conventional fuel-based sources of power to offer robust power availability.

A solar cell is a semiconductor device that can convert light instantaneously into direct-current (d-c) electricity. A number of cells are typically connected together in series in a weather-resistant package such that enough voltage is generated to recharge a 12-volt lead–acid storage battery, the most common storage device used in conjunction with solar power. Such a package of cells is designated a PV module, which is often constructed of an external sheet of strengthened glass and polymeric encapsulation. The most common size module is 0.5–1 m^2 in area and delivers between 25 and 150 watts of power. See also **Batteries**.

The advantages of photovoltaic cells as a source of electric power over alternative power sources may be characterized as follows: solar cells capture sunlight, an essentially inexhaustible and nonpolluting energy source which is freely distributed, and directly convert that light into electricity; photovoltaic generation of electricity requires no machinery with moving parts and produces no noise, waste, or polluting by-products; photovoltaic systems are modular and therefore can be adapted for a variety of applications. Solar power systems are particularly useful in areas where power lines cannot be readily or inexpensively routed.

Solar cells have been used extensively and successfully to power satellites in space since the late 1950s, where their high power-to-weight ratio and demonstrated reliability are especially desirable characteristics. On earth, where electrical systems typically provide large amounts of power at reasonable costs, three principal technical limitations have thus far impeded the widespread use of photovoltaic products: solar cells are expensive, sunlight has a relatively low power density, and commercially available solar cells convert sunlight to electricity with limited efficiency. Clearly, terrestrial solar cells must be reasonably efficient, affordable, and durable. International efforts are dedicated to obtaining such devices.

The power density of sunlight is about 1350 W/m^2 at elevations just above the earth's atmosphere. Less than 1000 W/m^2 is typically incident on earth after filtering through the atmosphere. Due to the low power density of sunlight and limited conversion efficiencies, the most efficient solar modules can generate about 250 W/m^2 in peak sunlight conditions. The maximum power output of a solar cell or module is defined in peak watts (W_{peak}), a rating based on a standard measurement method established by international consensus. A solar panel of one square meter area nominally produces one kilowatt hour of electricity per day. For most large-scale, power-producing applications, solar modules have conversion efficiencies above 10% in order to minimize the total cost of a generating system.

Chemistry

Crystalline silicon $p-n$ junction solar cells are the principal commercially available type and are used here to illustrate the operation of a solar cell. When sunlight falls on a solar cell, a voltage is induced and an electric current flows in an external circuit that is connected to the cell. Each atom in the silicon crystal lattice is surrounded by and bound to four equidistant neighboring atoms. The outermost shell of electrons of each silicon atom contains four valence electrons, and each of the four valence electrons in the crystal lattice is shared in a bonding orbital with an electron from one of its four nearest neighbors. This electron pair or covalent bond firmly binds the crystal. If all the valence electrons were inexorably bound, as they would be at 0 degrees kelvin, the silicon crystal would be an insulator because no free electrons would be available, and conduction would be precluded. See Fig. 1(a). However, the covalent bonds can be broken, e.g., by thermal excitation. See Fig. 1(b). The energy required to break a covalent bond is the bond energy or energy gap, E_g. In silicon, E_g is ca 1.1 eV.

The absence of an electron from a covalent bond leaves a hole and the neighboring valence electron can vacate its covalent bond to fill the hole, thereby creating a hole in a new location. The new hole can, in turn, be filled by a valence electron from another covalent bond, and so on. Hence, a mechanism is established for electrical conduction that involves the motion of valence electrons but not free electrons. Although a hole is a conceptual artifact, it can be described as a concrete physical entity to keep track of the motion of the valence electrons. Because holes and electrons move in opposite directions under the influence of an electric field, a hole has the same magnitude of charge as an electron but is opposite in sign.

The energy in light also can break the bonds of silicon valence electrons. Each photon has energy equal to the product of Planck's constant and the frequency of the light, i.e., $E = hv$, where E is photon energy, h is Planck's constant, and v is the frequency of light. Solar photons range in energy from 0.5 eV for infrared to 4 eV for ultraviolet.

When a photon having energy equal to or greater than E_g is absorbed by the silicon crystal, the photon breaks a covalent bond, thereby freeing an electron and forming a hole. An electron is excited by a photon from a valence-energy band in a covalent bond into a conduction-energy band. The electron, which is transformed into a mobile, negatively charged carrier, leaves behind a mobile hole and consequently the photon has formed a free electron–hole pair.

If the hole and electron are not kept apart, they recombine to produce a small amount of thermal energy within the crystal and no net current flow. When the holes and electrons are kept apart, collected, and made to flow in a circuit outside the crystal, they produce electric current in that circuit. Solar cells are equipped with a barrier or a junction which provides an internal electric field that segregates photogenerated electrons and holes. Thus, although unmodified silicon has an equal number of holes and electrons, a $p-n$ junction silicon solar cell consists of two charge-dissimilar regions which are separated by a junction: one region is rich in holes (positive), i.e., *p-type* silicon, and the other is rich in electrons (negative), i.e., *n-type* silicon. Such regions do not occur naturally; they are fabricated by doping, i.e., replacing some silicon atoms in the lattice with atoms having a valence other than four. Replacement of a few silicon atoms, i.e., ca one in several million, causes large increases in the electrical conductivity of the resultant doped crystal.

Atoms of elements that are characterized by a valence greater than four, e.g., phosphorus or arsenic (valence = 5), are one type of dopant. These high valence dopants contribute free electrons to the crystal and are called donor dopants. If one donor atom is incorporated in the lattice, four of the five valence electrons of donor dopants are covalently bonded, but the fifth electron is very weakly bound and can be detached by only ca 0.03 eV of energy. Once it is detached, it is available as a free electron, i.e., a carrier of electric current. A silicon crystal with added donor dopants has excess electron carriers and is called n-type (negative) silicon. See Fig. 1(c).

When a silicon crystal is doped with atoms of elements having a valence of less than four, e.g., boron or gallium (valence = 3), only three of the four covalent bonds of the adjacent silicon atoms are occupied. The vacancy at an unoccupied covalent bond constitutes a hole. Dopants that contribute holes, which in turn act like positive charge carriers, are acceptor dopants and the resulting crystal is *p-type* (positive) silicon. See Fig. 1(d).

Conductivity in doped silicon crystals is determined by the properties of the added charge carriers or majority carriers. In *n-type* silicon, electrons are majority carriers and holes are minority carriers. There are fewer holes in *n-type* silicon than in undoped silicon because the large number of electrons causes some recombination with preexisting holes. In *p-type* silicon, holes are the majority carriers and electrons are the minority carriers. Fewer electrons are present in *p-type* silicon than in undoped silicon because of the recombination of some electrons with the enhanced population of holes.

Junctions

Four different types of junctions can be used to separate the charge carriers in solar cells: (1) a homojunction joins semiconductor materials of the same substance, e.g., the homojunction of a $p-n$ silicon solar cell separates two oppositely doped layers of silicon; (2) a heterojunction is formed between two dissimilar semiconductor substances, e.g., copper sulfide, Cu_xS, and cadmium sulfide, CdS, in Cu_xS–CdS solar cells; (3) a Schottky junction is formed when a metal and semiconductor material are joined; and (4) in a metal–insulator–semiconductor junction (MIS), a thin insulator layer, generally less than 0.003-μm thick, is sandwiched between a metal and semiconductor material.

Fabrication methods that are generally used to make these junctions are diffusion, ion implantation, chemical vapor deposition (CVD), vacuum deposition, and liquid-phase deposition for homojunctions; CVD, vacuum deposition, and liquid-phase deposition for heterojunctions; and vacuum deposition for Schottky and MIS junctions.

Efficiency

The most efficient silicon cells produced are based on $p-n$ homojunctions and convert 23.1% of the energy in incident light set to simulate the global air mass (AM) 1.5 spectrum, an artificial reference spectrum used to standardize measurement of PV power, with an intensity of 1000 W/m^2

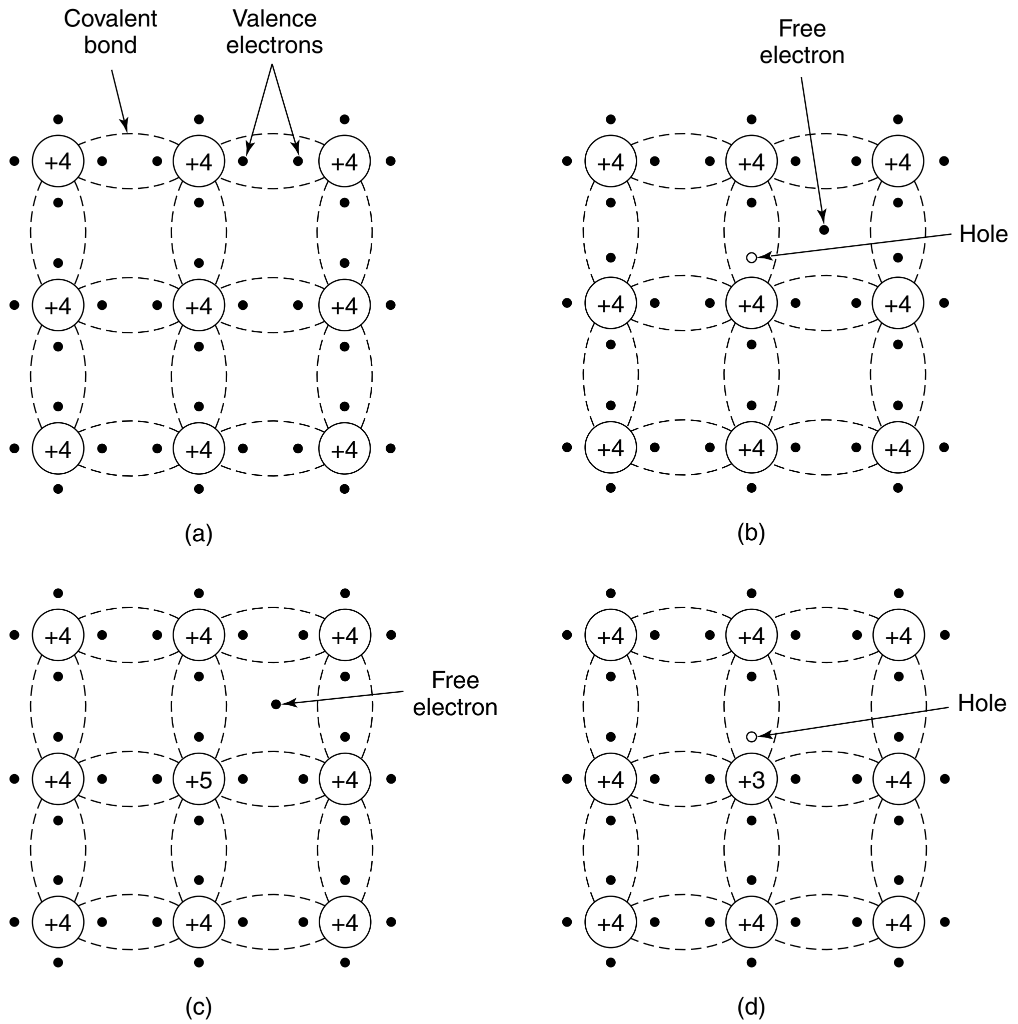

Fig. 1. (**a**) Silicon (valence = 4) crystal lattice shown in two dimensions with no broken bonds, $T = 0$ K; (**b**) silicon crystal lattice with a broken bond; (**c**) silicon crystal lattice with a silicon atom displaced by a donor dopant, i.e., n-doped (valence = 5); and (**d**) silicon crystal lattice with a silicon atom displaced by an acceptor dopant, i.e., p-doped (valence = 3)

at 25°C. This is the definition of peak sunlight test conditions. In theory, silicon $p - n$ junction solar cells can convert a maximum approaching 26% of the energy in AM 1.5 sunlight to electricity. Approximately 75% of the energy in sunlight is lost to factors intrinsic to the silicon material.

In comparison, $p - n$ homojunction cells made of more costly semiconductor materials, e.g., indium phosphide, InP, and gallium arsenide, GaAs, which have energy gaps of 1.2–1.4 eV, and maximum theoretical conversion efficiencies of ca 28–30%, depending on the device construction and layering of junctions.

Commercial Silicon Solar Cells

Silicon cells are hundreds of micrometers (μm) thick in order to facilitate handling with minimal breakage, although most solar radiation is absorbed in the first 20–30 μm. The junction in a silicon cell usually is ca 0.2–0.5 μm from the surface of the cell. The crystal surface has many broken bonds that act as recombination centers. In conventional silicon cells, a comb or narrow metal grid lattice is connected to a current-carrying bus to collect charge carriers from the side of the cell facing the sun. The fingers are small enough in total area so that minimal cell area is in their shadow.

Antireflection coatings are used over the silicon surface which, without the coating, reflects ca 35% of incident sunlight. Materials such as titanium dioxide, TiO_2, tantalum pentoxide, Ta_2O_5, or silicon nitride, Si_3N_4, ca 0.08-μm thick are common.

Types of Solar Cells. There are three basic technology options for making solar cells with dozens of variations on each. These approaches are conveniently grouped as follows: thick (~300 μm) crystalline materials, concentrator cells, and thin (~1 μm) semiconductor films.

Thick Crystalline Materials. Crystalline silicon technology is the worldwide industry standard. The total cost of solar cells made from ingots reflects the costs of the silicon raw material used in forming an ingot, cutting and etching thin silicon wafers from the ingot, fabricating and encapsulating the cells, and assembling them into modules. An attractive cost-reducing approach is to grow good quality crystalline sheets directly from molten silicon. Smoothly grown sheets ca 100-μm thick require little or no cutting and polishing and incur little waste.

Gallium arsenide is a promising material for gaining the advantages of high efficiency. It is superior to silicon in several respects. The Eg of GaAs, ca 1.4 eV, is higher than that of silicon and is in the range that provides the highest calculated conversion efficiency for a single-junction cell. Because of this high efficiency and the fact that it does not decline as rapidly as that of silicon cells with increasing temperature, GaAs single-crystal cells are attractive for use as concentrator cells.

Gallium arsenide solar cells advanced in the 1980s for space use because they weighed much less than silicon cells of similar output, since GaAs absorbs sunlight much more strongly than silicon.

Concentrator Cells and Systems. Concentrators circumvent the problem of high semiconductor material cost by using mirrors or lenses to concentrate sunlight on small surface areas of more expensive solar cells. Concentration allows more power to be produced from a given amount of photosensitive material.

Concentrator optics vary from low ratio designs, e.g., concentration of sunlight of an order of magnitude by Winston collectors, which do not require elaborate tracking of the sun, to much higher ratio systems based on parabolic mirrors or Fresnel lenses and which require precise, two-axis tracking. Three types of concentrator systems are being developed

which operate at low level (<30 times), mid-level (100–400 times), and high level (>400 times) sunlight concentrations. The cell specifications and engineering requirements for each of these types of systems are quite different. Specially designed silicon has shown potential for use in concentrator systems.

Thin Film. In the thin-film approach, raw material usage is generally more than two orders of magnitude less and patterning is more direct.

Good solar cell results have been obtained from cells of materials, including polycrystalline silicon, amorphous silicon–hydrogen (α-Si:H) alloys, Cu_xS–CdS, $CuInSe_2$–CdS, and CdTe.

Electrochemical Photovoltaic Cells. The application of photoelectrochemistry in solar energy conversion technologies includes biomass conversion, photoelectrolysis, photogalvanic cells, electrochemical photovoltaic cells, etc. In electrochemical photovoltaic cells, electric energy is converted directly from sunlight by absorption of light in a semiconductor electrode. In many respects, these cells closely resemble conventional solid-state cells, except that the charge-separating barrier layer is formed at the interface between a semiconductor surface with a liquid electrolyte. When sunlight is incident on the semiconductor electrode, free holes and electrons are created. The relevant minority carriers must migrate to the interface and be separated; these carriers then react with the electrolyte either through oxidation or reduction. The counterelectrode reverses the reaction, thereby maintaining the electrolyte balance. The semiconductor electrode material may be either polycrystalline or amorphous material because in some cases the poorer material properties cause relatively little degradation of conversion efficiencies. In addition, incorporation of a third electrode may make possible *in situ* storage. The main disadvantage of these cells is the instability of the semiconductor electrode, especially under sunlight, for extended periods of operation. Electrochemical cells could be inexpensive, since the electrode–electrolyte barriers usually are easy to form, but appropriate deployment strategies have not yet been identified. The stability problems encountered to date have been extensive.

Balance of Systems

A solar photovoltaic system contains, in addition to solar cells and module(s), an array structure to support the modules, power-conditioning circuitry for control and modification of the output, and a means of storing energy if required. All elements beyond the module are referred to as balance-of-system (BOS) components. The cost of BOS items is nominally about equal to the cost of the PV module. However, the BOS fractional cost contribution can vary from one- to two-thirds of the total installed cost of a system, depending on application.

Material Availability and Environmental Impact

Photovoltaic systems must satisfy four principal requirements before solar photovoltaic conversion can provide a significant portion of general energy needs. The system costs must be low enough to be competitive with other means of energy generation, the amount of energy generated during the life cycle of a photovoltaic system must be substantially greater than the energy required to fabricate the system to meet the criteria of a sustainable technology, the materials used in the cells must be available to generate a substantial portion, i.e., at least a few percent of world energy needs, and the fabrication and utilization of the conversion systems should not cause more environmental problems than other competing energy systems.

Silicon is the second most abundant element in the world and is not toxic. Inherent in the use of materials other than silicon for solar cells are challenges of material availability and environmental safety. In terms of production of CdS-based cells, sulfur is abundant, but the world's resources of cadmium, tellurium, selenium, and indium are much less than those of silicon. However, these resources are several orders of magnitude greater than the amount needed to provide photovoltaic power production of 50,000 MW/yr. Similarly, although arsenic is plentiful, the supply of gallium for GaAs cells is limited. However, studies have concluded that the gallium supply also is sufficient for substantial manufacturing scale.

Although photovoltaic conversion is nonpolluting, environmental, health, and safety aspects must be considered, especially with regard to harmful emission and waste products resulting from the production of the solar cell modules. It has been shown that, with proper encapsulation and a proactive recycling program, it should be possible to minimize environmental concerns.

Photovoltaic Markets

In the mid-1990s, utility applications have once again begun receiving a great deal of attention due to a profound paradigm shift that appears to be taking place in the utility industry. Rather than replacing or adding large central fossil-fueled or nuclear generation facilities, small PV systems deployed at the outer extremities of the grid can be cost-effectively used to manage demand profiles, defer transmission hardware upgrades, and support electrical service quality (voltage, power factor, etc) during periods of peak demand in locations where the utility grid transmission is unidirectional.

PV Market Segment Categories. Solar modules are used to provide power to a broad range of industrial, commercial, and consumer systems and products. Most participants in the PV industry use the following categories to describe the various market segments, which group applications by functional product requirement, system type, sales channel, and client base. These include the following: specialties, e.g., spacecraft circuits, calculator chips, automobile sunroofs, and building facades; industrial power, i.e., telecommunications, warning/signal lights, and remote data gathering; rural and off-grid electrification, e.g., lighting, water pumping and purification, refrigeration, and recreational travel and boating; consumer convenience, e.g., garden and security lighting and small battery charging; and grid-connected power, i.e., distributed grid support and peaking power augmentation.

PHTHALIC ACID. [CAS: 88-99-3]. $C_6H_4(COOH)_2$, formula weight 166.13, mp 208°C (ortho), 330°C (meta and iso), the ortho form sublimes and the meta and iso forms decompose with heat, sp gr 1.593 (ortho). Phthalic acid is very slightly soluble in H_2O, soluble in alcohol, and slightly soluble in ether. The solid form is colorless, crystalline. Because of their chemical reactivity and versatility, phthalic acid derivatives find wide use as starting and intermediate materials in important industrial organic syntheses. A common starting material is phthalic anhydride which is formed when phthalic acid loses water upon heating. See also **Phthalic Anhydride**; and **Terephthalic Acid**.

Orthophthalic acid is made by the oxidation of naphthalene (1) with H_2SO_4 fuming heated, in the presence of mercuric sulfate $-SO_2$ is also formed and recovered; (2) with air in the presence of vanadium pentoxide at 450 to 520°C. Orthophthalic acid also is formed when benzene compounds containing carbon ortho-substituted groups are oxidized. Orthophthalic acid is used in the manufacture of indigo and other dyes.

PHTHALIC ANHYDRIDE. [CAS: 85-44-9]. $C_6H_4(CO)_2O$, formula weight 148.11, mp 130.8°C, bp 284.5°C, sp gr 1.527. Phthalic anhydride is very slightly soluble in H_2O, soluble in alcohol, and slightly soluble in ether. The compound is a high-tonnage chemical and is widely used in a

variety of industrial organic syntheses. Although phthalic anhydride may be derived directly from phthalic acid by heating and dehydration, it usually is prepared on a large scale by (1) oxidizing naphthalene, or (2) from the petroleum derivative, orthoxylene. Phthalic anhydride, in addition to its use as a raw and intermediate material for syntheses, finds wide application in the chlorinated form as a compounding ingredient for plastics. The chlorine content is approximately 50%. The compound provides increased stability and improved resistance of plastics to high temperatures.

Representative reactions of phthalic anhydride include: (1) phthalic anhydride reacts with phosphorus pentachloride to form phthalyl chloride which, upon rearrangement, can be transformed to unsymmetrical phthalyl chloride; (2) both forms of phthalyl chloride react with zinc plus acetic acid to form unsymmetrical phthalide, or with benzene plus aluminum chloride to form unsymmetrical-diphenylphthalide (phthalophenone); (3) phthalic anhydride reacts with NH_3 to form phthalimide $C_6H_4(CO)_2NH$; (4) phthalimide reacts with KOH in alcohol to form potassium phthalimide; (5) treatment of potassium phthalimide with an alkyl halide (e.g., ethyl chloride) forms an alkyl phthalimide (e.g., ethyl phthalimide); (6) ethyl phthalimide, when heated with fuming HCl, yields the primary amine $C_2H_5NH_2$ (ethyl amine) in a reaction used for the production of many primary amines and known as Gabriel's synthesis; (7) ethyl phthalimide, when treated with sodium hypochlorite, forms sodium anthranilate which upon treatment with an acid yields anthranilic acid; (8) phthalic anhydride reacts with phenol to form phthaleins, such as phenolphthalein, when in the presence of concentrated H_2SO_4; (9) phthalic anhydride reacts with resorcinol to form resorcinolphthalein (fluorescein); (10) fluorescein reacts with bromine to form tetrabromo-fluorescein, the potassium salt of which is eosin (a red dye for wool and silk); (11) phthalic anhydride reacts with N-diethyl-meta-aminophenol to form N-diethyl-meta-aminophenolphthalein (rhodamine) which is a red dye.

Health and Safety Factors

Phthalic anhydride is a severe irritant to the eyes, respiratory tract, and skin, especially to moist tissue. The solid may burn skin tissue if it is in contact with it for a significant amount of time. Repeated exposure may result in asthma, irritation of mucous membranes, and diseases of the respiratory tract and digestive organs. Contact with skin or the eyes should be followed immediately by washing with large quantities of water.

There are explosion hazards with phthalic anhydride, both as a dust or vapor in air and as a reactant. Water, carbon dioxide, dry chemical, or foam may be used to extinguish the burning anhydride.

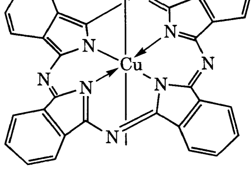
PHTHALOCYANINE COMPOUNDS. Phthalocyanine, $C_{32}H_{18}N_8$, compounds have found widespread acceptance in a variety of applications. The discovery of iron phthalocyanine and the elucidation of its structure led to the commercial application of copper phthalocyanine.

Copper phthalocyanine (**1**) was developed in the 1930s and is the most commonly used blue organic pigment in the coatings, paint, and printing inks industry. Phthalocyanine forms complexes with numerous metals. Various complexes with 66 chemical elements are known. Phthalocyanines are structurally related to naturally occurring dyes such as hemoglobin and chlorophyll A.



(**1**)

Physical Properties

The density of β-phthalocyanine, H_2Pc, is 1.43 g/cm^3; β-copper phthalocyanine, CuPc, 1.61 g/cm^3; and polychloro-copper phthalocyanine, 2.14 g/cm^3. The color of most phthalocyanines ranges from blue-black to a metallic bronze, depending on the manufacturing process and the chemical and crystalline form of the material. The colors of the finely divided pigment forms vary from dark blue to green, as phthalocyanines absorb in the visible region at 600–700 µm. Most compounds do not melt but sublime above 200°C. CuPc can be sublimed without decomposition at 500–580°C under an inert gas and normal pressure and at 900°C under vacuum. It decomposes vigorously, however, at 405–420°C in air and in nitrogen between 460–630°C. The thermodynamic stability of the five crystalline forms of CuPc increases in the sequence $\alpha = \gamma < \delta < \varepsilon < \beta$. The solubility of most phthalocyanines in water and organic solvents is very low. The α-form, however, is slightly soluble in polar solvents and converts rapidly to the β-form.

Chemical Properties

The chemical properties of phthalocyanines depend mostly on the nature of the central atom. Phthalocyanines are stable to atmospheric oxygen up to approximately 100°C. Mild oxidation may lead to the formation of oxidation intermediates that can be reduced to the original products. In aqueous solutions of strong oxidants, the phthalocyanine ring is completely destroyed and oxidized to phthalimide. Oxidation in the presence of ceric sulfate can be used to determine the amount of copper phthalocyanine quantitatively.

Phthalocyanine compounds exhibit favorable catalytic properties which makes them interesting for applications in dehydrogenation, oxidation, electrocatalysis, gas-phase reactions, and fuel cells.

Manufacturing and Processing

Phthalocyanine compounds have been synthesized with various metals. The most important metal phthalocyanines are derived from phthalodinitrile, phthalic anhydride, Pc derivatives, or alkali metal Pc salts.

The route from *o*-phthalodinitrile can be represented $4\ C_8H_4N_2 + M \longrightarrow MPc$, where M is a bivalent metal, metal halide, metal alcoholate, or an equivalent amount of metal of valence other than two in a 4:1 molar ratio. If a solvent, e.g., trichlorobenzene, benzophenol, pyridine, nitrobenzene, or quinoline, is used, the reaction takes place at approximately 180°C. Without a solvent the dry mixture must be heated to ca 300°C to initiate the exothermic reaction.

The synthesis from phthalimide derivatives, e.g., diimidophthalamide (or phthalimide) is usually carried out in a solvent such as formamide. Metal phthalocyanines may also be prepared using alkali metal salts or from metal-free phthalocyanine by boiling the latter in quinoline with metal salt.

Industrial production of copper phthalocyanine usually favors either the phthalic anhydride–urea process or the *o*-phthalodinitrile process. Both can be carried out continuously or batchwise in a solvent or bake process of the solid reactants.

Crude copper phthalocyanine must be treated to obtain a satisfactory pigment in regard to the crystal modification and optimal particle size. See also **Pigments (Organic)**. The particle size of crude phthalocyanine can be reduced by chemical or mechanical methods.

The second process to finish phthalocyanine, which is more important for β-copper phthalocyanine, involves grinding the dry or aqueous form in a ball mill or a kneader. Agents such as sodium chloride, which have to be removed by boiling with water after the grinding, are used. Solvents like aromatic hydrocarbons, xylene, nitrobenzene or chlorobenzene, alcohols, ketones, or esters can be used.

Incorporation of less than a stoichiometric amount of alkyl sulfonamides of copper phthalocyanines into copper phthalocyanine improves the pigment's properties in rotogravure inks.

Performance in ink and coatings can be improved by addition of surfactants, dispersants, resins, or copper phthalocyanine derivatives with long aliphatic chains, $CuPc(CH_2{-}NHR)_3$, to stabilize the pigment in the binder system. Another possibility is wet-milling of aqueous pigment dispersions incorporating an organic medium, e.g., glycols, polyethers, or surfactants.

Some references cover direct preparation of the different crystal modifications of phthalocyanines in pigment form from both the nitrile–urea and phthalic anhydride–urea process. Metal-free phthalocyanine can be manufactured by reaction of *o*-phthalodinitrile with sodium amylate and alcoholysis of the resulting disodium phthalocyanine. The phthalic anhydride–urea process can also be used. Other sodium compounds or an electrochemical process have been described. Production of the different crystal modifications has also been discussed.

Perchloro- and perchlorobromo copper phthalocyanine are important organic green pigments. They are accessible through direct chlorination of copper phthalocyanine in a eutectic melt of aluminum and sodium chloride or in a chlorosulfonic acid medium. Bromine can be used instead of chlorine in the $AlCl_3{-}NaCl$ melt to obtain polybromochloro copper phthalocyanine.

Phthalocyanine sulfonic acids, which can be used as direct cotton dyes, are obtained by heating the metal phthalocyanines in oleum.

Polymeric phthalocyanines, which possess a higher stability compared to the monomers, can be obtained by combining a phthalocyanine with a polymer. The linking of the polymeric chain can occur at the central metal atom, the phenyl rings, through bridging or attachment to a polymeric chain.

Uses

Approximately 90% of the phthalocyanines (predominantly copper phthalocyanine) are used as pigments. In addition, they have found acceptance in many types of dyestuffs, e.g., direct and reactive dyes, water-soluble and solvent-soluble dyes with physical and chemical binding, azo-reactive dyes, azo nonreactive dyes, sulfur dyes, and vat dyes.

Available Forms. Phthalocyanines are available as powders, in paste, or liquid forms. They can be dispersed in various media suitable for aqueous, nonaqueous, or multipurpose systems, e.g., polyethylene, polyamide, or nitrocellulose. Inert materials like clay, barium sulfate, calcium carbonates, or aluminum hydrate are the most common solid extenders. Predispersed concentrates of the pigments, like flushes, are interesting for manufacturers of paints and inks, who do not own grinding or dispersing equipment. Pigment–water pastes, i.e., presscakes, containing 50–75% weight of water, are also available.

Colorants. The pigmentary forms of copper phthalocyanine are by far the most important commercial products of that class. They provide excellent color properties, excellent resistance to heat and light, acid and alkali, and are extremely insoluble in most solvents. They are less expensive than other organic pigments and color practically every type of printing ink, paint, plastic, and textile. Other uses include the coloring of roofing granules, cements and plasters, fine art paint, soaps, detergents, and other cleaning products. The two principal classes of copper phthalocyanine pigments are the blues and the greens. The blues may be further classified as the α- and β-crystal types, and the greens as the chlorinated and brominated derivatives.

Phthalocyanines have interesting properties as catalysts, lasers, semiconductors, lubricants, or as photographic components.

Health and Safety Factors

Phthalocyanines do not pose any significant risk to human health in the environment or the workplace. In several studies, no carcinogenic risk or toxicity to humans was revealed. The FDA approved the use of CuPc in general and ophthalmolic surgery, for contact lenses, and food packaging. Phthalocyanine Blue may be used as a colorant for coatings that are used in manufacturing, packing, processing, preparing, treatment, packaging, transporting, or holding food. The TLV value for CuPc is 10 mg/m^3.

Polychlorinated biphenyls (PCBs) have been detected in pigments manufactured in trichlorobenzene, but not in those made with nonchlorinated solvents. High boiling hydrocarbons or esters are suitable replacements.

PHYCOCOLLOID. One of several carbohydrate polymers (polysaccharides) occurring in algae (seaweed). They are hydrophilic colloids having a tendency to absorb water, with swelling, and to form gels of varying strength and consistency. The chief types of phycocoloid are carrageenan from Irish moss, algin from brown algae, and agar from red algae. They contain complex galactose and mannose sugars and are sometimes considered seaweed mucilages.

PHYTOCHEMISTRY. That branch of chemistry dealing with (1) plant growth and metabolism and (2) plant products. The former includes the absorption of inorganic nutrients (nitrogen, phosphorus, potassium, carbon dioxide, water, etc.) to form sugars, starches, proteins, fats, vitamins, etc. and is closely associated with photosynthesis. Plant products comprise a vast group of natural materials and chemicals; besides those used directly as foods, these include alkaloids, cellulose, lignin, dyes, glucosides, essential oils, resins, gums, tannins, rubbers, terpene hydrocarbons, and glycerides (fats and oils). Some of these are basic raw materials for industry (paper, pharmaceuticals, food, paint, perfume, flavoring, leather, rubber); there are also many miscible plant products such as drugs, poisons, and pigments. Phytochemistry also embraces the study of plant hormones or growth regulators (auxin, gibberellin, synthetic types).

PICKLING. (1) Removal of scale, oxides, and other impurities from metal surfaces by immersion in an inorganic acid, usually sulfuric, hydrochloric, or phosphoric. Rate of scale removal varies inversely with concentration and temperature; the usual concentration is 15% at or above 100°C. The rate is also increased by electrolysis. (2) A method of food preservation involving use of salt, sugar, spices, and organic acids (acetic). (3) Preserving or preparing hides for tanning by immersion in a 6–12% salt solution, together with enough acid to maintain pH at 2.5 or less.

PICOLINES. See **Pyridine and Derivatives**.

PIDGEON PROCESS. Also referred to as ferrosilicon process or silicothermic process. Process for the production of high-purity magnesium

metal from dolomite or magnesium oxide by reduction with ferrosilicon at 1150°C under high vacuum.

PIEZOCHEMISTRY. Study of reactions occurring at very high pressures, e.g., in the interior of the earth's crust.

PIEZOELECTRIC EFFECT. The interaction of mechanical and electrical stress-strain variables in a medium. Thus, compression of a crystal of quartz or Rochelle salt generates an electrostatic voltage across it, and conversely, application of an electric field may cause the crystal to expand or contract in certain directions. Piezoelectricity is only possible in crystal classes which do not possess a center of symmetry. Unlike electrostriction, the effect is linear in the field strength.

The directions in which tension or compression develop polarization parallel to the strain are called the piezoelectric axes of the crystal. Thus the axis of a hexagonal quartz crystal indicated by the arrows in Fig. 1 is known as an "X-axis," and a plate cut, as shown, with its faces perpendicular to this direction is an "X-cut"; while one cut with its faces parallel to the lateral faces of the crystal is a "Y-cut."

The magnitude of the piezoelectric polarization is proportional to the strain and to the corresponding stress, and its direction is reversed when the strain changes from compression to tension. The principal piezoelectric constants of a crystal are the polarizations per unit stress along the piezoelectric axes. While these constants are much greater for Rochelle salt than for quartz, the latter is better adapted to some purposes because of its greater mechanical strength. It is also stable at temperatures over 100°C.

If a quartz plate is subjected to a rapidly alternating electric field, the inverse piezoelectric property causes it to expand and contract alternately. As an elastic body, the plate has a certain natural frequency of expansion and contraction in the direction of the field, and if the field is made to alternate with the same frequency, the plate responds with a vigorous resonant vibration. This reacts, through the direct piezoelectric property, to augment the electric oscillations. A circuit arranged for this purpose, as in Fig. 2, is known as a piezoelectric or crystal oscillator, the crystal itself, P, being the piezoelectric resonator; T is the oscillation transformer, and C a variable condenser. This device has been much used as a frequency control in radio transmitters. Both X-cut and Y-cut quartz plates are subject to changes of frequency with temperature, due to change of elastic modulus; but certain planes in the crystal have been found, oblique to both X and Y, such that plates cut parallel to them are nearly free from the temperature effect.

In addition to natural quartz, Rochelle salts, and tourmaline, synthetic crystals, such as ethylenediamine tartrate (EDT), dipotassium tartrate (DKT), and ammonium dihydrogen phosphate (ADP) have varying suitability as piezoelectric elements. While Rochelle salt has a greater piezoelectric effect than any other crystal, it has the disadvantage of a greater sensitivity to temperature change than quartz. EDT has an advantage over quartz when used in frequency-modulated oscillators because of the wide gap between its resonant and antiresonant frequencies. See also **Quartz**.

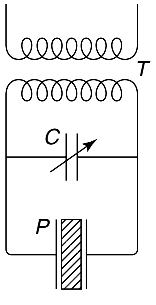

Fig. 2. Piezoelectric oscillator circuit

PIEZOELECTRICITY. Electric energy created by application of pressure to ceramics of plastics. Devices utilizing this phenomenon are gas flame igniters, ultrasonic welding tools, and sonar navigation aids.

See also **Piezoelectric Effect**.

PIG IRON. Product of blast-furnace reduction of iron oxide in the presence of limestone. About half the ore is converted to iron. Average analysis is 1% silicon, 0.03% sulfur, 0.27% phosphorus, 2.4% manganese, 4.6% carbon, balance iron. Pig iron is the basic raw material for steel and cast iron. In metal terminology a "pig" is a bar or ingot of cooled metal.

PIGMENT DISPERSIONS. A pigment dispersion in a concentrated form is a uniform distribution of very fine color pigment particles in a suitable medium or carrier. Such a dispersion is normally used for applying color to the surface of a substrate, such as an ink film on paper or a paint film on a steel surface. It is also used for mass coloring, as in the case of plastics. Considering the high cost and specialized equipment in its preparation, a dispersion is manufactured in relatively small batches in highest concentration of pigment. The concentrate made in such a manner is usually diluted, reduced, or extended to produce the finished product.

Dispersion

Organic and inorganic pigment powders are finely divided crystalline solids that are essentially insoluble in application media such as ink or paint. The carrier used for dispersion of a pigment is usually a liquid or solid, such as a polymer, that is deformable at the processing conditions of high temperature and/or shear. The color strength of the dispersed pigment increases markedly with decrease in particle size. Optimum color strength from a given pigment in practice requires a mean particle size of the order of 0.1 μm or less, which is half the wavelength of the light involved. Therefore, the dispersion process involves size reduction of the pigment particle to the smallest practical size, reasonably complete wetting of its solid surfaces by the carrier, and stabilization of the resulting dispersion.

Because the intensity and color strength of pigments are largely dependent on the exposed surface, it is desirable to reduce the particles to primary particle size. This is the size of the solid pigment crystals as they are precipitated in their synthesis. In practice, the size reduction processes are limited by the nature of pigment, dispersion system, constraints of the processing equipment, the requirements imposed by the product application, and the overall economics. The maximum aggregate size permissible in a given dispersion system depends on the thickness of the film or the coating. For example, the dispersion used for architectural coatings can tolerate a much larger pigment aggregate than a similar dispersion used for automotive finishes, which requires finer particles. Any dispersion system, however, is expected to contain a very small number of these largest aggregates. Generally, it is important to reduce most aggregates to the smaller size to achieve color strength, gloss, film integrity, and durability.

In a dispersed pigment system, a primary pigment particle refers to an individual crystal and a loosely formed association of the pigment crystals from the manufacturing process. Size reduction beyond primary particle size requires excessive energy, but it also has an adverse effect on the visual properties of the pigment. Generally, the particle size of most organic pigments is much smaller initially by precipitation than optimum primary particles, but the particles tend to grow to a much larger size when their formation is complete.

Organic pigments, such as the azo red and yellow pigments, in the process of striking the color undergo definite crystal growth following their precipitation from the aqueous media. The individual crystals are joined together due to forces on the crystal surfaces to form the aggregate. These are held together as static systems by van der Waals forces. Subsequent processing to recover the pigment product results in the formation of agglomerates, which are large associations of pigment crystals and aggregates. The agglomerates are held together by forces that are much weaker than those present within the aggregates. Typically, agglomerates are joined at the edges and corners in a loose matrix form. It is possible to generate an even larger association of pigment agglomerates or flocculates during further processing. These formations are loosely held together and are usually easy to break down by application of shear. Various surface

treatments are used to suppress the formation of large aggregates and, thereby, ease the dispersion process. These treatments range from the classical approach of rosination to additions of a variety of surface-active agents at the synthesis step. However, occasionally large agglomerates, several millimeters in diameter, form during the initial stages of dispersion in a highly viscous system. The commercial processes used in dispersion manufacturing may not fully eliminate the aggregates. However, the design and operation of pigment dispersion equipment is aimed at application of mechanical forces to break down the agglomerates and even some less tightly held aggregates. Ideally, an excellent dispersion should consist mainly of primary pigment particles and few loosely held aggregates.

Wetting of the pigment surface constitutes a critical step in achieving a stable and uniform pigment dispersion. Wetting refers to displacement of adsorbed gases (usually air) on the surface of pigment particles, followed by attachment of a vehicle system to the pigment surface. Since the vehicles used for many dispersion systems are viscous, it follows that the penetration of vehicles to the pigment surface is slow and, hence, aided by external mechanical forces. Thus, the grinding (size reduction) and wetting of pigment are frequently carried out simultaneously. The adsorbed gases are displaced on application of shear, and the action also provides smearing of vehicle on the pigment surface and exposes a new surface for wetting. The system of wetted fine primary pigment particles, must be stabilized to prevent reversal of the dispersion process. It is usually done by surrounding the particles with a protective colloid or buffer, which blocks the reagglomeration action of particles. In some cases, the stabilization is attained by addition of ions to establish similar charges on all particles.

Flushing

Flushing processes are used extensively in preparing organic pigment dispersion concentrates for color printing ink applications. The process can be described as a direct transfer of pigment from an aqueous phase to an oil or nonaqueous phase without drying. When the pigment presscake is mixed with an oil-based vehicle or a carrier, water is separated from the pigment surface and replaced by the vehicle. Most organic pigments demonstrate an affinity for hydrocarbon oils and lend themselves to easy dispersion in oil by the process of flushing. See also **Pigments (Organic)**. Inorganic pigments, on the other hand, have to be treated with cationic surfactants to make their surface lipophilic. The majority of inorganic pigments are usually dried and dispersed as dry powders in the carrier, as opposed to being flushed. Techniques used for dispersion of these pigments are different and should be treated as special cases. See also **Pigments (Inorganic)**.

The process of flushing typically consists of the following sequence: phase transfer; separation of aqueous phase; vacuum dehydration of water trapped in the dispersed phase; dispersion of the pigment in the oil phase by continued application of shear; thinning the heavy mass by addition of one or more vehicles to reduce the viscosity of dispersion; and standardization of the finished dispersion to adjust the color and rheological properties to match the quality to the previously established standard.

Flushing is frequently used for the manufacture of large quantities of a dispersion having a specific pigment in a compatible vehicle system. The flushed products, typically containing 28–40% pigment, offer sufficient flexibility to the formulator to produce the finished offset ink. The flushed products exhibit superior gloss, transparency, and strengths, compared to those produced by dispersing the dried pigment. Flushing is particularly important to dispersions of organic pigments, such as Diarylide Yellow (CI Pigment Yellow 12, CI 21090) and Alkali Blue (Pigment Blue 61, CI 42765) because the drying process is detrimental to the product quality of these pigments.

Equipment

Various types of equipment are used commercially to manufacture dispersed pigment concentrates or finished dispersion products used by printing ink, and the coatings and plastics industry. These include kneaders or internal mixers; close tolerance mills; high speed fluid energy mills; ball and pebble mills; san, bead, and shot mills.

Uses

The formulation of dispersed pigment concentrates is influenced by the manufacturing process, as well as the performance parameters desired in the final application. The finished product in many cases is significantly different in formulation than the concentrate to achieve desired properties. One of the principal factors to be considered is the concentration of pigment in the dispersion concentrate. Compatibility of the carrier (solvent additives, etc) used in the preparation of concentrated dispersion and that used in the finished color product also plays an important role. In some cases this can be difficult because the carriers having the best performance, from the standpoint of processing, could be poor in the application systems. However, in the majority of the applications, particularly in coatings and colored plastics, the concentration of the pigment in the finished product is quite low, and the incompatibility problem is easily overcome.

Generally, the pigment dispersion concentrates are formulated for specific end use. They can be supplied as flushed pigments, dispersions or pastes for offset inks, chip dispersions for solvent and aqueous inks, and color concentrates for coloring large quantities of plastics. Although it is feasible for the end user to prepare the pigment dispersion concentrates, it is usually more cost effective and technologically advantageous to manufacture these dispersions by the pigment manufacturers of specialty dispersion houses. Three significant areas of application for concentrated dispersions, i.e., printing inks, coatings, and plastics.

PIGMENTATION (Plants). The distinctive green color of leaves and other plant organs results from the presence in such organs of two pigments called chlorophyll *a* and chlorophyll *b*. In the higher plants these pigments occur only in the chloroplasts. These pigments play so important a role in the fundamental process of plant life, photosynthesis, that their chemical reactions are discussed at length in that entry. The chlorophylls are not water-soluble but can be readily dissolved out of leaf tissues with alcohol, acetone, ether, or other organic solvents. The resulting solutions exhibit the phenomenon of fluorescence; they are deep green when held between an observer and the light, but deep red when viewed in reflected light. By suitable treatments it is possible to obtain pure crystals of chlorophyll from such solutions. Most leaves contain considerably more chlorophyll *a* than chlorophyll *b*, often two to three times as much. In the organs of the higher seed plants, with rare exceptions, chlorophyll is synthesized only upon exposure to light. Leaves of grass that develop under a board, for example, contain no chlorophyll. In the leaves of mosses, ferns, and gymnosperms, however, chlorophyll develops in the dark as well as in the light.

Invariably associated with the chlorophylls in the chloroplasts are the yellow pigments, the carotenes and the xanthophylls. These pigments are not, however, restricted in their occurrence to the chloroplasts, but may also be present in nongreen parts of the plant where they commonly occur in chromoplasts. Collectively, these pigments, together with certain others which are closely related chemically, are called the carotinoids. Carotene refers to a class of orange-yellow pigments. They are especially abundant in the roots of carrots. These compounds are of considerable importance because they are the precursors of vitamin A, one molecule of β-carotene being split into two molecules of vitamin A by a simple hydrolytic reaction.

Lycopene, a red pigment of this class, is responsible for the red color of the fruits of tomato, pepper, rose, and some other species. The commonest xanthophylls found in leaves are lutein and zeaxanthin, although others also occur. Another xanthophyll is fucoxanthin, which imparts to brown algae their distinctive color. None of the carotenoids is water soluble, but all of them can be extracted from plant tissues with suitable organic solvents.

Most of the red, blue, and purple pigments of plants belong to the group of anthocyanins. In general, the anthocyanins are red in an acid solution and change in color through purple to blue as the solution becomes more alkaline. Red pigmentation resulting from the presence of the anthocyanins is found in flowers, fruits, bud scales, young leaves and stems, and sometimes even mature leaves as in those of the red cabbage. Blue and purple pigmentation due to the presence of anthocyanins occur principally

in flowers and fruits. The anthocyanins are diglucosides of the compounds pelargonidin, cyanidin, delphinidin and apigenidin. These compounds are closely similar in structure, all having the double ring benzopyrylium.

Another group of cell sap water-soluble pigments is the *anthoxanthins*. These pigments are also chemically related to the glucosides. Anthoxanthins often occur in the plant in a colorless form but under suitable conditions their typical yellow or orange color becomes apparent. Some yellow flowers, such as yellow snapdragons, owe their color to the presence of anthoxanthins, but the color of the majority of kinds of yellow or orange flowers is due to carotenoid pigments.

The autumnal coloration of leaves in temperate regions is one of the most spectacular accompaniments of the march of the seasons. Both carotenoid and anthocyanin pigments play an important role in autumnal leaf coloration which is not, contrary to popular opinion, a result of the action of frost. Brilliant development of the anthocyanin pigments in the fall is, however, favored by dry weather during which cool, but not frosty, nights alternate with clear days. During the late summer and early fall the chlorophyll in the leaves gradually decomposes. In many species this simply results in unmasking the yellow carotenoid pigments already present, accounting for the yellow autumnal pigmentation of such species as birch, sycamore, aspen, and tulip trees. In other species synthesis of anthocyanins occurs more or less concomitantly with the disintegration of the chlorophyll; this accounts for the reds or purplish reds characteristic in the autumnal coloration of such species as many oaks, maples, sumacs, and dogwood.

Except in flowers, white is an uncommon color in the externally visible parts of plants, and results from the complete absence of pigments. In some species white streaks or other markings are of common or regular occurrence in leaves, and in the leaves of some species such as roses completely white leaves or even entire branches bearing only white leaves sometimes occur. Such branches cannot be propagated because no photosynthesis can take place in the absence of chlorophyll. As long as such branches remain attached to a plant bearing green leaves they can obtain necessary food from the branches bearing normally pigmented leaves.

PIGMENTS (Inorganic). Inorganic pigments, black, white, or colored inorganic substances produced and marketed as fine powders, are an integral part of many decorative and protective coatings and are used for the mass coloration of plastics, fibers, paper, rubber, glass, cement, glazes, and porcelain enamels. See also **Enamels, Porcelain or Vitreous**. These materials are colorants in printing inks, cosmetics, and markers, e.g., crayons. In all these applications the pigments are dispersed, i.e., they do not dissolve, in the media forming a heterogeneous mixture. See also **Pigment Dispersions**. In nature, inorganic pigments contribute to the color of some rocks and minerals. See also **Colorants (Foods)**; and **Paints and Coatings**.

Originally, only fine powders used for coloring various media were defined as pigments. This definition has been expanded to include many powdery materials, e.g., metallic powders and powders having magnetic or anticorrosive properties, which are intentionally dispersed (not dissolved) into media to increase value and/or impart some special properties.

Chemically, inorganic pigments are quite simple materials and include elements, their oxides, mixed oxides, sulfides, chromates, silicates, phosphates, and carbonates. The application usefulness of inorganic pigments is determined by physical as well as chemical properties.

Properties

The value of pigments results from their physical–optical properties. These are primarily determined by the pigments' physical characteristics (crystal structure, particle size and distribution, particle shape, agglomeration, etc.) and chemical properties (chemical composition, purity, stability, etc.). The two most important physical–optical assets of pigments are the ability to color the environment in which they are dispersed and to make it opaque.

The opacity of a pigment lies in its ability to prevent a transmission of light through the medium. White pigments disperse the whole visible light spectrum more effectively than they absorb it; black pigments do the opposite. Color results when pigment particles absorb only certain portions of the visible light spectrum while dispersing the rest of it.

The opacity of pigments is a function of the pigment particle size and the difference between the pigment's refractive index and that of the medium in which pigment particles are dispersed. The multiple light dispersion in the pigment–medium interface results in the appearance that the light is transmitted through a much thicker layer than it actually is. A pigment having a particle size between 0.16–0.28 μm gives the maximum dispersion of the visible light.

The most common measurements of pigment properties comprise elemental analysis, impurity content, crystal structure, particle size and shape, particle size distribution, density, and surface area. These parameters are measured so that pigments' producers can better control production, and set up meaningful physical and chemical pigments' specifications. Measurements of these properties are not specific only to pigments. The techniques applied are commonly used to characterize powders and solid materials, and the measuring methods have been standardized in various industries.

Coloristic properties of pigments are best evaluated by dispersing them into the media they were developed to color, e.g., plastics, glass enamels, glazes, etc. The measured characteristics include color, color strength, opacity, lightfastness, weathering, heat stability, chemical stability, and rheological properties. The dispersing media and the processing conditions can strongly influence the results. Because pigments, as any fine powders, have a tendency to segregate by size during transportation and handling, the use of proper sampling methods is critical for getting meaningful physical and chemical data.

Chemical Properties. Elemental profile, impurity content, and stoichiometry are determined by chemical or instrumental analysis. Instrumental analytical methods are usually faster, can be automated, and can be used to determine very small concentrations of elements. Atomic absorption spectroscopy and x-ray fluorescence methods are the most useful instrumental techniques in determining chemical compositions of inorganic pigments. Chemical analysis of principal components is carried out to determine pigment stoichiometry.

Crystal Structure. Crystal structure, the information about compounds such as impurities or unreacted materials present in the pigment, the presence of various crystal phases, and the degree of the crystallinity, can be resolved using an x-ray diffractometer. In most cases, analyzed pigments are not completely unknown, and the powder diffraction pattern is sufficient in finding present phases or unreacted starting materials in the pigment. The x-ray analysis has become an indispensable tool of the inorganic pigments' development and production.

Physical Properties. Particle size and distribution are the most fundamental measured properties of powders (see **Size Measurement of Particles**). These properties impact a number of pigment characteristics. Those affected the most are the color, color strength, hiding power, and rheological properties. Actual powders consist of a population of particles of many different shapes. To permit a good description of powder population, a representative sample of the powder must be collected, measured, and the results interpreted using statistical methods. For inorganic pigments to be useful in most applications, they must have an average particle size between 0.1 and 10 μm. A character, i.e., color or pattern, of a substrate becomes obscured when coated with a pigment containing film such as a paint or a ceramic glaze. The degree of the obscuration (opacity) depends on the amount and type of pigment used and the thickness of the applied film.

The ability of a coating to hide the substrate is called its hiding power. Hiding power of a uniform coating is expressed as the area of substrate that can be hidden by a unit volume of the coating (ft^2/gal or m^2/L).

The ability of a pigment to change the color of an opaque film is known as its tinting strength. Both the hiding power and tinting strength are the fundamental pigment properties. Hiding power and tinting strength can be determined visually or instrumentally.

Color matching is a process in which a technician prepares a formulation, i.e., a mixture of pigments in a desired medium, that has the desired color effects. A good color match in one medium, e.g., plastic, is not always a good match in another medium, e.g., ceramic glaze.

Experienced color matchers can achieve a good color match by trial and error without using any instrumentation. In some cases, however, this technique can be a lengthy process. To get the most cost-effective match in the shortest possible time, the use of a computer color matching system is preferable.

Many pigments, when exposed to high intensity light such as direct sunlight or uv lamp, can get darker, change their shade or lose the color saturation. The color and its saturation change mainly for organic pigments. Inorganic pigments, particularly those containing ions that can exist in

several oxidation states, usually get darker. Some color changes can be reversible; others are permanent.

Lightfastness is measured by exposing pigmented film to an artificial or natural light for a predetermined time. It is a relative term where the color of a sample exposed to a known light source is compared to its original color values.

Weathering is the ability of the colored system, i.e., the coating, paint, etc., not the pigment alone, to resist light and environmental conditions. Changes in color and gloss are two main factors that are evaluated in weathering tests.

Heat stability is measured as a change in the hue of the colored system and a degree of yellowing of the white system after exposure to a desired high temperature for a certain time. This property can also be expressed as the maximum temperature at which the color of the system does not change.

In determining the chemical resistance, color changes of pigmented binder surfaces are measured after their exposure to various chemicals, such as water–sulfur dioxide or water–sodium chloride systems. These systems imitate the environment to which the colored articles could become exposed.

The surfaces of pigment particles can have different properties and composition than the particle centers. This disparity can be caused by the absorption of ions during wet milling, e.g., the $-OH$ groups, on the surface.

Most inorganic pigments are hydrophilic and therefore can be readily wetted only by polar solvents, e.g., water. The wettability and dispersion of inorganic pigments in an organic matrix (polymer, solvent) can be improved by the physical or chemical absorption of surface-active compounds containing polar groups, such as $-NH_2$, $-OH$, or longer aliphatic chains on pigment particles. The absorption of these compounds makes the pigment surface hydrophobic. Compounds that help to form a bridge between inorganic particles and an organic polymeric matrix are called coupling agents, the most common being tetrafunctional organometallic compounds.

Specifications, Standards, and Quality Control

Production and product quality of most pigment producers are controlled through pigments' standards. Whenever a pigment is developed or significantly improved, a new standard is set that represents the average production results, not necessarily the best ones. If all production processes are under control, the properties of the produced pigment's lots are evenly distributed around those of the standard.

White Pigments

The most common white pigments are titanium dioxide, zinc oxide, leaded zinc oxide, zinc sulfide, and lithopone, a mixture of zinc sulfide and barium sulfate. The use of lead whites and antimony oxides has been decreasing steadily for environmental reasons.

Titanium Dioxide. Chemically, titanium white is titanium dioxide either in an anatase or rutile form.

Properties. Crystals of titanium dioxide, TiO_2, can exist in one of the three crystal forms: rutile, anatase, and brookite. Only anatase and rutile forms have good pigmentary properties, and rutile is more thermally stable. Compared to other white pigments, titanium dioxide has the highest refractive index, giving white paints formulated with these pigments the highest coverage, ca 38 m^2/g.

Titanium whites resist various atmospheric contaminants such as sulfur dioxide, carbon dioxide, and hydrogen sulfide. Owing to its chemical inertness, titanium dioxide is a nontoxic, environmentally preferred white pigment.

Titanium is the seventh most common metallic element in the earth's crust. Titanium minerals are plentiful in nature. The most common mineral/raw materials used for the production of titanium dioxide pigments are shown in Table 1.

TABLE 1. MINERAL/RAW MATERIALS FOR TiO_2 PRODUCTION

Mineral/raw material	Main composition	TiO_2, %
ilmenite	$FeO-TiO_2$	35–65
leucoxene	$Fe_2O_3-TiO_2(+TiO_2)$	60–90
rutile	TiO_2	90–98
rutile, synthetic	TiO_2	85–96
anatase	TiO_2	80–90
titanium slag	$TiO_2(Fe)$	70–85

Use. Titanium dioxide is used mainly in the production of paints and lacquers, plastics, and paper. Other applications include the pigmentation of printing inks, rubber, textiles, leather, synthetic fibers, ceramics, white cement, and cosmetics.

Other White Pigments.

Zinc Oxide. By volume, zinc oxide is the second most significant white pigment. Its pigmentary properties are good, providing good coverage. It has a good lightfastness and is well miscible with other pigments. With the increasing popularity of titanium dioxide white pigment in the twentieth century, the pigmentary use of zinc oxide has been declining.

Whereas zinc oxide was originally used as a pigment, its most important modern application is to aid in vulcanizing synthetic and natural rubber. Paint and coating industries use zinc white mainly as an additive to improve anticorrosion properties, mildew resistance, and durability of external coatings.

Zinc Sulfide. Whereas zinc sulfide is important mainly as a component of the composite white pigment lithopone, it also has a limited use as a single pigment. After titanium white, it has the second highest refractive index of all the white pigments. However, its chemical and thermal resistances are inferior to those of TiO_2.

Zinc sulfide is used in applications where white color shade and low abrasivity are required. In printing inks and paints it also contributes to stability and good rheological and printing properties.

Lithopone. Lithopone is a mixture of ZnS and $BaSO_4$. The pigmentary properties of the mixture are determined by zinc sulfide, and therefore lithopone pigments are characterized by the amount of ZnS present in the mixture. The amount of ZnS in commercial lithopones varies from 15 to 60%.

Lithopones are used in water-based paints because of their excellent alkali resistance, in paper manufacturing as a filler and opacifying pigment, and in rubber and plastics as a whitener and reinforcing agent.

Lead Whites. Basic lead carbonate, sulfate, silicosulfate, and dibasic lead phosphite are commonly referred to as lead whites. Usage is limited because of environmental restrictions placed on the use of lead-containing compounds.

Colored Pigments

Iron Oxide Pigments. In general, all iron pigments are characterized by low chroma and excellent lightfastness. They are nontoxic, nonbleeding, and inexpensive. They do not react with weak acids and alkalies, and if they are not contaminated with manganese, do not react with organic solvents. However, properties vary from one oxide to another.

Natural Iron Oxides. The earth's crust contains about 7 wt % iron oxides, but only a few deposits are rich enough in iron to be suitable for mining pigmentary-quality iron oxides. Deposits that are a suitable source of natural iron oxide pigments are usually hydrated aluminum silicates that contain various amounts and forms of iron oxide.

Iron oxides are supplied to the market as red, ocher, sienna, and umber natural pigments. The hue of the natural iron oxide pigments is determined by raw material composition and processing.

About 60% of the natural iron oxide pigments is used to color cement and other building materials. About 30% is consumed in the production of paints. For coloring plastics and rubber, synthetic iron oxide pigments are preferred. The main advantage of the natural iron oxide pigments, as compared to the synthetic ones, is cost. However, the quality is inferior, and in most cases, they are consumed in close proximity to the mines.

Synthetic Iron Oxides. Advantages of synthetic iron oxides over their natural counterparts include chemical purity, more uniform particle size and size distribution, and in the case of precipitated oxides the ability to prepare the pigment in predispersed vehicle systems by flushing techniques.

Iron Oxide Reds. From a chemical point of view, red iron oxides are based on the structure of hematite, α-Fe_2O_3, and can be prepared in various shades, from orange through pure red to violet. Different shades are controlled primarily by the oxide's particle size, shape, and surface properties.

Synthetic red iron oxides are prepared in a variety of grades from light to dark. These are sold under a variety of names, e.g., Indian red, Turkey red, and Venetian red.

Iron Oxide Yellows. From a chemical point of view, synthetic iron oxide yellows, also known as iron gelbs, are based on the iron(III) oxide–hydroxide, α-FeO(OH), known as goethite. Color varies from light yellows to dark buffs and is primarily determined by particle size, which is usually between 0.1 and 0.8 μm. Because of their resistance to alkalies, these are used by the building industry to color cement.

Iron Blacks. Chemically, iron blacks are based on the binary iron oxide, $FeO \cdot Fe_2O_3$. Most of the black iron oxide pigments contain iron(III) oxide impurities, giving a higher ratio of iron(III) than would be expected from the theoretical formula.

Iron Browns. Iron browns are often prepared by blending red, yellow, and black synthetic iron oxides to the desired shade. The most effective mixing can be achieved by blending iron oxide pastes, rather than dry powders.

Complex Inorganic Color Pigments. Based on the crystal structure, the Color Pigments Manufacturers' Association (CPMA) has classified 53 key inorganic pigments into 14 categories; these inorganic colorants are known as complex inorganic color pigments. The original name, mixed-metal oxide are pigments (MMO), did not accurately describe the chemical nature of all the classified pigments.

Mixed-Metal Oxide Pigments. Mixed-metal oxide pigments can be considered a subcategory of complex inorganic color pigments. In reality these pigments are not mixtures but rather solid solutions or compounds consisting of two or more metal oxides. Structurally, mixed-metal oxide pigments belong to one of 14 structure types. The most common ones are rutile and spinel. The commercial significance is in their thermal, chemical, and light stability, combined with low toxicity. When these are employed for coloring glass enamels and ceramics, they are sometimes referred to as colors or stains; when used to color paints and plastics, they are known as pigments.

The color of mixed-metal oxide pigments results from the incorporation of chromophores, into the structure of stable host oxides.

Pigments having a spinel structure are widely used by the ceramic and plastic industries. They cover a wide range of colors and many are thermally stable up to 1400°C and are resistant to molten glass. Another advantage is their intermiscibility, allowing the user a choice of creating many intermediate colors.

Spinel compounds have a common chemical formula, AB_2X_4. Structurally they have a cubic symmetry and are derived from magnesium aluminate, $MgAl_2O_4$, a naturally occurring mineral.

Structurally, all rutile pigments are derived from the most stable titanium dioxide structure, i.e., rutile. The crystal structure of rutile is very common for AX_2-type compounds such as the oxides of four-valent metals, as well as halides of divalent elements.

Zircon pigments are derived from the tetragonal zirconium silicate, $ZrSiO_4$. Because of the high temperature (up to 1600°C) and chemical stability of zirconium silicate, zircon pigments can be used in the formulations of high temperature (1300–1400°C) glazes. Zirconium silicate is also used as an opacifier in porcelain and vitreous enamels.

In pigments, zirconium silicate serves as the host lattice for various chromophores, such as vanadium, praseodymium, iron, etc.

Bismuth Vanadate. The use of bismuth vanadate, $BiVO_4$, as a nontoxic, yellow pigment with good hiding strength and lightfastness was patented by DuPont in 1978. At least two pigment producers, Ciba and BASF, are marketing this pigment primarily for plastic and paint applications. Some users have already replaced the toxic pigment lead chromate in their paint formulations with a combination of organic pigments and bismuth vanadate.

Chromium(III) Pigments. There are two green pigments based on chromium in the +3 oxidation state. The first one is chromium oxide, Cr_2O_3; the second is hydrated chromium oxide, $Cr_2O_3 \cdot xH_2O$.

Chromium(III) Green Pigment. Chromium oxide green is characterized by outstanding lightfastness and has excellent resistance to acids, alkalies, and high temperatures. Because it weathers extremely well, chromium oxide green is applied as a colorant for roofing granules, cement, concrete, and outdoor industrial coatings. It is also used in ceramic applications.

Hydrated Chromium(III) Green Pigment. Hydrated chromium oxide has a brilliant green color and is referred to as Gingnet's green. It exhibits a limited hue range, is semitransparent, and has a low opacity, but provides excellent lightfastness and alkali resistance.

Ultramarine Pigments. Ultramarines are derived from lazurite (Lapis Lazuli), a semiprecious stone; they can be prepared in many shades.

Chemically, ultramarines are complex sodium aluminates having a zeolite structure. Composition varies within certain wt % ranges, i.e., Na_2O, 19–23; Al_2O_3, 23–29; SiO_2, 37–50; and S, 8–14.

Ultramarine pigments are used in printing inks, textiles, rubber, artists' colors, cosmetics, and laundry bluing. Because of their thermal stability they are also used to color roofing granules.

Cyanide Iron Blues. Cyanide iron blue, also known as Prussian blue, is one of the oldest industrially produced, inorganic pigments. Chemically, cyanide iron blues are based on the $\{Fe^{2+}[Fe^{3+}(CN)_6]\}^-$ anion. The charge is balanced by sodium, potassium, or ammonium cations.

Iron blues are mainly used by the printing industry for coloring printing inks. In Europe, cyanide blues are used for coloring fungicides.

Cadmium Pigments. Historically, cadmium pigments have been very important, providing a range of clean, bright shades of yellow, orange, red, and maroon colors. This importance, however, has decreased because of environmental issues. Only a few pigment producers are willing to continue cadmium pigment production.

Lead Chromate Pigments. Lead chromate, $PbCrO_4$, occurs in nature as the orange-red mineral crocoite. Synthetically prepared lead chromate and its solid-state solutions with lead sulfate, $PbSO_4$, or lead molybdate, $PbMoO_4$, are known to have excellent pigmentary properties. The usage of these pigments has been steadily decreasing because of environmental regulations restricting the production and the use of lead-containing products.

Black Pigments

Black pigments can be divided into two basic groups. The first group is represented by carbon blacks. Many other inorganic black pigments, called noncarbon blacks, also are available. These belong chemically to the colored pigment category. Examples are spinel and rutile blacks, iron blacks, and some inclusion zircon pigments.

Carbon Blacks. Carbon black is one of the oldest pigments known. More than 90% of the production of this pigment is consumed by the rubber industries, in particular, by the tire industry as a reinforcing agent. The rest is used for coloring plastics, printing inks, and paints. Particle size of carbon blacks varies from 5 to 500 μm and can be controlled by the process conditions and feedstock (see **Carbon Black**).

Environmentally, carbon blacks are relatively stable and unreactive. There is no evidence that these materials are toxic to humans or animals.

Extenders and Opacifiers

Extender pigments are low-cost, generally colorless or white pigments with a refractive index less than 1.7. Sometimes these pigments are also referred to as fillers. Many extenders are derived from natural sources and display many diverse properties. They are added to various formulations to improve technical and application properties and to reduce costs. Like pigments, extenders are dispersed in media in which they do not dissolve, but compared to pigments they do not have any significant coloristic properties.

In coating applications, extender pigments control gloss, viscosity, texture, suspension, and durability. Extender pigments also enhance the opacity of white hiding pigments, e.g., TiO_2. In plastics applications, extenders influence numerous properties of the resin including melt viscosity, thermal conductivity, and electrical properties, tensile strength, and moisture resistance.

Opacifiers are fine inorganic powders, usually white, that are used to reduce the transparency of ceramic glazes and porcelain enamels. The coating becomes opaque because the particles of the opacifier scatter and reflect the incident light. When inorganic pigments are combined with white opacifiers, pastel colors are obtained.

Commercially, the most important opacifiers for glazes are ZrO_2, $ZrSiO_4$, and SnO_2.

Miscellaneous Pigments

Luminescent Pigments. Luminescence is the ability of matter to emit light after it absorbs energy. Materials that have luminescent properties are known as phosphors, or luminescent pigments. If the light emission ceases shortly after the excitation source is removed ($>10^{-8}$ s), the process is fluorescence. The process with longer decay times is referred to as phosphorescence.

Semiconducting sulfides that can be represented by the formula nZnS$(1-n)$CdS:A, where A stands for an activator, and $n = 0.15{-}1$, are typical of fluorescence pigments. Phosphorescence pigments can be expressed by the general formula nZnS$(1-n)$CdS:Cu, where $n = 0.78{-}1.0$ and the amount of the $Cu+$ activator is only a few hundredths of a percent.

Phosphorescent pigments are used in military applications, plastics, and paints. Zinc sulfide doped with $Ag+$ (blue) cations, or with $Cu+$ (green) cations are important pigments for the production of color television screens.

Metal Effect Pigments. Some metals, when prepared as small flakes, impart a special metallic appearance to the coatings and plastics in which they are dispersed. Metals most often used in these applications are aluminum (aluminum bronzes), copper and copper-zinc alloys (gold bronzes), and in smaller amounts zinc, tin, nickel, gold, silver, and stainless steel.

Nacreous Pigments. Nacreous, i.e., pearlescent pigments are used for creating special decorative effects typical of natural pearls. Nacreous pigments are fine, thin, plate-like transparent particles having a high refractive index. Because of these physical characteristics, when dispersed in a transparent film, they produce a silky appearance.

Manufacture of the most popular nacreous pigments involves coating mica with 50–300-nm films of TiO_2, Fe_2O_3, or Cr_2O_3. The mica, which alone does not have a high enough refractive index for creating nacreous luster, provides the required transparent platelet base. The oxide coating provides the necessary high refractive index.

Transparent Pigments. Pigments having chemical composition corresponding to colored or white opaque pigments can, under certain circumstances, appear transparent in a medium. This happens when the particle size of these pigments becomes very small (2–15 nm), and if the particle refractive index is comparable to the refractive index of the media in which the particles are dispersed. Because of the very small particle size, the preparation of these pigments is much more complicated than the preparation of their nontransparent analogues. Their large surface area makes their dispersion difficult and they have a strong tendency to agglomerate.

Environmental Aspects

Some inorganic pigments contain heavy metals. Thus production, use, and disposal are becoming more and more regulated. In the United States there are several federal regulations that control the use and disposal of heavy metals.

The Resource Conservation and Recovery Act (RCRA) controls the disposal of hazardous waste. SARA Title III governs the toxic inventory and emission reporting; the Clean Water Act (CWA) sets the limits for metals that can be present in water discharge; and the Clear Air Act (CAA) Amendments of 1990 control the abatements of all materials in the air.

TABLE 2. ELEMENTS POTENTIALLY PRESENT IN INORGANIC PIGMENTS

	Federal regulation[a]				
Element	RCRA	SARA	OSHA	CWA	CAA
Al				+	
Ag	+	+			
As	+	+		+	+
Ba	+	+		+	
Be		+		+	
Cd	+	+	+	+	+
Co		+		+	+
Cr	+	+		+	+
Cu		+		+	
Hg	+	+		+	+
Mn		+			+
Mo				+	
Ni		+		+	
Pb	+	+	+	+	+
Sb	+	+		+	
Se	+	+		+	
Ti				+	
Tl		+			
Zn				+	

[a] A + indicates that the element is regulated by the particular act.

The Occupational Safety and Health Administration (OSHA) regulates the exposure to chemicals in the workplace. From the point of view of the inorganic pigments industry, the limits established for lead and cadmium exposure are particularly important. A comprehensive lead standard adopted by OSHA in 1978 has been successful in reducing the potential for lead contamination in the workplace.

Table 2 lists those metals regulated by federal law that are or might be present in inorganic pigments.

To assure the future of inorganic pigments, research efforts are directed toward the development of environmentally acceptable pigments, pigments that when produced under well-controlled conditions do not release any toxic materials into the environment whether during production, use, or disposal.

PIGMENTS (Organic). Pigments are colored, colorless, or fluorescent particulate organic or inorganic finely divided solids which are usually insoluble in, and essentially physically and chemically unaffected by, the vehicle or medium in which they are incorporated. They alter appearance either by selective absorption and/or scattering of light. They are usually incorporated by dispersion in a variety of systems and retain their crystal or particulate nature throughout the pigmentation process. The large number of systems vary widely from paints to plastics to inks and fibers.

Dyes, on the other hand, are colored substances which are soluble or go into solution during the application process and impart color by selective absorption of light. In contrast to dyes, whose coloristic properties are almost exclusively defined by their chemical structure, the properties of pigments also depend on the physical characteristics of its particles.

The description of colored organic pigments excludes consideration of inorganic pigments, as well as black pigments which consist of specially treated forms of carbon and white pigments which are entirely of inorganic origin.

Pigments are categorized according to their generic name and chemical constitution in the *Color Index* (CI), published by the Society of Dyers and Colourists, and the American Association of Textile Chemists and Colorists.

Significant pigment attributes are tinctorial strength, durability (photochemical stability), hiding power, transparency, and heat and solvent resistance. Other properties include brightness (saturation), gloss, rheology, crystal stability, bleed resistance, flocculation resistance, and other properties associated with specialized applications.

The development of modern organic pigments started with the synthesis of dyestuffs for the textile industry. The period up to 1900 was characterized by the discovery and development of many dyes derived from coal-tar intermediates. Rapid advances in color chemistry were initiated after the discovery of diazo compounds and azo derivatives (shown to be largely hydrazone derivatives). The wide color potential of this class of pigments and their relative ease of preparation led to the development of azo colors, which represent the largest fraction of manufactured organic pigments.

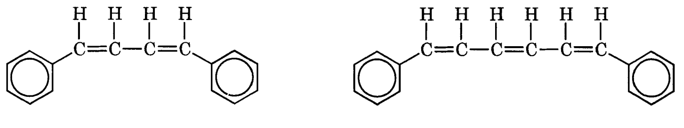
The most important advance in pigment technology after World War I was the discovery of the relatively complex structure but easily synthesized copper phthalocyanines, which were characterized by excellent brightness, strength, bleed resistance, and lightfastness. See also **Phthalocyanine Compounds**.

After World War II the most important discovery was the family of red-violet quinacridone pigments, followed by the mostly yellow-orange benzimidazolone, the isoindolinone pigments, and the red diaryl pyrrolopyrroles.

Color and Constitution

The term chromophore is used to designate π-electron-containing moieties (conjugated double bonds) which contribute to the selective absorption of visible light. Generally, organic compounds absorb light in the ultraviolet (210–400 nm) and visible (400–750 nm) region of the spectrum at characteristic wavelengths. The intensities of these absorptions vary due to the excitation of the more loosely held electrons in the molecule. All unsaturated groups have remarkably similar $\pi - \pi^*$ transitions regardless of the atoms contained in the common chromophores.

The presence of π–π or n–π conjugated systems does not assure absorption of visible light or generation of color. However, all colored organic compounds, including pigments, possess extended conjugated resonance systems. Thus, whereas 1,4-diphenylbutadiene is colorless, 1,6-diphenylhexatriene is colored.



colorless colored

All absorbed light is complementary to reflected light which produces observed color. All colors are a function of the wavelength of absorbed light as shown in Table 1. Thus, if a pigment absorbs only blue light it imparts an orange color, whereas when it absorbs orange light the observed color is blue.

Properties of Pigments

The physical and chemical characteristics that control and define the performance of a commercial pigment in a vehicle system include its chemical composition, chemical and physical stability, solubility, particle size, shape and particle size distribution, degree of dispersion, crystal morphology including polymorphic forms, refractive index, specific gravity, electronic spectra with particular emphasis on extinction coefficients in the visible spectrum, surface area, and the presence of impurities, extenders, and surface modifying agents. Invariably a pigment is used in a vehicle system, therefore its ultimate performance in use derives from both physical and chemical pigment-vehicle interaction. Performance of most pigments is system dependent.

Unlike inorganic pigments, organic pigments are relatively strong and bright (saturated), but their fastness properties, though adequate for the purposes for which they are used, vary widely from poor to outstanding.

Strength. The inherent strength of a pigment depends on its light-absorbing characteristics, which are related to its molecular and crystalline structure. In addition, strength is a function of particle size or surface area. The ability of a pigment to absorb light increases with decreasing particle size or increasing surface area, until the particles become entirely translucent or transparent to incident light. Being finely divided pigment particles have a great tendency to aggregate and agglomerate into crystal assemblies. To obtain the inherent strength of a pigment the aggregates must be completely broken down to individual crystals by application of work and their reagglomeration or flocculation prevented. Total breakdown to single crystals in practical systems seldom happens.

Pigment strength in a vehicle also depends on the typical character of other components in a pigmented system insofar as they absorb or scatter light. Strength comparisons are usually made with a series of samples featuring varying amounts of a pigment incorporated in a vehicle with a corresponding series in the same vehicle containing a reference pigment. Instrumental comparisons are commonly practiced.

A good absolute theoretical comparison of strength is represented by the area under the absorption bands in the visible spectrum, or less accurately by the molecular extinction coefficients at the maximum wavelength of absorption.

Brightness or Saturation. The saturation of a colored pigment is a measure of its brightness or cleanliness as opposed to dullness of hue. Generally, if a pigment absorbs light over a wide range of wavelengths, i.e., shows broad absorption bands, or contains more than one chromophore, the pigment is likely to be duller than a pigment with sharp absorption bands due to a single chromophore. Because pigments are frequently used in combinations or blends, the brightness is determined by the selective absorption of the individual pigments and this significantly affects the brightness of the reflected color.

TABLE 1. COLORS OF ABSORBED LIGHT AND THE CORRESPONDING COMPLEMENTARY COLORS AS A FUNCTION OF WAVELENGTH

Wavelength, nm	Color of absorbed light	Complementary color
400–420	violet	yellow-green
420–450	indigo blue	yellow
450–490	blue	orange
490–510	blue-green	red
510–530	green	purple
530–545	yellow-green	violet
545–580	yellow	indigo blue
580–630	orange	blue
630–720	red	blue-green

Fastness. Fastness describes the characteristics of a pigment in terms of its color stability in a pigmented system upon exposure to light, weather, heat, solvents, or various chemical agents. Ideally, a pigment should be insoluble and chemically and photochemically inert. Only a few organic pigments approach such perfection.

The development of resins, plastics, fibers, elastomers, etc. that are processed at progressively higher operating and curing temperatures has created a need for pigments that stand up for relatively long periods of time to a hostile environment. They must remain essentially unaltered when incorporated into plastics such as polypropylene, ABS, or nylon at relatively high temperatures.

Once a pigment is incorporated into a system, it is expected to be durable and withstand the combined chemical and physical stresses of weather, solar radiation, heat, water, and industrial pollutants. Because a pigment is totally enveloped by the medium which is itself not inert, various pigments perform differently in different systems. Thus, a pigment may be lightfast or weatherfast in one system and fail in another.

Dispersibility. The dispersibility of a pigment is measured by the effort required to develop the full tinctorial potential of a pigment in a vehicle system. Dispersibility differs from system to system depending on pigment–medium interaction and compatibility.

Small particle size pigments, especially the very small crystals, seldom exist as individual entities, but as strongly coherent aggregates or less firmly bound agglomerates. A wide variety of additives are being used to reduce aggregation or agglomeration and flocculation to improve dispersibility and color strength of organic pigments. These include resins, especially those related to abietic acid, aliphatic amines, amides, substituted derivatives of pigments themselves, and various combinations thereof. The additives are most effective if they are present when the pigment crystals are being generated.

Hiding Power and Transparency. Hiding power of a pigment is a function of its strength, that is, its absorption coefficients, its particle size, or light-scattering coefficient, and relative refractive indexes of pigment and vehicle. Light scattering has a powerful influence on opacity and goes through a maximum as a function of particle size. The maximum occurs at a particle size which is approximately half the wavelength of absorbed visible light.

Similarly, a pigment which absorbs much light increases hiding even when light scattering is insufficient, and the higher the refractive index the greater the hiding power of a pigment.

Conversely, to increase transparency light scattering must be minimized by particle size reduction. The smaller the particle size and the better the dispersion the greater the transparency.

Other Working Properties. Other properties which facilitate pigment incorporation and use include compatibility with a system, oil absorption, rheological characteristics, gloss, distinctness of image, wettability, migration fastness, plate-out, polymer distortion, etc. Most of these properties are controlled during pigment manufacture or formulation, others require special treatments to overcome undesirable effects.

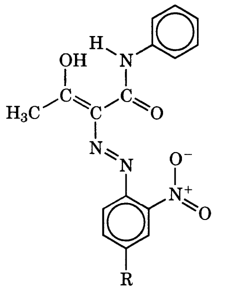
Types of Pigments

All organic pigments have to be synthesized and nearly all have to be conditioned or finished. The physical conditioning is as important as its chemical constitution, and it has become an important separate process step in the manufacture of organic pigments.

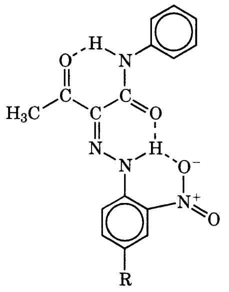
Azo Pigments. Azo pigments provide good examples of materials in which conditioning is an integral part of the synthesis process. The coupling

process for azo components is simple. An aromatic amine is diazotized by treatment with nitrous acid under conditions which vary from dilute mineral acid to concentrated sulfuric acid, depending on the basicity of the amine. The simplest method, i.e., direct coupling, involves running the diazo solution directly into the solution or suspension of the coupling component. In inverse coupling, the coupling component is run into the diazo solution. The most elegant technique, simultaneous coupling, entails running both the diazo and coupling component simultaneously into water or a dilute buffer.

The monoazo and disazo pigments contain one or more chromophoric groups usually referred to as the azo ⁅N=N⁆ group. However, it has been shown by x-ray diffraction analysis and nuclear magnetic resonance (nmr) techniques that azo pigments exist in the hydrazone rather than the azo tautomeric form. The hydrazone form, which has three intramolecular hydrogen bonds, renders the molecule planar (with the exception of the aniline moiety) which is a stabilizing influence.



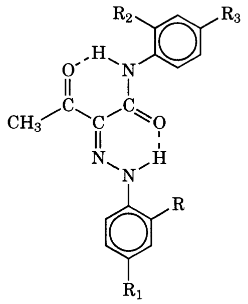
azo form



hydrazone form

Azo pigments, one of the oldest and most diverse group of pigments, comprise two types. One type consists of pigments that are insoluble in the aqueous reaction medium in which they are synthesized. Most simple azo pigments show poor bleed characteristics, but relatively good acid and alkali resistance. They show acceptable lightfastness in deep shades but poor tint lightfastness. The second type are laked or precipitated azo pigments derived from components substituted with sulfonic and/or carboxylic acid groups. These pigments are characterized by good to excellent bleed resistance, poor acid and alkali resistance, fair to good lightfastness in deep shades, and poor tint lightfastness. Also available are special azo pigments which show very good overall properties and therefore find applications in fairly demanding systems.

Monoazo Pigments. Monoazo yellow pigments are represented by the following general formula:



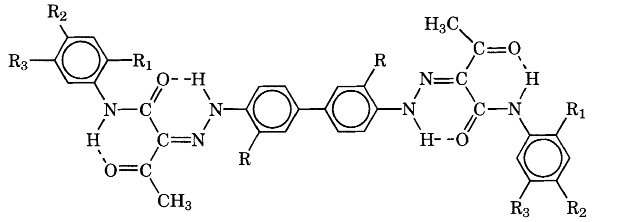
Many of the pigments carry a nitro group in the diazonium component, usually in the ortho position ($R = NO_2$). Among the acetoacetarylide components the *o*-methoxy derivative ($R_2 = OCH_3$, $R_3 = H$) is one of the most important in the production of azo pigments. The colors of these pigments range from red to green-shade yellows.

These pigments are sensitive to heat and bleed in most paint solvents. They are, however, resistant to acids and bases. They are used extensively in emulsion paints, paper coating compositions, inks, and, depending on particle size, can in some cases be used outdoors because of excellent lightfastness in full shades.

Benzimidazolones. This class of pigments derives its name from 5-aminobenzimidazolone, which upon reaction with diketene or 2-hydroxy-3-naphthoyl chloride leads to compounds that can be coupled with a variety of diazotized amines.

The acetoacetarylides yield yellow to orange pigments and the naphthoic acid amides yield red and brown pigments.

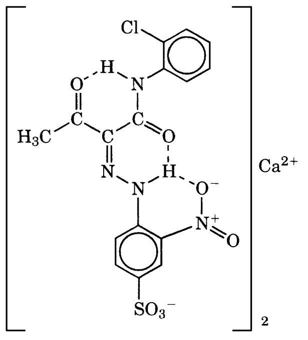
Diarylide Yellows. Diarylide or disazo yellow pigments are represented by the following general structural formula:



The chemistry and process of manufacture are very similar to the monazo pigments. Diarylides show significantly greater tinctorial strength and superior bleed and heat resistance than the conventional monoazo pigments. However, they are generally inferior to the monoazo pigments in lightfastness.

Based on high strength and versatile transparency most of the diarylides are used in a variety of printing inks, and in some plastics where temperature restrictions of 200°C have been imposed.

Monoazo Yellow Salts. Several monoazo yellow salts have gained popularity since the 200°C temperature restriction on the use of diarylide yellows has been imposed. An example Pigment Yellow 168, the calcium salt of diazotized 3-nitro-4-aminobenzenesulfonic acid coupled with acetoaceto-2-chloroanilide, provides a clean, somewhat greenish yellow color which shows good migration resistance but relatively poor tinctorial strength. It is used in polyethylene and inexpensive industrial finishes where the durability requirements are not high.



PY 168

Dinitraniline Orange. Dinitraniline Orange or Pigment Orange 5 is a strong and bright orange pigment with relatively low hiding power and good lightfastness in full shades, but poor tint lightfastness. It shows poor bleed but acceptable base resistance and finds principal application in air-drying systems, including a variety of printing inks.

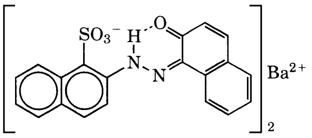
Pyrazolone Orange. Pyrazolone Orange or Pigment Orange 13 is a disazo pigment of high strength and bright color with good lightfastness in full shades and poor tint lightfastness. It is characterized by fair base and chemical resistance and is used primarily in inks, with limited application in paints and plastics.

Azo Reds and Maroons. Pigment Red 3 is one of the most popular organic red pigments used in industrial finishes. Its hue varies considerably with particle size and therefore several shades are commercially available. Its principal application is in air drying paints, and to a limited extent in printing inks.

Para Red or Pigment Red 1 is an intense, reasonably opaque red which shows poor lightfastness, particularly in tints. The related pigment Parachlor Red (Pigment Red 4) is an intense yellowish red. Both pigments show poor bleed and bake resistance and a tendency to bloom in enamels. The pigments are used in some inks and in low cost articles such as detergents, floor polishes, colored pencils, etc. The use of these pigments has declined markedly as a result of greater quality demands by the coatings industry.

Lithol Red or Pigment Red 49:1 is one of the most important of the precipitated salt pigments. A family of sodium (PR 49), barium (PR 49:1), calcium (PR 49:2), and strontium (PR 49:3) salts of diazotized Tobias acid or 2-naphthylamine-1-sulfonic acid coupled with 2-naphthol. These reds are used where brightness, bleed resistance, and low cost are of

primary importance.



PR 49:1

The BON or BONA Reds and Maroons derive their name from β-hydroxynaphthoic acid, also known as 3-hydroxy-2-naphthoic acid. BON is used as a general coupling component for the entire group with various diazotized amines containing salt-forming groups.

Lithol Rubine (Pigment Red 57) is the calcium salt of diazotized 2-amino-5-methylbenzenesulfonic acid coupled with 3-hydroxy-2-naphthoic acid. It ranks high among organic pigments in production volume and use.

Lithol Rubine is characterized by high tinctorial strength, good bleed, and bake resistance but poor alkali, soap, and acid resistance. Its lightfastness is considered fair and varies within a wide range of shades obtained by inclusion of auxiliary agents.

Red 2B defines the important barium (PR 48:1), strontium (PR 48:3), calcium (PR 48:2), and manganese (PR 48:4) salts of diazotized 2-amino-4-chloro-5-methylbenzenesulfonic acid coupled with 3-hydroxy-2-naphthoic acid, bright red pigments. They exhibit high strength, good bleed, and bake resistance, but poor resistance to alkali, soap, and acids, and fair lightfastness. The main fields of application are printing inks, plastics, and inexpensive industrial paints.

The manganese salt, i.e., manganese 2B (PR 48:4) is a bluish red, characterized by superior masstone lightfastness and outdoor durability. It finds use in some automotive and other high quality industrial finishes, as well as in some plastics and a variety of printing inks.

The pyrazolone reds are disazo pigments which provide high color strength and reasonable lightfastness in full shades but poor tint lightfastness, good bake, bleed, and chemical resistance. Some find application in plastics such as poly(vinyl chloride) where they show good dielectric properties, making them useful for cable insulations, in rubber, and specialized printing inks.

Naphthol Reds and Maroons. Naphthol Reds and Maroons are monoazo pigments which provide a wide range of colors from yellowish and medium red to bordeaux, maroon, and violet, and are characterized by high strength but marginal migration resistance. Depending on the substitution pattern some are strongly migrating and others are more or less resistant to migration. Lightfastness is generally marginal to good. Pigment Red 112 is a brilliant medium red pigment, approaching the shade of Toluidine Red, which is used in a variety of printing inks, air drying, and emulsion paints.

Another important pigment in this class is Pigment Red 170 which provides medium shades of red, and when particle-grown produces an opaque modification which shows improved migration resistance and lightfastness. It is used in high grade industrial paints and, in combination with high performance pigments, in automotive finishes. The transparent type which is tinctorially strong finds applications in a variety of printing inks.

Azo Condensation Pigments. A further improvement in heat stability of azo pigments was achieved by the condensation disazo pigments due to an enlarged molecular framework and higher molecular weight. Formally they are composed of two monoazo or more accurately two monohydrazone units, which are attached to each other by an aromatic dicarbonamide bridge.

The pigments are used primarily in plastics, including polypropylene fibers, because of very good bleed resistance, heat stability, and light-fastness. The reds also find use in printing inks, primarily for high quality products.

Lakes. Lakes are either dry toner pigments that are extended with a solid diluent, or an organic pigment obtained by precipitation of a water-soluble dye, frequently a sulfonic acid, by an inorganic cation or an inorganic substrate such as aluminum hydrate.

Basic dyes are characterized by bright shades and high strength but poor lightfastness. However, when laked by precipitation with soluble salts of organic acids such as tannic acid, or inorganic heteropoly-acids like phosphotungstic (PTA; M = W) and phosphomolybdic (PMA; M = Mo), and the combined phosphotungstomolybdic acid (PTMA), the resulting pigments retain the dyes' tinctorial attributes, but become insoluble and show improved lightfastness.

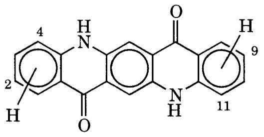
Copper Phthalocyanines. Copper phthalocyanine (CPC) approximates an ideal pigment (Pigment Blue 15). This class of pigments offers extreme brightness, tinctorial strength, bleed and chemical resistance, stability to heat, and migration. The pigments show excellent weatherfastness but are restricted to the blue and green regions of the spectrum. Phthalocyanine blue and green are among the most important organic pigments on the worldwide market.

Copper Phthalocyanine Blue. CPC blue exists in several polymorphic modifications, two of which, the red-shade blue alpha and greenshade blue beta form, are of great commercial significance. Beta is the thermodynamically more stable phase and is the product resulting from manufacture by the two basic processes using either phthalonitrile or phthalic anhydride as starting materials. The alpha form is usually obtained by conversion from the beta form and has to be stabilized to prevent phase reconversion.

Copper Phthalocyanine Green. CPC green is obtained by electrophilic substitution of CPC blue with chlorine. The typical polychloro-CPCs are blue-shade green pigments. To provide yellower shades of green, bromine is substituted for chlorine. Like CPC blue the green pigments show outstanding pigmentary properties, but are lower in tinting strength with progressive halogen substitution, particularly with bromine. See also **Phthalocyanine Compounds**.

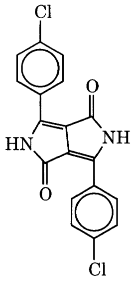
Quinacridones. Quinacridone pigments offer generally outstanding fastness properties across the visible spectrum from red-shade yellows to scarlet, maroon, red, magenta, and violet color ranges. The pigments are practically insoluble in most common solvents and therefore show excellent migration resistance in most application media. The low solubility is attributed to effective intermolecular hydrogen bonding which is also responsible for the photochemical stability. The various available colors are the result of polymorphism and various substitution patterns. The parent compound Pigment Violet 19 exists in three polymorphic modifications. The red gamma and violet beta forms are commercial pigments, whereas the red alpha form is metastable.

Due to the excellent pigmentary properties, quinacridones are used in many industries but particularly in automotive finishes, emulsion paints, plastics, and fibers.



Pigment Violet 19

Diaryl Pyrrolopyrroles. The 1,4-diketo-3,6-diarylpyrrolo(3,4-c)pyrroles are the most recently discovered class of pigments ranging in color from orange to bluish reds. These pigments are synthesized by base-catalyzed condensation of higher diakyl esters of succinic acid with aromatic nitriles. One important member of this class is Pigment Red 254, which is a very opaque yellowish red pigment of outstanding durability, brightness, and chemical resistance. Another is the parent compound Pigment Red 255, which is a high performance orange pigment. Both are used in automotive finishes, and a higher strength variation of PR 254 is used in plastics applications.



PR 254

Vat Dye Pigments. Vat dyes have been used for a long time for coloring textile fibers. As pigment technology evolved, new methods of particle size reduction have been successfully applied to largely insoluble dyes. Only

a few of the very large number of vat dyes have found application in the pigment field.

Perylenes. Perylene pigments are either the 3,4,9,10-tetracarboxylic dianhydride or more often N, N'-substituted diimides.

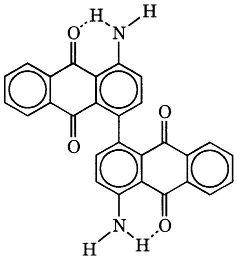
The pigments are manufactured either by reaction of the dianhydride with an amine or N, N'-dialkylation of the diimide. They are characterized by high tinctorial strength, excellent solvent stability, very good weatherfastness, moderate brightness, and range in color from red to violet.

Most applications are in high grade industrial paints, especially automotive finishes. Some types are used primarily in plastics and fibers.

Perinones. The most important pigment in this family is the orange perinone, Pigment Orange 43; is fairly weatherfast and heat stable, and is used primarily in plastics and fiber applications.

Thioindigo. The most important thioindigo pigment is the redviolet Pigment Red 88. Although still used in some paint and plastic systems, it is being replaced by pigments of higher quality.

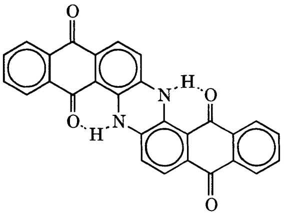
Aminoanthraquinone Pigments. Pigment Red 177 has the chemical structure of 4, 4′-diamino-1, 1′-dianthraquinonyl. It is the only known pigment with unsubstituted amino groups which are involved in both intra- and intermolecular hydrogen bonding. The bluish red pigment is used in plastics, industrial and automotive paints, and specialized inks. See also **Dyes: Anthraquinone**.



PR 177

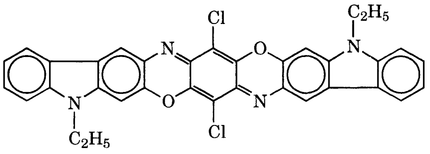
Pigment Yellow 147 is a reddish shade yellow pigment used primarily in certain plastics and in polyester and polypropylene fibers.

Indanthrone. Pigment Blue 60 is a very red-shade blue pigment that shows outstanding weatherfastness in full shade as well as in light white reductions. It is used primarily in metallized automotive finishes where it is sometimes more weatherfast than some copper phthalocyanine blues.

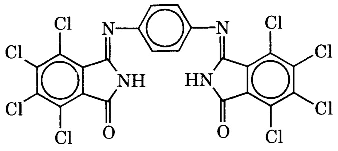


PB 60

Dioxazine. Carbazole Violet (Pigment Violet 23) is a bluish violet pigment that is uncommonly strong, resistant to solvents, and shows fair weatherfastness. It is used primarily as a shading pigment with copper phthalocyanines and for toning whites in a variety of systems.



Isoindolinones and Isoindolines. Tetrachloroisoindolinone pigments are characterized by very good lightfastness, heat stability, migration resistance, and chemical inertness. Although Pigment Yellow 110, a red-shade yellow, is relatively weak, it finds extensive use in automotive and other high grade finishes and in a variety of plastics and ink applications.



PY 110

Among the isoindoline pigments is Pigment Yellow 139, a reddish yellow pigment which differs in color as a function of particle size. The opaque version is the reddest. Although marginal in chemical resistance the pigment is used in the paint and plastics industries.

Quinophthalones. The quinophthalone pigments are prepared by condensation of quinaldines with a variety of aromatic anhydrides. One pigment in this series, Pigment Yellow 138, is a reasonably weatherfast greenish yellow pigment of good heat stability. The main field of application is paints and plastics.

Uses

Organic pigments are used for decorative and/or functional effects. In paints, for example, pigments provide color and contribute to exposure durability of the systems, which is particularly true for high performance pigments. Other functional effects include hiding power and high visibility, such as is displayed with daylight fluorescent pigments. They are used in various printing processes for textiles, plastics, and safety markings of various types.

The most important and established use for pigments is the imparting of color to a variety of materials and compositions. Examples are surface coatings for exteriors and interiors of automobiles and houses with oil- or water-based paints; wood stains, leather and artificial leather finishes, printing inks and many other applications.

Testing and Standardization

Pigments are subjected to a number of tests before they are released to customers. Testing is complicated because of the great diversity of pigment types and uses. A given pigment may be dispersible in one system but poorly dispersible in another, and can exhibit different durability depending on the system; performance is system dependent. Standardization is carried out against a standard sample for coloristics and a variety of working properties. Among the tests, depending on the pigment type, may be thermal stability, hiding power, rheology, migration, chemical stability, gloss, distinctness of image, durability, etc.

In the process of testing, color deviations are expressed in the CIELAB system or the equivalent polar LHC system. In either case tested samples must fall within acceptable ranges or limits established versus a standard by the pigment manufacturer and accepted by the pigment user.

In dispersing a pigment by an established method, acceptable pigment strength vs a standard must be achieved, even though an ideal dispersion normally is rarely realized.

Health and Safety Factors

Since pigments are generally insoluble, unlike most dyes, they are usually not bioavailable and consequently are generally not absorbed or metabolized. Nevertheless many health-related studies have been carried out and reported in the literature.

Acute toxicity of organic pigments has been studied extensively. The most common measure of toxicity is LD_{50} expressed in mg/kg of body weight which has a lethal effect on 50% of test animals after a single (oral, dermal, etc.) administration. These tests assess toxicity vs other known compounds. A large LD_{50} value represents a low degree of toxicity. Pigments in general have very low levels of acute toxicity.

Chronic toxicity defines a specific dose or exposure level that will produce measurable, long-term toxic effects, including carcinogenicity.

One area which requires special comment is a study which showed that certain diarylide pigments processed in polymers above 200°C and particularly above 240°C decompose to give off 3,3-dichlorobenzidine, an animal carcinogen. As a consequence diarylide pigments (not, however, condensation disazo pigments) are not recommended for use in any applications where they might be exposed to temperatures exceeding 200°C.

The hazards associated with handling pigments are specified by an OSHA Hazards Communication Standard, which also requires labeling and employee information and training.

Ecological Effects. The starting materials for manufacture of organic pigments are as diverse as the pigments themselves. However, most starting materials are derived from petroleum or natural gas sources. Although many pigments are synthesized in water, a variety of organic solvents are also employed by the industry. The effective utilization of all starting materials and solvents, and reduction of undesirable by-products, is a primary objective of the organic pigment industry.

PILOT PLANT. A trial assembly of small-scale reaction and processing equipment that is the intermediate stage between laboratory experiment and full-scale operation in the production of a new product. The functions of this stage are (1) to furnish chemical engineers with design data needed to construct a large-scale plane, (2) to resolve the many problems inherent in conversion from batch to continuous production, (3) to eliminate the differences that accompany change from constant laboratory conditions to a less closely controlled environment, and (4) to provide management with a basis for cost evaluation and estimation of the capital requirements of the new product. Because the size of the pilot plant varies with the nature of the product, it must be determined on a individual basis.

PINACOL REARRANGEMENT. See **Rearrangement (Organic Chemistry)**.

PINNER REACTION. Formation of imino esters (alkyl imidates) by addition of dry hydrogen chloride to a mixture of a nitrile and an alcohol. Treatment of alkyl imidates with ammonia or primary or secondary amines affords amidines, while treatment with alcohols yields ortho-esters.

PIPETTE. A slender glass tube open at both ends and having an expanded area at or near the center designed to contain a specific volume of liquid, e.g., 5 ml. Liquid is drawn into the tube by oral or, for the sake of safety, some other form of suction.

PIRIA REACTION. Formation of arylsulfamic acids or sulfonation products or both by refluxing aromatic nitro compounds with a metal sulfite and boiling the mixture with dilute acid to yield the amines and sulfamic acids.

PITCH. (1) A carbonaceous, tacky residue resulting from distillation of coal tar, petroleum, pine tar, and fatty acids. Some types, such as glance pitch, occur naturally. They are used chiefly as sealants, roofing compounds, and wood preservatives. Synthetic carbon fibers are made from petroleum pitch. (2) In papermakers' terminology, a mixture of calcium carbonate, calcium soaps from wood components, and miscellaneous residues from materials used in paper manufacture. Pitch of this type is a production nuisance that requires close control. (3) The degree of slope of an inclined plane as in a screw auger, as measured by the distance between the flights or treads.

See also **Coal Tar and Derivatives**.

PITCHBLENDE. A massive variety of uraninite or uranium oxide found in metallic veins. Contains 55–75% UO_2, up to 30% UO_3, usually a little water, and varying amounts of other elements. Thorium and the rare earths are generally absent.

See also **Uranium**.

PITZER EQUATION. Equation for the approximation of data for heats of vaporization for organic and simple inorganic compounds. It is derived from temperature and reduced temperature relationships.
